CLINICAL RESPIRATORY MEDICINE

FOURTH EDITION

Stephen G. Spiro, BSc, MD, FRCP

Professor of Respiratory Medicine, Honorary Consultant Physician, Department of Cancer Medicine, University College London Hospitals, National Health Service Foundation Trust; Honorary Consultant Physician, The Royal Brompton Hospital, London, United Kingdom

Gerard A. Silvestri, MD, MS

Professor of Medicine, Medical University of South Carolina, Charleston, South Carolina

Alvar Agustí, MD, PhD, FRCPE

Professor, Senior Consultant and Director, Thorax Institute, Hospital Clinic, University of Barcelona, Barcelona, Spain; Scientific Director, CIBER Enfermedades Respiratorias, Fundacio D'Investigacio Sanitaria Illes Balears, Mallorca, Spain

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

DEDICATION

To my parents, Ludwig and Anna, who supported me in my earlier years and taught me the importance of education and knowledge. To Alison, who always gave me the time to work and enjoy my career while she cared for the family and engaged in her own profession.
STEPHEN SPIRO

For my father, who taught me to aspire to greatness in my career while never forgetting where I came from and those who truly matter—my family. For my mother, who passed along a love of reading and the gift of memory. For my children, Nate and Mia, who are already better people than I could ever have hoped. Most of all, for my wife, Joanne, whose love and support are the glue that holds it all together.
GERARD SILVESTRI

To my wife Gemma, daughters Belén and Inés, and son Alvaro, the best family any man could think of.
ALVAR AGUSTÍ

CONTRIBUTORS

Asia A. Ahmed, MBBS, MRCP, FRCR
Senior Specialist Registrar in Radiology, Department of Imaging, University College London Hospital National Health Service Foundation Trust, London, United Kingdom
Percutaneous Biopsy Procedures: Techniques and Indications

Richard K. Albert, MD
Chief of Medicine, Denver Health; Professor of Medicine, University of Colorado, Aurora, Colorado
Chest Pain

Mark S. Allen, MD
Professor of Surgery, Chair, Division of General Thoracic Surgery, Mayo Clinic, Rochester, Minnesota
Diagnostic Thoracic Surgical Procedures

Douglas Arenberg, MD
Associate Professor, Division of Pulmonary and Critical Care Medicine, University of Michigan Medical Center, Ann Arbor, Michigan
Lung Cancer: Treatment

Phil Bearfield, MB, ChB, FRCA, EDIC, FFICM
Consultant Intensivist, Royal Free Hospital, London, United Kingdom
Hemodynamic Monitoring in Critical Illness

Thomas Benfield, MD, DMSc
Associate Professor, Department of Infectious Diseases, University of Copenhagen, Hvidovre University Hospital, Hvidovre, Denmark
Noninfectious Conditions in Patients with Human Immunodeficiency Virus Infection

Ilya Berim, MD
Fellow, Pulmonary and Critical Care Medicine, School of Medicine and Biomedical Sciences, University at Buffalo, The State University of New York, Buffalo, New York
Community-Acquired Pneumonia

Kathryn G. Bird, MD
Occupational Physician, Concentra, Golden, Colorado
Toxic Inhalational Lung Injury

Surinder S. Birring, MD, MRCP
Honorary Senior Lecturer Division of Asthma, Allergy and Lung Biology, King's College London; Consultant Physician, Department of Respiratory Medicine, King's College Hospital, London, United Kingdom
Cough

Lukas Brander, MD
Department of Intensive Care Medicine, Inselspital, Bern University Hospital, University of Bern, Bern, Switzerland
Invasive Mechanical Ventilation

Jeremy S. Brown, MBBS, PhD, FRCP
Reader, Centre for Respiratory Research, University College London, London, United Kingdom
Pneumonia in the Non–HIV-Infected Immunocompromised Patient

Kevin K. Brown, MD
Professor and Vice Chairman, Department of Medicine, Division of Pulmonary and Critical Care Medicine, National Jewish Health, University of Colorado, Aurora, Colorado
Idiopathic Pulmonary Fibrosis and Other Interstitial Lung Diseases

Todd M. Bull, MD
Associate Professor, Pulmonary Sciences and Critical Care Medicine; Director, Pulmonary Vascular Center, University of Colorado, Aurora, Colorado
Pulmonary Embolism

Felip Burgos, MSc, RPFT, RN
Servei de Pneumologia i Allèrgia Respiratòria, ICT, Departament de Medicina, Institut D'Investigacions Biomèdiques August Pi i Sunyer, Hospital Clínic, Universitat de Barcelona, Barcelona, Spain
Exercise Testing

Peter M.A. Calverley, MB, ChB, FRCP, FRCPE
Professor of Respiratory Medicine, Institute of Ageing and Chronic Disease, University of Liverpool; Consultant Physician, Clinical Sciences Centre, University Hospital Aintree, Liverpool, United Kingdom
Bronchodilators

Philippe Camus, MD
Professor, Division of Pulmonary and Critical Care, Centre Hospitalier Universitaire de Dijon, Hôpital du Bocage, Université de Bourgogne, Dijon, France
Drug-Induced and Iatrogenic Respiratory Diseases

Paolo Carbonara, MD
Physician, Division of Respiratory and Critical Care Medicine, Sant'Orsola-Malpighi Hospital, University of Bologna, Bologna, Italy
Noninvasive Mechanical Ventilation

William Graham Carlos III, MD
Assistant Professor of Clinical Medicine, Indiana University School of Medicine, Indianapolis, Indiana
Nonbacterial Infectious Pneumonia

Stephen D. Cassivi, MD, MSc, FRCSC
Associate Professor of Surgery, Division of General Thoracic Surgery; Director of Lung Transplantation, Mayo Clinic, Rochester, Minnesota
Chest Tube Insertion and Management
Diagnostic Thoracic Surgical Procedures

Rodrigo Cavallazzi, MD
Assistant Professor of Medicine, Assistant Director, Intensive Care Services, University of Louisville Health Sciences Center, Louisville, Kentucky
Pulmonary Complications of Hematopoietic Stem Cell Transplantation

Bartolome R. Celli, MD
Professor of Medicine, Harvard Medical School, Brigham and Women's Hospital, Boston, Massachusetts
Treatment of the Stable Patient with Chronic Obstructive Pulmonary Disease

William Y.C. Chang, MBMCh, MA(Oxon)
Research Fellow, Division of Therapeutics and Molecular Medicine, University of Nottingham, Nottingham, United Kingdom
Rare Diffuse Interstitial Lung Diseases

Chung-Wai Chow, MD, PhD
Assistant Professor, Division of Respirology, Department of Medicine, University of Toronto; Staff Respirologist, Division of Respirology, Multiorgan Transplant Unit, University Health Network, Toronto, Ontario, Canada
Pulmonary Host Defenses

Andrew M. Churg, MD, FRCP(C)
Professor of Pathology, University of British Columbia; Pathologist, Vancouver General Hospital, Vancouver, Canada
Macro and Micro Structure of the Lung

Jean-François Cordier, MD
Professor of Respiratory Medicine, Claude Bernard Lyon 1 University; Head of Department of Respiratory Medicine, Reference Center for Rare Pulmonary Diseases, Louis Pradel University Hospital, Lyon, France
Eosinophilic Lung Disease
Organizing Pneumonia

Borja G. Cosio, MD, PhD, MCP
Consultant, Department of Respiratory Medicine, Hospital Universitario Son Espases, Palma de Mallorca, Spain
Asthma: Epidemiology, Pathophysiology, and Risk Factors

Vincent Cottin, MD, PhD
Professor of Respiratory Medicine, Claude Bernard Lyon 1 University; Department of Respiratory Medicine, Reference Center for Rare Pulmonary Diseases, Louis Pradel University Hospital, Lyon, France
Eosinophilic Lung Disease
Organizing Pneumonia

Bruce H. Culver, MD
Associate Professor of Medicine, Division of Pulmonary and Critical Care Medicine, University of Washington School of Medicine, Seattle, Washington
Respiratory Mechanics
Pulmonary Circulation
Pulmonary Function Testing

Charles L. Daley, MD
Professor and Chief, Division of Mycobacterial and Respiratory Infections, National Jewish Health; Professor, Division of Pulmonary and Critical Care Medicine and Infectious Diseases, University of Colorado, Aurora, Colorado
Tuberculosis and Nontuberculous Mycobacterial Infections

Helen E. Davies, MD, MRCP
Consultant in Respiratory Medicine, University Hospital of Wales, Cardiff, United Kingdom
Pleural Effusion, Empyema, and Pneumothorax

Chadrick E. Denlinger, MD
Assistant Professor, Medical University of South Carolina, Charleston, South Carolina
Diagnostic Thoracic Surgical Procedures

Christophe Deroose, MD, PhD
Assistant Professor, Catholic University; Deputy Clinical Head, Positron Emission Tomography Centre, Department of Nuclear Medicine, University Hospital Gasthuisberg, Leuven, Belgium
Positron Emission Tomography Imaging

Claude Deschamps, MD
Professor of Surgery, Division of General Thoracic Surgery; Chair, Department of Surgery, Mayo Clinic, Rochester, Minnesota
Chest Tube Insertion and Management

Christophe Dooms, MD, PhD
Assistant Professor of Internal Medicine, Catholic University; Deputy Clinical Head, Pulmonology, University Hospital Gasthuisberg, Leuven, Belgium
Positron Emission Tomography Imaging

Gregory P. Downey, MD
Professor and Executive Vice President, Academic Affairs, Division of Pulmonary and Critical Care Medicine, Departments of Medicine and Pediatrics, National Jewish Health; Professor, Department of Medicine, Integrated Department of Immunology, University of Colorado, Aurora, Colorado
Pulmonary Host Defenses

Miquel Ferrer, MD, PhD
Assistant Professor of Medicine, University of Barcelona; Senior Consultant, Respiratory Intensive Care Unit, Thorax Institute, Hospital Clinic, Barcelona, Spain
Nosocomial Respiratory Infections

Rodney J. Folz, MD, PhD
Professor of Medicine, Biochemistry, and Molecular Biology; Chief, Pulmonary, Critical Care, and Sleep Disorders Medicine; Director; Adult Cystic Fibrosis Program; Distinguished University Scholar, University of Louisville Health Sciences Center, Louisville, Kentucky
Pulmonary Complications of Hematopoietic Stem Cell Transplantation

Edward R. Garrity, Jr., MD, MBA
Professor of Medicine, Section of Pulmonary and Critical Care Medicine, University of Chicago, Chicago, Illinois
Lung Transplantation

Alex H. Gifford, MD
Assistant Professor of Medicine, Dartmouth Medical School, Hanover, New Hampshire
Dyspnea

Robb W. Glenny, MD
Professor of Medicine, Physiology, and Biophysics; Head, Division of Pulmonary and Critical Care Medicine, University of Washington, Seattle, Washington
Pulmonary Circulation

Kelsey Gray, MD, MS
Fellow, Pulmonary and Critical Care Medicine, University of Colorado, Aurora, Colorado
Extrinsic Allergic Alveolitis

Ruth H. Green, MBChB, MSc, MD, FRCP
Consultant Respiratory Physician and Honorary Senior Lecturer, Institute for Lung Health, Glenfield Hospital, University Hospitals of Leicester National Health Service Foundation Trust, Leicester, United Kingdom
Diagnosis and Management of Asthma in Adults

Michael P. Gruber, MD
Assistant Clinical Professor, University of Colorado, Aurora, Colorado
Pulmonary Embolism

J.C. Grutters, MD, PhD
Professor, Department of Pulmonology, Center of Interstitial Lung Diseases, St. Antonius Hospital, Nieuwegein, The Netherlands; Division of Heart and Lungs, University Medical Center Utrecht, Utrecht, The Netherlands
Connective Tissue Diseases

Andrew R. Haas, MD, PhD
Assistant Professor of Medicine, Perelman School of Medicine; Director of Clinical Operations, Section of Interventional Pulmonology and Thoracic Oncology, Pulmonary, Allergy, and Critical Care Division, University of Pennsylvania Medical Center, Philadelphia, Pennsylvania
Bronchoscopy

Chadi A. Hage, MD
Assistant Professor of Medicine, Indiana University; Staff Physician, Roudebush VA Medical Center, Indianapolis, Indiana
Nonbacterial Infectious Pneumonia

Pranabashis Haldar, MD, MRCP
Senior Lecturer, Department of Respiratory Medicine, Institute for Lung Health, Glenfield Hospital, University Hospitals of Leicester National Health Service Foundation Trust, Leicester, United Kingdom
Diagnosis and Management of Asthma in Adults

David M. Hansell, MD, FRCP, FRCR
Professor of Thoracic Imaging, National Heart and Lung Institute, Imperial College School of Medicine; Consultant Radiologist, Royal Brompton and Harefield National Health Service Foundation Trust, London, United Kingdom
Imaging Techniques

Nicholas Hart, BSc, PhD, MRCP, FFICM
Clinical Research Consultant, Respiratory and Critical Care Medicine, National Institute of Health Research, Comprehensive Biomedical Research Centre, King's College London; Clinical and Academic Director, Lane Fox Respiratory Unit, St. Thomas' Hospital, Guy's and St. Thomas' National Health Service Foundation Trust, London, United Kingdom
Diseases of the Thoracic Cage and Respiratory Muscles

Felix J.F. Herth, MD, PhD, FCCP
Professor of Medicine, Chairman and Head, Department of Pneumology and Critical Care Medicine, Thoraxklinik, University of Heidelberg, Heidelberg, Germany
Endobronchial and Endoesophageal Ultrasound Techniques

Kristin B. Highland, MD, MSCR
Associate Professor of Medicine, Division of Pulmonary, Critical Care, Allergy, and Sleep Medicine, Medical University of South Carolina, Charleston, South Carolina
Pulmonary Hypertension

Andre Holmes, MD
Senior Pulmonary Fellow, Division of Pulmonary, Critical Care, Allergy, and Sleep Medicine, Medical University of South Carolina, Charleston, South Carolina
Pulmonary Hypertension

John R. Hurst, PhD, FRCP
Senior Lecturer, Academic Unit of Respiratory Medicine, University College London Medical School, London, United Kingdom
Management of Exacerbations in Chronic Obstructive Pulmonary Disease

Michael C. Iannuzzi, MD, MBA
Edward C. Reifenstein Professor and Chair, Department of Medicine, State University of New York, Upstate Medical University, Syracuse, New York
Sarcoidosis

Ferrán Barbé Illa, MD
Respiratory Department, Hospital University Arnau de Vilanova, University of Lleida, Lleida; CIBERES, Madrid, Spain
Obstructive Sleep Apnea: Epidemiology, Risk Factors, and Pathophysiology

Cyrielle Jardin, MD
Pulmonary Medicine Fellow, Service de Pneumologie et Immuno-allergologie, Centre de Competence des Maladies Pulmonaires Rares, Hôpital Albert Calmette, CHRU at Universite de Lille 2, Lille, France
Silicosis and Coal Worker's Pneumoconiosis

Simon R. Johnson, MBBS, DM, FRCP
Professor of Respiratory Medicine, Division of Therapeutics and Molecular Medicine, University of Nottingham and National Centre for Lymphangioleiomyomatosis, Nottingham, United Kingdom
Rare Diffuse Interstitial Lung Diseases

Robert M. Kacmarek, RRT, PhD
Professor, Department of Anesthesia, Harvard University; Director, Department of Respiratory Care, Massachusetts General Hospital; Boston, Massachusetts
Acute Respiratory Distress Syndrome

Harsha H. Kariyawasam, MBBS, MRCP, BSc, PhD
Consultant Physician, Department of Allergy and Medical Rhinology, Royal National Throat, Nose and Ear Hospital, London, United Kingdom
Upper Airway Disease: Rhinitis and Rhinosinusitis

Joel D. Kaufman, MD, MPH
Professor, Departments of Medicine, Environmental and Occupational Health Sciences, and Epidemiology, University of Washington, Seattle, Washington
Air Pollution

John W. Kreit, MD
Professor of Medicine and Anesthesiology and Director of Fellowship Training Programs, Division of Pulmonary, Allergy, and Critical Medicine, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Hemoptysis

Michael J. Krowka, MD
Professor of Medicine, Division of Pulmonary and Critical Care Medicine, Mayo Clinic, Rochester, Minnesota
Hepatic and Biliary Disease

Mark Lambert, FRCA, BA(Hons), MBBS
Specialist Registrar in Anaesthesia, Royal Free Hospital, London, United Kingdom
Hemodynamic Monitoring in Critical Illness

J.-W.J. Lammers, MD, PhD
Professor, Division of Heart and Lungs, Department of Respiratory Medicine, University Medical Center Utrecht, Utrecht, The Netherlands
Connective Tissue Diseases

Stephen E. Lapinsky, MB BCh, MSc, FRCPC
Professor of Medicine, University of Toronto; Site Director, Intensive Care Unit, Mount Sinai Hospital, Toronto, Canada
Pregnancy

Y.C. Gary Lee, MBChB, PhD, FCCP, FRACP
Winthrop Professor of Respiratory Medicine, The University of Western Australia; Consultant and Director of Pleural Services, Respiratory Department, Sir Charles Gairdner Hospital; Head, Pleural Disease Unit, Lung Institute of Western Australia, Perth, Australia
Pleural Effusion, Empyema, and Pneumothorax

Gianluigi Li Bassi, MD
Researcher, Institut D'Investigacions Biomèdiques August Pi i Sunyer; Attending Physician, Respiratory Critical Care Unit, Thorax Institute, Hospital Clinic, Barcelona, Spain
Nosocomial Respiratory Infections

Marc C.I. Lipman, MC, FRCP
Senior Lecturer and Consultant Physician, Centre for Respiratory Medicine, Royal Free Hospital, University College London, London, United Kingdom
Pulmonary Infections in Patients with Human Immunodeficiency Virus Disease

David A. Lomas, PhD, ScD, FRCP, FMedSci
Professor, Department of Medicine, University of Cambridge, Cambridge Institute for Medical Research, Cambridge, United Kingdom
Basic Aspects of Cellular and Molecular Biology

William MacNee, MBChB, MC(Hons), FRCP(Glas), FRCP(Edin)
Professor, The Edinburgh Lung and the Environment Group Initiative Colt Research Laboratories, Medical Research Council Centre for Inflammation Research, Queen's Medical Research Institute, University of Edinburgh, Edinburgh, Scotland, United Kingdom
Chronic Obstructive Pulmonary Disease: Epidemiology, Pathophysiology, and Clinical Evaluation

Donald A. Mahler, MD
Professor of Medicine, Dartmouth Medical School; Director, Pulmonary Function and Cardiopulmonary Exercise Laboratories, Dartmouth-Hitchcock Medical Center, Lebanon, New Hampshire
Dyspnea

Jean-Luc Malo, MD
Professor, Université de Montréal, Hôpital du Sacré-Coeur de Montréal, Montreal, Canada
Occupational Asthma

Stefan J. Marciniak, MA, FRCP, PhD
Medical Research Council Senior Clinical Fellow, Cambridge Institute for Medical Research, University of Cambridge; Honorary Consultant Physician, Addenbrooke's Hospital National Health Service Foundation Trust, Cambridge, United Kingdom
Basic Aspects of Cellular and Molecular Biology

José M. Marin, MD, PhD
Hospital Universitario Miguel Servet, Aragon Institute of Health Sciences, Zaragoza, Spain
Obstructive Sleep Apnea: Clinical Features, Diagnosis, and Treatment

Miguel Ángel Martínez-García, MD
Respiratory Department, Polytechnic and University Hospital, Valencia, Spain
Obstructive Sleep Apnea: Epidemiology, Risk Factors, and Pathophysiology

Peter Mazzone, MD, MPH, FCCP
Director, Lung Cancer Program, Cleveland Clinic Respiratory Institute, Cleveland, Ohio
Preoperative Pulmonary Evaluation

Alan McGlennan, BSc, MBBS, FRCA
Consultant Anaesthetist, Royal Free Hospital, London, United Kingdom
Airway Management in the Intensive Care Unit

Pamela J. McShane, MD
Assistant Professor of Medicine, Section of Pulmonary and Critical Care Medicine, University of Chicago, Chicago, Illinois
Lung Transplantation

Tarek Meniawy, MBBS, FRACP
Medical Oncology Fellow, Department of Medical Oncology, Sir Charles Gairdner Hospital; Research Fellow, University of Western Australia School of Medicine and Pharmacology and National Centre for Asbestos Related Diseases, Nedlands, Australia
Malignant Pleural Mesothelioma

David E. Midthun, MD
Professor of Medicine, Mayo Clinic, Rochester, Minnesota
Benign Lung Tumors

Robert F. Miller, MBBS, FRCP, CBiol, FSB
Professor and Reader in Clinical Infection; Honorary Consultant Physician, Camden Provider Services, University College London, London, United Kingdom
Pulmonary Infections in Patients with Human Immunodeficiency Virus Disease

Theo J. Moraes, MD, PhD
Assistant Professor, Department of Pediatrics, University of Toronto; Pediatric Respirologist, Division of Respirology, Department of Pediatrics, The Hospital for Sick Children, Toronto, Canada
Pulmonary Host Defenses

Alison Morris, MD, MS
Associate Professor of Medicine, Immunology, and Clinical and Translational Research, Department of Medicine, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Pulmonary Infections in Patients with Human Immunodeficiency Virus Disease

Gimbada B. Mwenge, MD
Center for Sleep Medicine, Cliniques Universitaires Saint-Luc, Université Catholique de Louvain, Brussels, Belgium
Obesity Hypoventilation Syndrome

Stefano Nava, MD
Director, Division of Respiratory and Critical Care Medicine, Sant'Orsola-Malpighi Hospital, Bologna, Italy
Noninvasive Mechanical Ventilation

Lee S. Newman, MD, MA
Professor, Department of Environmental and Occupational Health, Colorado School of Public Health, Department of Medicine, School of Medicine, University of Colorado, Aurora, Colorado
Asbestosis
Toxic Inhalational Lung Injury

Aynur Okcay, MD
Cardiopulmonary Research Fellow, Mayo Clinic, Rochester, Minnesota
Hepatic and Biliary Disease

Simon P.G. Padley, BSc, MBBS, FRCP, FRCR
Reader in Radiology, Imperial College School of Medicine; Consultant Radiologist, Chelsea and Westminster Hospital National Health Service Foundation Trust, Royal Brompton Hospital and Harefield National Health Service Foundation Trust, London, United Kingdom
Imaging Techniques

Ganapathi Iyer Parameswaran, MBBS
Research Assistant Professor, Department of Medicine, University at Buffalo, State University of New York; Physician, Division of Infectious Diseases, VA Western New York Healthcare System, Buffalo, New York
Viral Pneumonia

Nicholas J. Pastis, MD
Assistant Professor of Medicine, Division of Pulmonary and Critical Care Medicine, Medical University of South Carolina, Charleston, South Carolina
Chest Tube Insertion and Management

Manju Paul, MD
Fellow, Division of Pulmonary and Critical Care Medicine, Department of Medicine, State University of New York Upstate Medical University, Syracuse, New York
Sarcoidosis

Ian D. Pavord, DM, FRCP
Consultant Physician and Honorary Professor of Medicine, Institute for Lung Health, Glenfield Hospital, University Hospitals of Leicester National Health Service Foundation Trust, Leicester, United Kingdom
Cough
Diagnosis and Management of Asthma in Adults

Hilary Petersen, MPAS, PA-C
Physician Assistant, Lung Cancer Program, Cleveland Clinic Respiratory Institute, Cleveland, Ohio
Preoperative Pulmonary Evaluation

Michael I. Polkey, PhD, FRCP
Professor of Respiratory Medicine, National Institute for Health Research, Respiratory Biomedical Research Unit, Royal Brompton and Harefield National Health Service Foundation Trust, National Heart and Lung Institute, Imperial College London, London, United Kingdom
Diseases of the Thoracic Cage and Respiratory Muscles

Jennifer Quint, MBBS, MRCP, PhD
Doctor, London School of Hygiene and Tropical Medicine, University College London, National Health Service Foundation Trust, London, United Kingdom
Pneumonia in the Non–HIV-Infected Immunocompromised Patient

Klaus F. Rabe, MD, PhD
Professor of Medicine, Department of Internal Medicine, Christian-Albrechts University, Kiel, Germany; Medical Director, Grosshansdorf Clinic, Grosshansdorf, Germany
Antiinflammatory Drugs

Michelle Ramsay, BSc, MRCP
Clinical Research Fellow in Respiratory Physiology, Department of Asthma, Allergy, and Respiratory Science, Division of Asthma and Lung Biology, King's College London; Lane Fox Respiratory Unit, St. Thomas' Hospital, Guy's and St. Thomas' National Health Service Foundation Trust, London, United Kingdom
Diseases of the Thoracic Cage and Respiratory Muscles

Felix Ratjen, MD, PhD, FRCPC
Professor, Department of Pediatrics, University of Toronto; Head, Division of Respiratory Medicine, H.E. Sellers Chair in Cystic Fibrosis, Hospital for Sick Children, Toronto, Canada
Cystic Fibrosis

M. Katayoon Rezaei, MD
Assistant Professor of Pathology, The George Washington University Medical Center, Washington, DC
Lung Cancer: Epidemiology, Surgical Pathology, and Molecular Biology

Seppo T. Rinne, MD, PhD
Senior Pulmonary Fellow, University of Washington, Seattle, Washington
Air Pollution

Bruce W.S. Robinson, MBBS, MD, FRACP, FRCP, DTM&H, FCCP
Professor of Medicine, University of Western Australia School of Medicine and Pharmacology; Consultant Respiratory Physician, Department of Respiratory Medicine; Sir Charles Gairdner Hospital; Director, National Centre for Asbestos Related Diseases, Nedlands, Australia
Malignant Pleural Mesothelioma

Josep Roca, MD
Servei de Pneumologia i Allèrgia Respiratòria, ICT, Departament de Medicina, Institut D'Investigacions Biomèdiques August Pi i Sunyer, Hospital Clínic, Universitat de Barcelona, Barcelona, Spain
Exercise Testing

Daniel Rodenstein, MD, PhD
Professor, Pneumology Department and Center for Sleep Medicine, Cliniques Universitaires Saint-Luc, Université Catholique de Louvain, Brussels, Belgium
Obesity Hypoventilation Syndrome

Jaime Rodríguez Rosado, MD
Pulmonologist, Department of Respiratory Medicine, Hospital Universitario Son Espases, Palma de Mallorca, Spain
Asthma: Epidemiology, Pathophysiology, and Risk Factors

Melissa L. Rosado-de-Christenson, MD, FACR
Clinical Professor of Radiology, University of Missouri–Kansas City; Section Chief, Thoracic Radiology, Department of Radiology, Saint Luke's Hospital of Kansas City, Kansas City, Missouri
Disorders of the Mediastinum

Cecile Rose, MD, MPH
Professor of Medicine, University of Colorado, Aurora; Occupational Medicine Program Director, National Jewish Health, Denver, Colorado
Extrinsic Allergic Alveolitis

Federico Fiorentino Rossi, MD
Pulmonologist, Department of Respiratory Medicine, Hospital Universitario Son Espases, Palma de Mallorca, Spain
Asthma: Epidemiology, Pathophysiology, and Risk Factors

Luis G. Ruiz, MD
Pulmonologist, Kaiser Permanente Mid Atlantic Medical Group, Washington, DC
Lung Transplantation

Glenis K. Scadding, MA, MD, FRCP
Honorary Consultant Physician, Department of Allergy and Medical Rhinology, Royal National Throat, Nose and Ear Hospital, London, United Kingdom
Upper Airway Disease: Rhinitis and Rhinosinusitis

Frank Schneider, MD
Assistant Professor of Pathology, Department of Pathology, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Inflammatory Bowel Disease

Arnold M. Schwartz, MD, Phd
Professor of Pathology and Surgery, The George Washington University Medical Center, Washington, DC
Lung Cancer: Epidemiology, Surgical Pathology, and Molecular Biology

Amen Sergew, MD
Instructor, Division of Pulmonary and Critical Care Medicine, National Jewish Health, University of Colorado, Aurora, Colorado
Idiopathic Pulmonary Fibrosis and Other Interstitial Lung Diseases

Sanjay Sethi, MD, FACP
Division Chief, Pulmonary, Critical Care, and Sleep Medicine, University at Buffalo, The State University of New York; Staff Physician, Pulmonary, Critical Care, and Sleep Medicine, VA Western New York Healthcare System, Buffalo, New York
Community-Acquired Pneumonia
Viral Pneumonia

Penny J. Shaw, MBBS, MRCP, DMRD, FRCR
Consultant Radiologist, Department of Imaging, University College London Hospital National Health Service Foundation Trust, London, United Kingdom
Percutaneous Biopsy Procedures: Techniques and Indications

Anita K. Simonds, MD, FRCP
Professor, NIHR Respiratory Disease Biomedical Research Unit, Royal Brompton and Harefield National Health Service Foundation Trust, London, United Kingdom
Scoliosis and Kyphoscoliosis

Arthur S. Slutsky, MD, PhD
Professor of Medicine, Surgery, and Biomedical Engineering, University of Toronto; Director, Interdepartmental Division of Critical Care Medicine, Department of Critical Care Medicine, St. Michael's Hospital, Keenan Research Center, Li Ka Shing Knowledge Institute of St. Michael's Hospital, Toronto, Canada
Invasive Mechanical Ventilation

Ulrich Specks, MD
Professor of Medicine, Mayo Clinic College of Medicine, Division of Pulmonary and Critical Care Medicine, Mayo Clinic, Rochester, Minnesota
Pulmonary Vasculitis and Hemorrhage

Jonathan R. Spiro, MBBS, BSc, MD, MRCP
Specialist Registrar in Cardiology, University Hospitals Birmingham, The New Queen Elizabeth Hospital, Birmingham, United Kingdom
Echocardiography in Respiratory Medicine

Michael Spiro, MBBS, BSc, FRCA
Specialist Registrar in Anaesthesia and Critical Care Medicine, Royal Free Hospital, London, United Kingdom
Airway Management in the Intensive Care Unit

Stephen G. Spiro, BSc, MD, FRCP
Professor of Respiratory Medicine, Honorary Consultant Physician, Department of Cancer Medicine, University College London Hospitals, National Health Service Foundation Trust; Honorary Consultant Physician, Royal Brompton Hospital, London, United Kingdom
Chest Pain

Richard P. Steeds, MA, MC, FRCP
Honorary Lecturer, University of Birmingham; Consultant Cardiologist with Special Interest in Imaging, University Hospitals Birmingham, The New Queen Elizabeth Hospital, Birmingham, United Kingdom
Echocardiography in Respiratory Medicine

Daniel H. Sterman, MD
Assistant Professor of Medicine, Perelman School of Medicine; Chief, Section of Interventional Pulmonology and Thoracic Oncology, Pulmonary, Allergy, and Critical Care Division; Co-Director, PENN Mesothelioma and Pleural Program, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania
Bronchoscopy

Kaylan E. Stinson, MSPH
Senior Professional Researcher, Colorado School of Public Health, University of Colorado, Aurora, Colorado
Asbestosis

Robert Stockley, MD, DSc, FRCP
Professor, Department of Lung Function and Sleep, The New Queen Elizabeth Hospital, Birmingham, United Kingdom
Bronchiectasis

Diane C. Strollo, MD, FACR
Associate Professor of Radiology, Thoracic Radiology, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Disorders of the Mediastinum

Demet S. Sulemanji, MD
Instructor, Department of Anesthesia, Harvard University; Research Coordinator, Department of Respiratory Care, Massachusetts General Hospital, Boston, Massachusetts
Acute Respiratory Distress Syndrome

Lynn Tanoue, MD
Professor of Medicine, Section of Pulmonary and Critical Care Medicine; Vice-Chair for Clinical Affairs, Department of Internal Medicine, Yale School of Medicine, New Haven, Connecticut
Lung Cancer: Clinical Evaluation and Staging

Magali N. Taylor, BSc, MBBS, FRCR
Consultant Radiologist with Thoracic Subspecialty Interest, Department of Imaging, University College London Hospital National Health Service Foundation Trust, London, United Kingdom
Percutaneous Biopsy Procedures: Techniques and Indications

Antoni Torres, MD, PhD
Professor of Medicine, University of Barcelona; Director, Respiratory Intensive Care Unit, Thorax Institute, Hospital Clinic, Barcelona, Spain
Nosocomial Respiratory Infections

Elizabeth Tullis, MD, FRCP
Associate Professor of Medicine, Department of Respirology, University of Toronto; Head, Division of Respirology; Director, Adult Cystic Fibrosis Program, St. Michael's Hospital, Toronto, Canada
Cystic Fibrosis

Anil Vachani, MD
Assistant Professor of Medicine, Pulmonary, Allergy, and Critical Care Division, Perelman School of Medicine; Attending Physician, Philadelphia VA Medical Center, Philadelphia, Pennsylvania
Bronchoscopy

Olivier Vandenplas, MD, PhD
Professor of Medicine, CHU Mont-Godinne, Université Catholique de Louvain, Yvoir, Belgium
Occupational Asthma

Johan Vansteenkiste, MD, PhD
Professor of Internal Medicine, Catholic University; Deputy Clinical Head Pulmonology, University Hospital Gasthuisberg, Leuven, Belgium
Positron Emission Tomography Imaging

Theodoros Vassilakopoulos, MD, PhD
Associate Professor, Department of Critical Care and Pulmonary Services, University of Athens Medical School, Evangelismos Hospital, Athens, Greece
Control of Ventilation and Respiratory Muscles

Kristen L. Veraldi, MD, PhD, FCCP
Assistant Professor of Medicine, University of Pittsburgh School of Medicine, Division of Pulmonary, Allergy, and Critical Care Medicine, The Dorothy P. and Richard P. Simmons Center for Interstitial Lung Disease, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Inflammatory Bowel Disease

Jesús Villar, MD, PhD, FCCM
Chief, Group 29, CIBER de Enfermedades Respiratorias, Instituto de Salud Carlos III, Madrid, Spain; Director, Research Unit, Hospital Universitario Dr. Negrin, Las Palmas de Gran Canaria, Spain; Adjunct Scientist, Keenan Research Center, Li Ka Shing Knowledge Institute, St. Michael's Hospital, Toronto, Canada
Acute Respiratory Distress Syndrome

Peter D. Wagner, MD
Distinguished Professor of Medicine and Bioengineering, University of California–San Diego, La Jolla, California
Gas Exchange

Benoit Wallaert, MD
Professor of Medicine, Service de Pneumologie et Immuno-allergologie, Centre de Competence des Maladies Pulmonaires Rares, Hôpital Albert Calmette, CHRU at Universite de Lille 2, Lille, France
Silicosis and Coal Worker's Pneumoconiosis

Nicholas Walter, MD, MS
Instructor, Division of Pulmonary Sciences and Critical Care Medicine, University of Colorado, Aurora, Colorado

PREFACE

We have been very encouraged by the success of the previous editions of *Clinical Respiratory Medicine*, and we are proud to publish the fourth edition. Although the contents have changed considerably with each edition, we still hold to the principle of providing a book that teaches both the basics of respiratory medicine and the details of individual diseases.

When we set out in 1999, our idea was to bring the global respiratory medicine community together within a single publication. We aimed to use the extraordinary advances in computer graphics and publishing to combine detailed presentations of lung structure and physiology with clinical material. In this fourth edition we extended this philosophy to include videos of most practical procedures to help explain how these investigations are performed.

This edition has seen the departure of co-editors Professors James Jett and Richard Albert, and we welcome the “new blood” and ideas from Professors Alvar Agusti and Gerard Silvestri, both preeminent in the respiratory medicine field. They helped enormously in giving the book a new look. We changed more than 30% of authors to ensure the material in this edition is current. The chapters with the same author as in the previous edition have been rewritten and updated. Also, each chapter includes five multiple-choice questions to aid the learning process. We are fortunate to include many of the most world-renowned writers in their respective fields, who have contributed willingly and on time, and we are most grateful to them for their kindness and commitment.

The senior editor has always felt the importance of pulmonary physiology in understanding lung function and the disease processes that occur. Therefore we make no apology for strengthening this part of the book, with superb chapters from the leaders in their specialty areas. Entirely new chapters are included on lung structure, echocardiography, obesity and its effects, and benign tumors, as well as a much expanded section on lung cancer.

The format of the book has remained essentially unchanged, with the first 300 or so pages focusing on physiology, host defenses, techniques and indications (much improved with videos), and principles of respiratory care. This is followed by detailed, disease-focused chapters. The book has never been intended as an exhaustive source of references, but summary reading lists are provided for each topic.

The fourth edition remains directed at trainees in respiratory medicine, physicians practicing general medicine, respiratory therapists, and all respiratory medicine clinicians. Once again, we have been well supported by Elsevier and in particular by Anne Snyder, who has kept the project on schedule and worked so efficiently on our behalf. Her guidance and always prompt advice are greatly appreciated.

We have enjoyed preparing this text as a teaching tool for the profession and hope *Clinical Respiratory Medicine* maintains its place among the leading respiratory texts. Enjoy it.

NORMAL STRUCTURE AND FUNCTION

Chapter 1

Macro and Micro Structure of the Lung*

Joanne L. Wright • Andrew M. Churg

LUNG DEVELOPMENT

The emergence of a normal, functioning respiratory system requires simultaneous development of the conducting airway system and the vascular system. Of interest, the mechanisms that drive this process also hold true for other branched-structure organ systems, such as the kidney and breast. Lung development, beginning with organogenesis, is divided into several stages, as indicated in **Table 1-1.** However, considerable overlap of the signaling cascades between the various stages is recognized.

The earliest stage of lung development is known as the *embryonic* stage—that of organogenesis—and continues to approximately week 7. The primary lung buds arise from the ventral wall of the anterior foregut at approximately day 28. The trachea develops independently as a foregut tube anterior to the lung buds. Although it initially also includes the esophagus, the tube subsequently separates into two parts, with the ventral aspect forming the trachea, which then connects to the lung buds. The lung bud–tracheal domain is characterized by expression of Nkx2-1 (also called Titf1 [thyroid transcription factor 1]). Signal proteins from the mesenchyme, including bone morphogenetic proteins (BMPs), Noggin, fibroblast growth factors (FGFs), and Wnts, influence patterning, and deficiencies in some of these proteins result in failure of foregut separation with or without abnormal differentiation of epithelium and mesenchyma. Retinoic acid also plays an important role in lung morphogenesis during primary bud formation. Canonical Wnt signaling appears to be important in the regulation of cell proliferation and differentiation and also plays a role in lung branching. Beta-catenin phosphorylation is an integral portion of this pathway, with subsequent translocation to the cell nucleus and activation of T cell factor/lymphoid enhancer factor (TCF/LEF) target genes. Epigenetic changes, including methylation of DNA or histones, may influence developmental processes.

Vasculogenesis is initiated at the same time as that for development of the foregut bud. The vascular endothelial growth factor (VEGF) signaling cascade is integral to lung development and is necessary for endothelial proliferation and continued maintenance of the maturing vessels. The VEGF signaling event may be downstream from the *Fgf* signaling pathway.

The *pseudoglandular* stage generally is considered to encompass weeks 5 to 17, during which the lung has the appearance of a tubular gland. Continuing development of the lung buds is dependent on expression of FGF10 in the mesoderm and FGF receptor 2 (FGF2) in the endoderm. Branching is controlled by expression of Br1 (Branchless), a ligand of FGF, in small clusters of endodermal and mesodermal cells. Patterning genes determine the position of the clusters. The signaling network involved in this stage is complex, with feedback loops that significantly influence the morphogenetic signals.

In the *canalicular* stage (weeks 16 to 26) and extending into the saccular stage (weeks 24 to 38), the endoderm differentiates to form type I and II epithelial cells, and the air-blood barrier forms as capillaries remodel and become applied to the type I cells. The *saccular* stage is characterized by formation of saccules, the precursors of the alveoli. Matrix proteins assemble into a scaffold configuration at this time and also act as a reservoir for growth proteins such as transforming growth factor-β (TGF-β). Multiple signaling pathways are involved, with the *Fgf* pathway appearing to have a critical role in alveolar development.

The *postnatal* stage is characterized by rapid alveolarization and microvascular maturation, with an approximate 20-fold multiplication of surface area and an increase from approximately 50 million to 300 million alveoli. New alveoli arise from septa containing a double capillary network, or new septa are formed from mature septa, with induced formation of capillary network. Myofibroblasts and collagen and elastic fibers appear to be necessary for continued septation, and platelet-derived growth factor (PDGF) is necessary in this process, whereas VEGF is necessary for capillary maturation and maintenance.

NORMAL LUNG ANATOMY

The lungs can move freely within the thorax, attached normally only at the hila. The lungs are covered by a serosal membrane known as the visceral pleura. This membrane is then reflected as the parietal pleura over the hilum to cover the mediastinum, chest wall, and diaphragm. The serosal space is a theoretic space between the two pleural layers; normally, only a thin layer of pleural fluid separates the two layers. The pleura itself is formed as a layer of mesothelial cells supported by an elastic fiber network, which in turn is supported by a loose fibroconnective tissue layer. Mesothelial cells are characterized by their long microvilli.

As shown in **Table 1-2** and **Figure 1-1**, *A* to *D*, the lungs are asymmetrically paired. The right lung is divided by major and minor fissures into three lobes: the upper, lower, and middle lobes. By contrast, the left lung has a single fissure dividing it into upper (superior) and lower (inferior) lobes. In the left lung, the homologue of the right lung's middle lobe is the *lingula*, made up of the anterior and inferior portions of the upper lobe. In some persons there may be an incomplete fissure separating the lingula from the upper lobe. Bronchopulmonary segments are subunits of the lobes that derive from

---

Table 1-1 **Stages of Lung Development**

Stage	Time	Growth Characteristics	Important Genes/ Growth Factors
Embryonic	4-7 weeks	• Beginning organogenesis • Development of major airways	Nkx2-1, BMPs, FGFs, Wnts, retinoic acid, VEGF
Fetal pseudoglandular	5-17 weeks	• Bronchial tree formation • Beginning of parenchyma differentiation	FGFs, Wnt, PDGF, BMP
Fetal canalicular	16-26 weeks	• Conducting airways • Epithelial differentiation	Wnts, FGFs, TGF-β
Fetal saccular	24 weeks–term	• Air space expansion • Beginning alveolarization	VEGF, PDGF
Postnatal	Term–early childhood	• Remodeling with continued septation and alveolarization • Maturation of capillary bed	PDGF, VEGF

BMP, bone morphogenetic protein; *FGFs*, fibroblast growth factors; *PDGF*, platelet-derived growth factor; *TGF-β*, transforming growth factor-β; *VEGF*, vascular endothelial growth factor.

the first generation of bronchi below the lobar bronchi. These also are asymmetric between lungs; Table 1-1 shows the nomenclature.

The next-smallest unit of the lung below the gross level of definition is the *pulmonary lobule*, also known as the secondary lobule of Miller. On the pleural surface, the secondary lobule is outlined by connective septa and has a roughly polygonal shape, measuring between 1 and 2 cm in diameter. Examination of the cut surface of lung again shows the interlobular septa demarcating the edges of the lobule (**Figures 1-2 and 1-e1**); these are best seen in the periphery, because interlobular septa are less well developed in the center of the lungs. Lobules also can be identified on microscopic examination (**Figures 1-e2** and **1-e3**). Each lobule contains three to five acini, which are the basic units of gas exchange. An *acinus* is defined as the lung parenchyma that derives from a single terminal membranous bronchiole and includes three successive generations of respiratory bronchioles and their subtending alveolar ducts, alveolar saccules, and alveoli. The terminal bronchioles branch near the center of the lobules, and their acini abut the interlobular septa. This relationship allows assessment of alterations in the lung parenchyma in terms of its location within the lung lobule (centrilobular, panlobular, paraseptal).

AIRWAYS

The bronchial system generally is divided into conducting and respiratory airways. The conducting airways extend from the trachea to the membranous bronchioles, and the architecture changes as the airways decrease in size. The trachea has a membranous posterior aspect composed of transverse smooth muscle bundles that together make up the trachealis muscle,

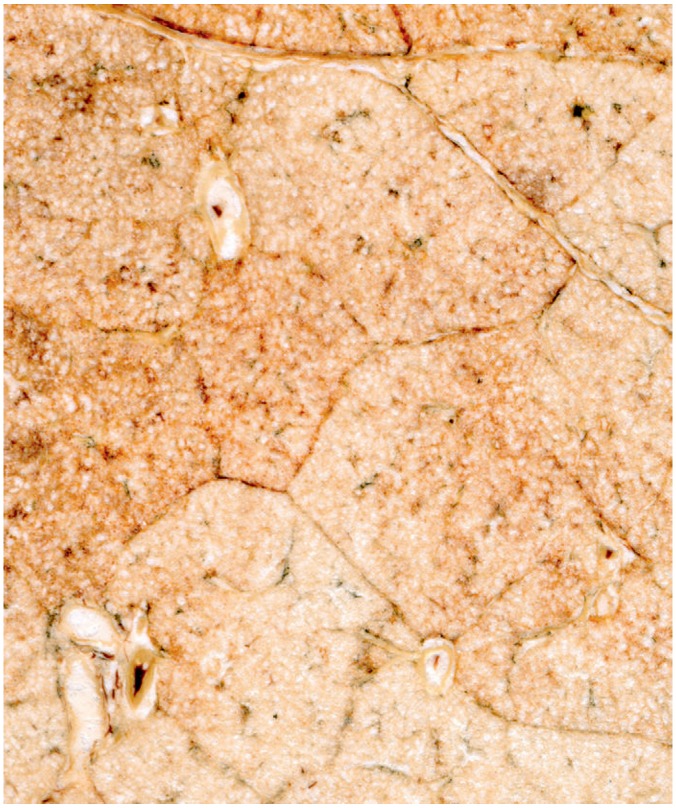

Figure 1-e1 Gross photo of Gough section showing multiple normal lung lobules.

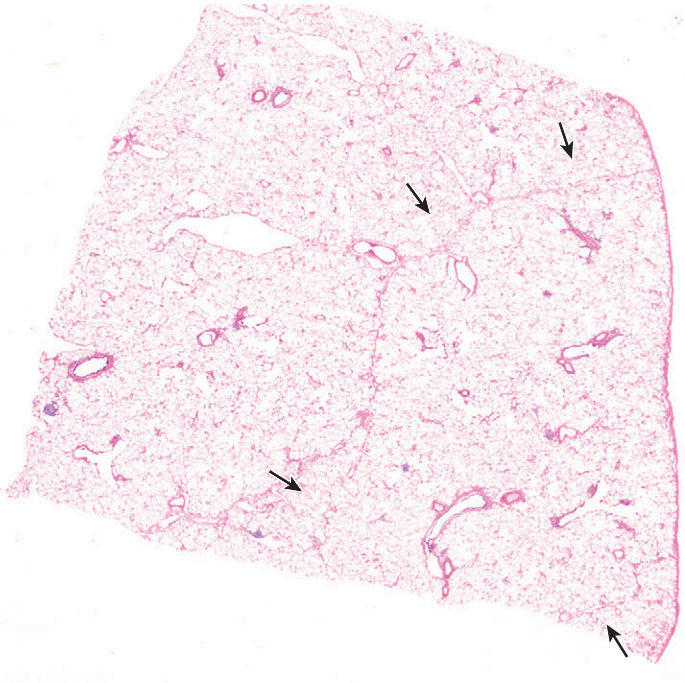

Figure 1-e3 Whole-mount histologic section demonstrating the microscopic equivalent of a secondary lobule of Miller. The *arrows* point to the pleura and the venous septa. Note the several respiratory bronchioles within the lobule.

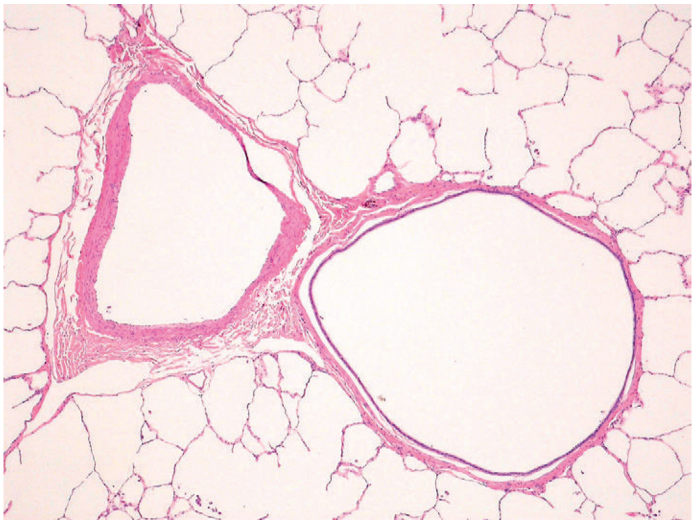

Figure 1-4 Membranous bronchiole with adjacent pulmonary artery. The diameters of the airway and the artery are roughly similar.

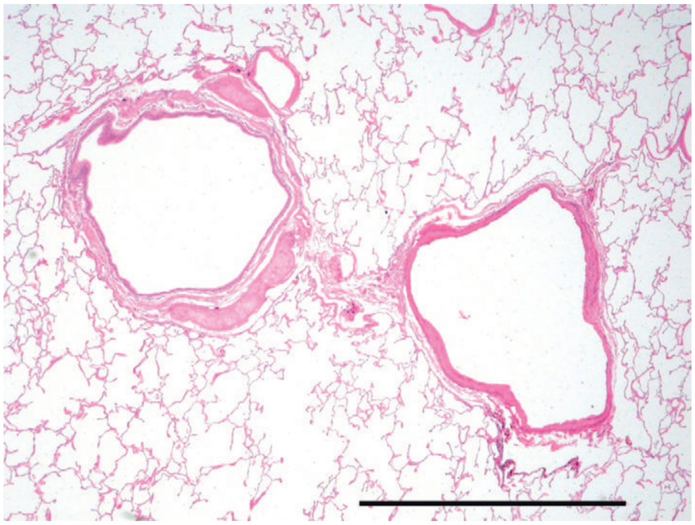

Figure 1-3 A cartilaginous intrapulmonary conducting airway with adjacent pulmonary artery. Of note, the diameters of airway and artery are similar. *Bar* indicates 2 mm.

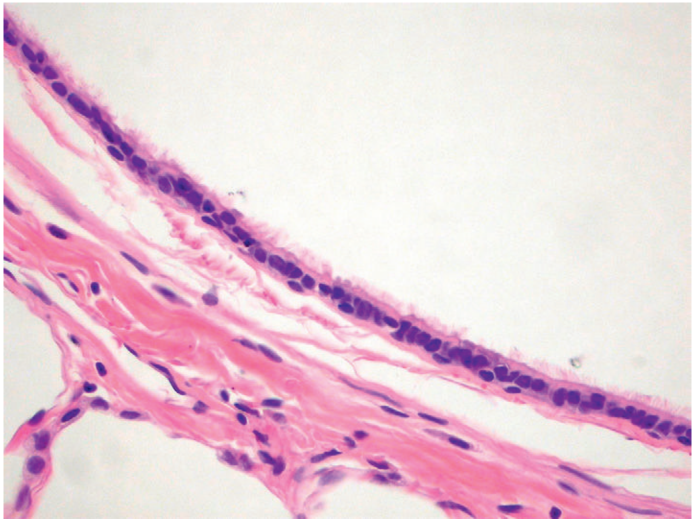

Figure 1-5 Bronchiolar epithelium with predominantly ciliated cells.

with protective cartilaginous rings on the anterior aspect (**Figure 1-e4**). In the *cartilaginous* bronchi, the cartilage plates enclose but do not completely surround the airway, and the muscle fibers wind around the airway in a spiral. These airways are surrounded by loose connective tissue, which contains the bronchial arteries, venous trunks, lymphatics, and nerves (Figures 1-3 and 1-e5). In the upper airways, the epithelium is predominantly ciliated, with a modest number of goblet cells. The cells are supported by a thin basement membrane. The bronchial mucous glands lie deep to the epithelium, with the mucous gland pits emptying onto the surface of the airway (**Figure 1-e6**). The glands contain both serous and mucous cells, with myoepithelial cells, all enclosed within the basal lamina of the glands (**Figure 1-e7**).

The noncartilaginous conducting airways extend from approximately generation 5 to generation 14 and are termed membranous bronchioles (Figure 1-4). The more proximal airways have a ciliated cell predominance (Figure 1-5), whereas the more distal airways acquire increasing numbers of nonciliated bronchiolar (Clara) cells until they account for approximately 11% of the total epithelial cell numbers in the terminal membranous bronchioles. Each bronchiole has a complete fibromuscular wall, with the muscle arranged in a tight spiral. An inconspicuous compartment located between the basement membrane and the muscle layer contains a few collagen fibers and longitudinally oriented elastic fibers. The bronchioles have an adventitial sheath into which adjacent alveoli insert.

The respiratory bronchioles have an incomplete fibromuscular wall, because they are partially alveolarized (Figure 1-6); the degree of alveolarization increases in each generation. The muscle bundles continue down the walls of the alveolar ducts, which are airways with completely alveolate walls, and end at the alveolar saccule entrance rings (**Figure 1-e8**).

AIRWAY EPITHELIAL CELLS

Mucin-secreting cells are differentiated toward goblet cells and are characterized by a bulging apex distended by secretory vacuoles.

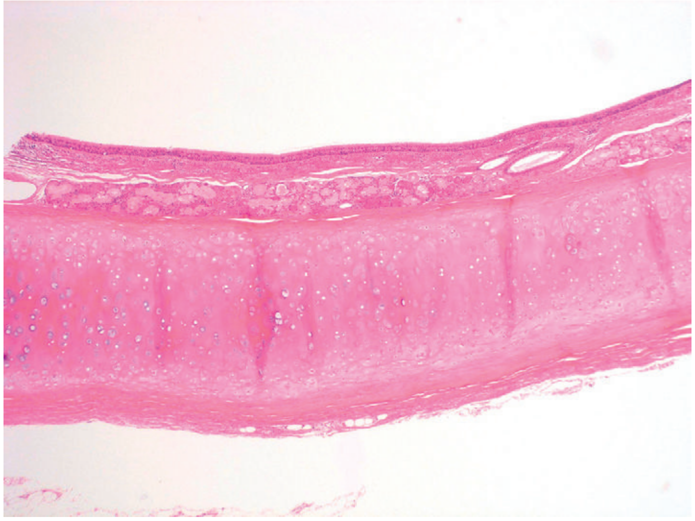

Figure 1-e4 Low-power view of trachea demonstrating epithelium, mucous gland and pit, hyaline cartilage, and perichondral fibrous tissue.

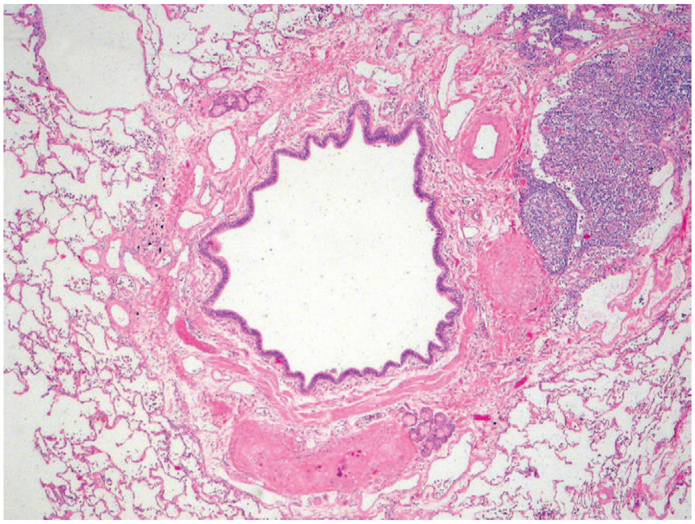

Figure 1-e5 Segmental cartilaginous bronchus with adjacent bronchial lymphoid tissue.

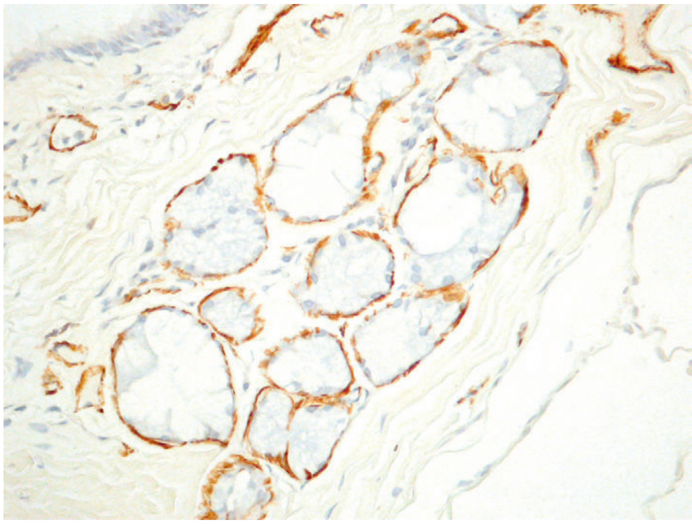

Figure 1-e7 Smooth muscle actin immunohistochemical staining of bronchial gland reveals the myoepithelial cells surrounding the acini.

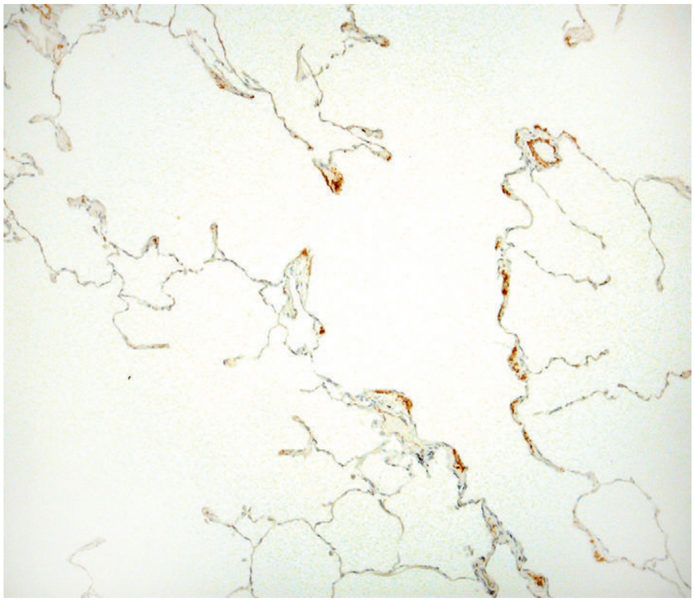

Figure 1-e8 Smooth muscle actin immunohistochemical staining reveals muscle bundles in the mouths of the alveolar ducts and alveolar saccules.

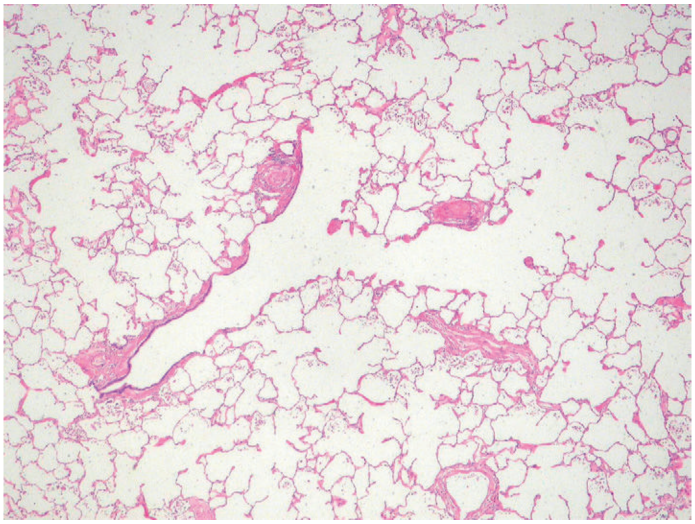

Figure 1-6 Terminal membranous bronchiole bifurcating into two respiratory bronchioles, which in turn have subtending alveolar ducts, saccules, and alveoli.

The *ciliated cells* arise from differentiation of the basal and nonciliated cells; they are columnar in type and attach to the basal lamina. The cilia are complex structures with dynein arms, nexin links, and radial spokes, all configured to utilize adenosine triphosphatase to control cilial beat.

Clara cells are nonciliated secretory cells that produce Clara cell secretory protein, some of the surfactant apoproteins, and antileukoproteinase and are a rich source of oxidases.

Neuroendocrine cells are known by several different names: *Feyrter cells* and *Kulchitsky cells* are more modern terms, but *amine precursor uptake and decarboxylation (APUD) cells* and *"small granular" cells* are found in earlier literature. The cells are roughly flask-shaped, with an apical protrusion found between the columnar cells extending to the airway surface. They express immunohistochemical neural markers such as chromogranin and synaptophysin, in addition to peptide hormones such as substance P, calcitonin, and gastrin-releasing peptide.

ALVEOLUS

The alveolus is the main gas exchange area of the lung and is composed of a thin epithelial layer supported by its basement membrane, a capillary endothelium supported by its own basement membrane, and the interstitium between the two basement membranes (Figures 1-7 and 1-e9). Where the two basement membranes are fused, the alveolus is optimized for gas exchange; this region is known as the "thin" portion of the blood-air barrier. In the "thick" portion, by contrast, the basement membranes are separate, and there are fibroblasts, collagen and elastin fibers, and contractile interstitial cells (myofibroblasts, pericytes, and smooth muscle cells).

The alveolus is penetrated by openings known as the pores of Kohn (Figure 1-8). These appear early in postnatal life and increase in number with age. A majority of the pores are filled by alveolar lining fluid, but their geometry is affected by lung volumes. They may be important in collateral ventilation or may represent an acquired degenerative lesion.

Alveolar Epithelial Cells

Most of the alveolar surface is covered by simple squamous cells known as type I pneumocytes (Figure 1-9). These cells have a small nucleus with highly branched cytoplasmic

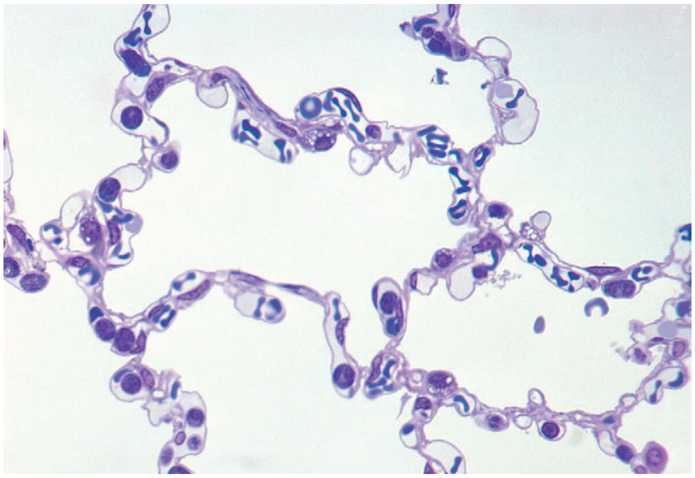

Figure 1-7 Plastic section showing the components of an alveolus.

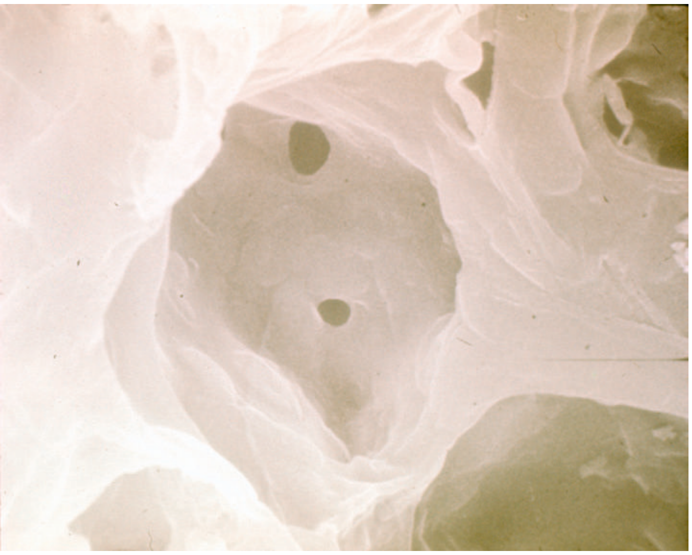

Figure 1-8 Scanning electron micrograph of pore of Kohn. *(Courtesy Dr. William Thurlbeck.)*

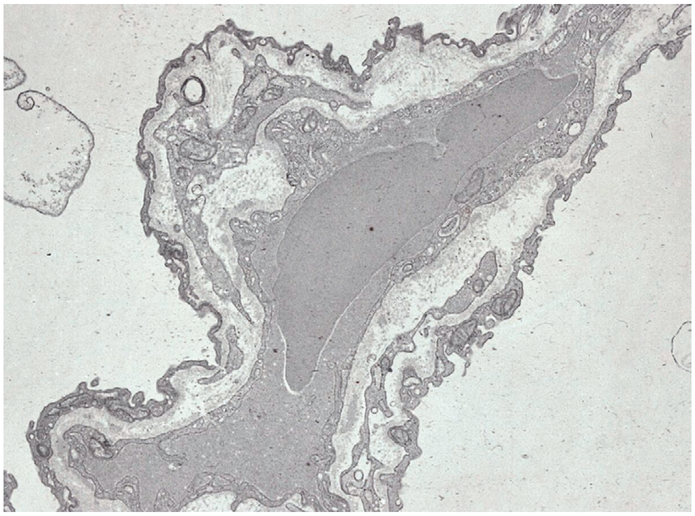

Figure 1-9 Transmission electron micrograph of a type I cell.

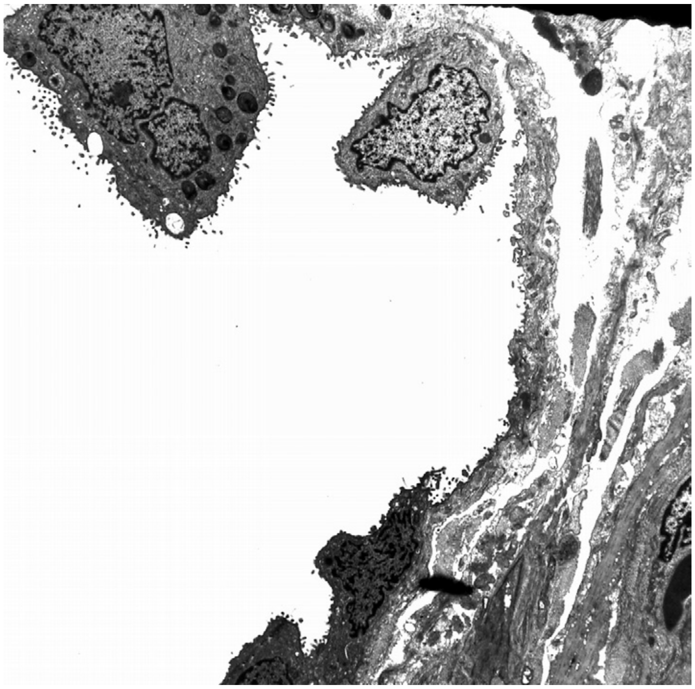

Figure 1-e9 Transmission electron micrograph showing the relationships of type I and type II alveolar cells to the capillaries and interstitium of alveolar wall.

processes covering 4000 to 5000 µm^2. The cytoplasm contains sparse organelles. Type I cells form by mitotic division and transformation of type II cells. The normal ratio of type I to type II cells is 1:2.

Type II epithelial cells have a granular appearance and, in humans, are noted to protrude into the alveolar space (**Figure 1-10**). They have abundant mitochondria, endoplasmic reticulum, and a large Golgi apparatus, in addition to conspicuous secretory granules, called lamellar bodies, which are composed of surfactant. Surfactant is approximately 90% lipid in nature, the major portion of which is phosphatidylcholine; surfactant apoproteins A, B, C, and D make up the remainder.

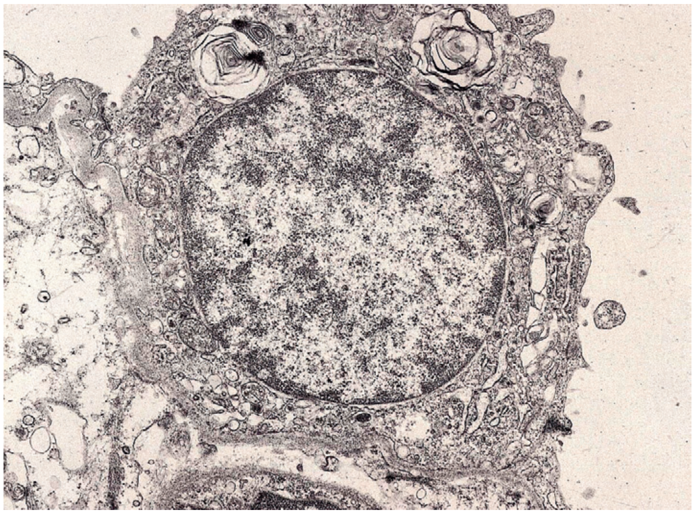

Figure 1-10 Transmission electron micrograph of a type II cell. Lamellar granules are evident within the cytoplasm.

VASCULAR SYSTEM

The main pulmonary artery splits into its two main branches within the mediastinum and beneath the aortic arch. The right pulmonary artery passes beneath the aortic arch and enters the lung anterior to the main bronchus. The left pulmonary artery travels above the main bronchus, passes over the superior lobar bronchus, and can then be identified posterior to the bronchus. The pulmonary arteries branch in company with the bronchi (see Figures 1-3 and 1-4) and can be identified down to the level of the tertiary respiratory bronchioles–alveolar ducts where they are small and poorly muscularized (see Figure 1-6). These precapillary vessels feed into the alveolar-capillary network, which consists of a gridlike mesh (**Figure 1-11**). The capillaries empty into the pulmonary veins, which travel a path independent of the bronchi, at the periphery of the acinus. When the interlobular septa are well formed, the veins lie within the septal fibrous tissue. At the hilus of each lung, the two pulmonary veins independently enter into the left atrium.

The bronchial blood supply is through the systemic circulation, arising from the aorta or the intercostal, internal mammary, or subclavian arteries. In gross specimens, the bronchial arteries can be identified in the connective tissue of the bronchial wall. Venous blood from the central bronchial circulation flows through bronchial veins and empties into the azygos and hemiazygos veins; that from the peripheral bronchi enters into the pulmonary venous system.

LYMPHATIC SYSTEM

The lymphatic vessels run in the visceral pleura as a superficial network of channels and are present in the fibroconnective tissue of the interlobular septa and the bronchovascular bundles, where they form a deep plexus. These vessels have valves to direct the flow toward the lung hilus. Lymph travels to the

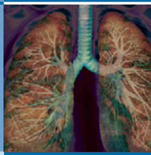
NORMAL STRUCTURE AND FUNCTION



Chapter 2

Basic Aspects of Cellular and Molecular Biology

Stefan J. Marciniak • David A. Lomas

The 20th century saw pulmonary medicine blossom with scientific advances. Although physiology remains at the core of this specialty, pulmonologist investigators are now at the leading edge of research in cell and molecular biology. These laboratory-based disciplines provide tools to study lung disease both in entire populations and at the level of individual proteins. Molecular biology encompasses both genetics and structural biology, which underpin cell biology, from which physiology emerges. Genetics helps to identify the alleles of genes that increase the risk of disease; structural and cell biology then aim to provide the mechanism. It is through an understanding of disease mechanisms that this century will see its major clinical breakthroughs. A working knowledge of these disciplines is therefore essential for today's pulmonologist.

MOLECULAR BIOLOGY

THE GENETIC BASIS OF LUNG DISEASE

Genetic factors play an important role in diseases that affect the airways (asthma, chronic obstructive pulmonary disease [COPD], cystic fibrosis, primary ciliary dyskinesia), parenchyma (pulmonary fibrosis, Birt-Hogg-Dubé syndrome, tuberous sclerosis), and vasculature (hereditary hemorrhagic telangiectasia) of the lung (Table 2-1). Such conditions include simple monogenic disorders such as Kartagener syndrome and α_1-antitrypsin deficiency, in which mutations of critical genes are sufficient to induce well-defined disease phenotypes. By contrast, many other disease processes affecting the lung are complex genetic traits in which inheritance subtly affects pathogenesis. This group of entities includes COPD, asthma, and idiopathic pulmonary fibrosis. Extending current understanding of the genetic basis of pulmonary conditions will be essential to provide new insights into their underlying pathophysiology, to make predictions about outcome, and to develop novel therapeutic strategies.

Identification of single-gene defects in families that show the same phenotype is now relatively straightforward, owing to completion of the human genome project and improvements in DNA sequencing. Consequently, the past 20 years have seen rapid progress in elucidation of the genetic basis of disease. This rate of progress can be appreciated by a consideration of the many years required to identify the gene associated with cystic fibrosis. Dorothy Hansine Andersen first defined the condition in 1938 when she described cystic fibrosis of the pancreas in association with lung and intestinal disease. Only later was it recognized to be a recessive condition. The sweat test that is used to diagnose the condition was developed after the detection of abnormal sweat electrolytes by Paul di Sant' Agnese in 1952. The search for the cystic fibrosis gene started in the early 1980s, and the gene was localized to chromosome 7 in 1985 through recognition of linkage with the highly polymorphic gene paraoxonase in many populations. This achievement was followed by the identification of additional markers more closely linked to the cystic fibrosis locus, MET and D7S8, allowing prenatal diagnosis of the disorder and eventually leading directly to the mapping of the causative gene in 1989 by teams headed by Lap-Chi Tsui, Francis Collins, and Jack Riordan. This gene was called the cystic fibrosis transmembrane conductance regulator (*CFTR*), and now more than 1000 different mutations have been identified that cause cystic fibrosis.

By contrast, today, what had once taken many groups a decade to complete can be undertaken in a single laboratory in days. For example, modern exome sequencing enables all 180,000 exons encoded by the human genome to be characterized in an individual patient or an entire kindred. Although the exome equates to only 1% of the genome, or about 30 megabases, it is thought to contain 85% of the mutations responsible for mendelian disorders. This technology, for example, was recently used to identify the causative gene of Miller syndrome, a rare disorder that manifests with cleft palate, absent digits, and ocular anomalies. The entire exomes of four persons so affected were sequenced, allowing mutations to be identified in the causative gene encoding dihydroorotate dehydrogenase (*DHODH*).

The major challenges now are therefore no longer the single-gene disorders but complex genetic diseases such as cancer, COPD, asthma, and interstitial lung disease. These diseases are the result of interactions between multiple genes and environmental factors. Consequently, the diseases cluster within families but do not show a clear pattern of inheritance.

SINGLE-GENE DISORDERS AND RESPIRATORY DISEASE

Many single-gene disorders have been linked with respiratory disease (see Table 2-1). They are perhaps best typified by the autosomal recessive condition α_1-antitrypsin deficiency. This condition shows a clear genotype-phenotype correlation with current understanding of the molecular basis providing new insights into the pathogenesis of disease. α_1-Antitrypsin is the archetypal member of the serine proteinase inhibitor

Table 2-1 Examples of Genetic Factors That Underlie Lung Disease

Condition	Inheritance	Gene(s) Associated With Disease	Chromosomal Location	Affected Protein(s)
Respiratory distress syndrome	Multifactorial	*SFTPA1*	10q22.2-q23.1	Surfactant protein A
		SFTPB	2p12-p11.2	Surfactant protein B
		SFTPC	8p21	Surfactant protein C
Primary ciliary dyskinesia (CILD1-13)	Autosomal recessive	*CILD1* (*DNAI1*)	9p21-p13	Dynein intermediate chain 1, axonemal
		CILD2 (?)	19q13.3	?
		CILD3 (*DNAH5*)	5p	Dynein heavy chain 5, axonemal
		CILD4 (?)	15q13	?
		CILD5 (?)	16p12	?
		CILD6 (*TXNDC3*)	7p14.1	Thioredoxin domain containing 3
		CILD7 (*DNAH11*)	7p21	Dynein heavy chain 11, axonemal
		CILD8 (?)	15q24-q25	?
		CILD9 (*DNAI2*)	17q25	Dynein intermediate chain 2, axonemal
		CILD10 (*KTU*)	14q21.3	Kintoun
		CILD11 (*RSP4A*)	6q22	Radial spoke head 4 A
		CILD12 (*RSPH9*)	6p21	Radial spoke head 9
		CILD13 (*LRRC50*)	16p24.1	Leucine-rich repeat containing 50
Asthma	Multifactoral	*ADAM-33*	20p13	A disintegrin and metalloproteinase domain 33
		CHI3L1	1q32.1	Chitinase 3-like 1
		DPP10	2q12.3-q14.2	Dipeptidyl peptidase X
		HLA-G	6p21.3	Histocompatibility antigen class I G
		ORMDL3	17q21.1	Orosomucoid 1-like protein 3
		GSDMB	17q21	Gasdermin B
Interstitial lung disease	Multifactoral	*TERT*	5p15.33	Telomerase reverse transcriptase
		TERC	3q21-q28	Telomerase RNA component
		SFPA1	10q22.2-q23.1	Surfactant protein A1
		SFTPA2	10q22-q23	Surfactant protein A2
		SFTPC	8p21	Surfactant protein C
Cystic fibrosis	Autosomal recessive	*CFTR*	7q31.2	Cystic fibrosis conductance regulator
α_1-Antitrypsin deficiency	Autosomal recessive	*SERPINA1*	14q32.1	α_1-Antitrypsin
Pneumothorax and emphysema secondary to Marfan syndrome	Autosomal dominant	*FBN1*	15q21.1	Fibrillin
Emphysema secondary to Menkes disease	X-linked recessive	*ATP7A*	Xq12-q13	Copper-transporting ATPase
COPD	Single-gene defect	*ELN*	7q11.2	Elastin
Emphysema secondary to cutis laxa	Autosomal recessive	*FBLN4*	11q13	Fibulins
		FBLN5	14q32.1	
COPD	Multifactoral	*SERPINE2*	2q33-q35	Thrombin protease inhibitor
		MMP12	11q22.2-q22.3	Matrix metalloproteinase-12
		CHRNA-3/5	2q24-q32	α-Nicotinic acetyl choline receptor
		HHIP	4q28-q32	Hedgehog-interacting protein
		FAM13A	4q22.1	Family with sequence similarity, member A

Table 2-1 **Examples of Genetic Factors That Underlie Lung Disease—cont'd**

Condition	Inheritance	Gene(s) Associated With Disease	Chromosomal Location	Affected Protein(s)
Hyper-IgE (Job's syndrome)	Autosomal dominant	*STAT3*	17q21	Signal transducer and activator of transcription 3
Familial pneumothorax (Birt-Hogg-Dubé syndrome)	Autosomal dominant	*FLCN*	17p11.2	Folliculin
Tuberous sclerosis with pulmonary cysts/ lymphangioleiomyomatosis	Autosomal dominant	*TSC1*	9q34	Hamartin
		TSC2	16p13.3	Tuberin
Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome)	Autosomal dominant	*HHT1*	9q34.1	Endoglin
		ALK1	12q11-q14	Activin receptor–like kinase-1
Primary pulmonary hypertension	Autosomal dominant	*BMPR2*	2q33	Bone morphogenetic protein receptor type II
		ALK1	12q11-q14	Activin receptor–like kinase-1

("serpin") superfamily. It is synthesized in the liver and secreted into the plasma, where it is the most abundant circulating proteinase inhibitor. Most people of North European descent carry the normal M allele, but 1 in 25 carries the Z variant (Glu342Lys), which results in plasma α_1-antitrypsin levels in the homozygote that are 10% to 15% of the normal M allele. The Z mutation causes the accumulation of α_1-antitrypsin in the rough endoplasmic reticulum of the liver, predisposing the homozygote to the development of juvenile hepatitis, cirrhosis, and hepatocellular carcinoma. The greatly reduced circulating levels of α_1-antitrypsin are unable to protect the lungs against proteolytic damage by neutrophil elastase, predisposing the Z homozygote to the development of early-onset emphysema.

The structure of α_1-antitrypsin is based on a dominant β-pleated sheet A and nine α-helices (**Figure 2-1**). This scaffold supports an exposed mobile reactive loop that presents a peptide sequence as a pseudosubstrate for the target proteinase. After docking, the proteinase is inactivated by a mousetrap-type action that swings it from the top to the bottom of the serpin in association with the insertion of an extra strand into β-sheet A (see Figure 2-1). This six-stranded protein bound to its target enzyme is then recognized by hepatic receptors and cleared from the circulation. The structure of α_1-antitrypsin is central to its role as an effective antiproteinase but also renders it liable to undergo conformational change in association with disease. The Z mutation is at residue P_{17} (17 residues proximal to the key P_1 amino acid that defines the inhibitory specificity of α_1-antitrypsin) at the head of a strand of β-sheet A and the base of the mobile reactive loop (see Figure 2-1). The mutation opens β-sheet A, thereby favoring the insertion of the reactive loop of a second α_1-antitrypsin molecule to form a dimer (see Figure 2-1). This dimer can then extend to form polymers that tangle in the endoplasmic reticulum of the liver to form the inclusion bodies resulting in liver disease. Support for this pathomechanism comes from the demonstration that Z α_1-antitrypsin formed chains of polymers when incubated under physiologic conditions. The rate was accelerated by raising the temperature to 41° C and could be blocked by peptides that compete with the loop for annealing to β-sheet A. The role of polymerization in vivo was clarified by the finding of α_1-antitrypsin polymers in inclusion bodies from the livers of Z α_1-antitrypsin homozygotes (see Figure 2-1).

Although many α_1-antitrypsin deficiency variants have been described, only three other mutants of α_1-antitrypsin have similarly been associated with plasma deficiency and hepatic inclusions: α_1-antitrypsin Siiyama (Ser53Phe), α_1-antitrypsin Mmalton (Phe52 deleted), and α_1-antitrypsin King's (His334Asp). All of these mutants lie in the shutter domain that controls opening of β-sheet A. They destabilize the molecule to allow the formation of loop-sheet polymers in vivo. Further investigations have shown that polymerization also underlies the mild plasma deficiency of the S (Glu264Val) and I (Arg39Cys) variants of α_1-antitrypsin. The point mutations that are responsible for these variants have less effect on β-sheet A than does the Z variant. Thus, the associated rate of polymer formation is much slower than that for Z α_1-antitrypsin, which results in less retention of protein within hepatocytes, milder plasma deficiency, and the lack of a clinical phenotype. However, if a mild, slowly polymerizing I or S variant of α_1-antitrypsin is inherited with a rapidly polymerizing Z variant, then the two can interact to form heteropolymers within hepatocytes. These polymers underlie the inclusions that cause cirrhosis.

Emphysema associated with α_1-antitrypsin deficiency results from lack of protection against proteolytic attack in the lungs associated with reduced levels of circulating proteinase inhibitor. This is particularly the case with individuals who smoke tobacco. The Z α_1-antitrypsin that does escape from the liver into the circulation is less efficient in protecting the tissues from enzyme damage and, like M α_1-antitrypsin, may be inactivated by oxidation of the P1 methionine residue. The demonstration that Z α_1-antitrypsin can undergo a spontaneous conformational transition in association with liver disease raised the possibility that this might also occur within the lung. Indeed, polymers have been detected in bronchoalveolar lavage fluid in patients with Z α_1-antitrypsin deficiency. This observation may have important implications for the pathogenesis of disease, because polymerization obscures the reactive loop of α_1-antitrypsin, rendering the protein inactive as an inhibitor of proteolytic enzymes. Thus, the spontaneous polymerization of α_1-antitrypsin within the lung will exacerbate the already reduced antiproteinase screen, thereby increasing the

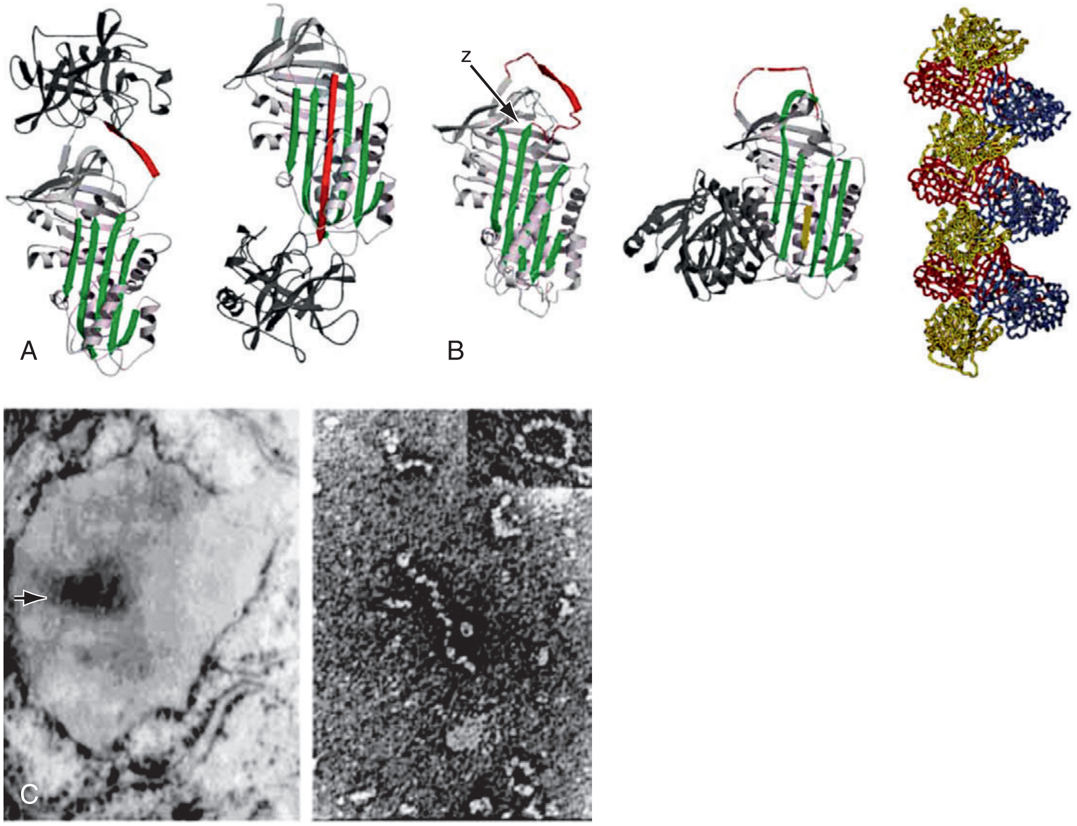


Figure 2-1 The molecular basis of α_1-antitrypsin deficiency. α_1-Antitrypsin may be considered to act by a mousetrap mechanism. **A,** After docking (*left*), the target proteinase (*gray*) is inactivated by movement from the upper to the lower pole of the protein (*right*). This is associated with insertion of the reactive loop (*red*) as an extra strand into β-sheet A (*green*). The mousetrap mechanism may be triggered spontaneously by point mutations in association with disease. The Z mutation (Glu342Lys) of α_1-antitrypsin is at the head of a strand of β-sheet A (*green*) and the base of the reactive loop. **B,** Mutations in this region can destabilize β-sheet A to allow the insertion of a reactive loop of a second molecule (*middle*). This dimer then extends to form long chains of polymers (*right*). Each molecule of α_1-antitrypsin in the polymer is shown in a different color. It is these polymers that tangle in the endoplasmic reticulum to cause inclusions resulting in liver disease. **C,** An inclusion body (*arrow*) from the liver of a patient with α_1-antitrypsin deficiency (*left*). The inclusions are composed of chains of molecules of α_1-antitrypsin (*right*). *(Modified from Gooptu B, Lomas DA: Conformational pathology of the serpins—themes, variations and therapeutic strategies,* Annu Rev Biochem *78:147–176, 2009.)*

susceptibility of the tissues to proteolytic attack and increasing the rate of progression of emphysema. Finally, the α_1-antitrypsin polymers themselves are inflammatory for neutrophils, which will also increase the proteolytic load in the lung. Recent data suggest that cigarette smoke can induce the intrapulmonary polymerization of Z α_1-antitrypsin, thereby exacerbating the lung damage associated with smoking.

GENE HUNTING FOR COMPLEX GENETIC DISEASES AND ITS PITFALLS: COPD AND ASTHMA

One approach to looking for genes associated with complex genetic disorders is by means of an *association study,* which analyzes genetic variation between cases and controls (i.e., without disease) matched for various factors. The genetic variation commonly used in such studies is the single-nucleotide polymorphism (SNP) (DNA sequence variation) found approximately every 300 base pairs across the genome. These studies have been undertaken in patients with COPD matched with control subjects who do not have COPD but who are the same age and have the same smoking history and the same ethnic background. The early studies typically were small (100 to 150 cases plus controls) and often were confounded by failure to match carefully cases and controls. To increase the likelihood of finding a disease-associated gene, such studies frequently included SNPs in multiple genes in the same cohort. However, such *multiple comparisons* can result in false-positive results. With study of sufficient numbers of genes, purely by chance a variant will arise that erroneously appears to be associated with the disease being studied. Careful statistical analysis is necessary to avoid this problem.

The analysis was made more complex in COPD by the inherent complexity of the disease phenotype—a heterogeneous mix of airway disease and emphysema. Indeed, larger family-based studies have shown the independent clustering of the airway disease and emphysema components of COPD within families. This finding suggests that different genetic factors predispose to each of these components of the phenotype. The only way to overcome the inherent variation in COPD is to focus on groups of patients with well-characterized disease components or to undertake studies with large sample sizes and then to replicate any positive findings in other cohorts. This is now the case with candidate gene studies, and good evidence has emerged to show that heterozygosity for α_1-antitrypsin deficiency (phenotype PiMZ) and polymorphisms in genes involved in oxidative stress—those encoding microsomal epoxide hydrolase (*EPHX1*), glutathione *S*-transferase (*GST-P1* and *GST-M1*), heme oxygenase (*HMOX1*), and superoxide dismutase 3 (*SOD3*)—are associated with an increased risk of COPD (Figure 2-2). More recently, a minor

Figure 2-2 Genes implicated in chronic obstructive pulmonary disease (COPD). When smoke enters the alveolus, many of its constituent compounds are absorbed. Some of these are detoxified by an array of enzymes; those that escape detoxification cause local damage and inflammation. The influx and activation of inflammatory cells lead to the liberation of proteases that attack the extracellular matrix, primarily elastin. The effect of these proteases is attenuated by endogenous antiprotease activities, whereas growth factor signals are thought to modulate the repair and remodeling of the extracellular matrix.

allele of an SNP in the matrix metalloprotease-12 gene (*MMP12*) has been shown to protect against COPD in adult smokers.

The limitation of association studies using a *candidate gene approach* is that they are by definition restricted to pathways already recognized to be associated with the disease—in the case of COPD, the proteinase-antiproteinase balance, the oxidative stress pathway, and the integrity of the extracellular matrix (see later). Consequently, this approach lacks the capacity to identify unanticipated players and is thus restricted to *hypothesis testing*, rather than *hypothesis generation*.

In recent years, the collection of large cohorts of patients combined with technologic advances has allowed unbiased *genome-wide association studies* of many patients with lung disease. It is currently possible to use microarrays to assay up to a million different SNPs in the genome in the same patient. The variation in SNPs is then compared between cases and controls. The largest study was undertaken in a cohort from Bergen, Norway, and then replicated in the International COPD Genetics Network, the National Emphysema Treatment Trial with controls from the Normative Ageing study, and then finally in the Boston Early Onset COPD cohort. Top hits from this analysis were SNPs in the α-nicotinic acetylcholine receptor *CHRNA-3/5* and the hedgehog-interacting protein *HHIP*. The first of these (rs8034919) in the α-nicotinic acetylcholine receptor also was identified in three genome-wide association studies of lung cancer and also is thought to be important in peripheral vascular disease and nicotine addiction. It is possible that this SNP functions as a marker for an addiction gene. People who carry this SNP may require more cigarettes to satisfy nicotine addiction, may inhale more deeply, and may find it more difficult to withdraw from cigarette smoking. If this hypothesis is correct, the disease-associated allele of this gene would account for 12% of the population risk for COPD.

In interpreting any association study, it is important to consider two important caveats. First, many genetic associations studies report false-positive findings owing to a failure to appreciate the *prior probability* of an association and the *power* of the study to detect a meaningful effect. When the prior probability of an association is low, that is to say when there is little functional or epidemiological data to support an association, the numbers of subjects required to guard against a false-positive result increases. Consequently, the identification of a genetic association in a single study must always be treated with caution. Clearly, in the case of the α-nicotinic acetylcholine receptor, it is possible to construct very plausible models for its potential role in COPD, so the prior probability is not low. Moreover, those studies in which it was identified were well powered. The second caveat, however, relates to the phenomenon of *linkage disequilibrium*. The combination of more than one genetic variant or *allele* is called a *haplotype*. Some haplotypes occur in the population more often than one would expect by random association of alleles. This can be caused by, but is not restricted to, the inheritance of blocks of adjacent genes on a chromosome. Clearly, nearby genes are less likely to be separated by recombination during gametogenesis than are more distantly spaced genes. Each population of humans has its own characteristic set of common haplotypes. In this light, a disease-associated SNP can more accurately be viewed as a marker of the haplotype that is associated with the disease under study and the causative gene must be identified within that group. Indeed, in the case of disease-associated SNPs in the α-nicotinic acetylcholine receptor, there does appear to be linkage disequilibrium with SNPs in the iron-responsive element binding protein 2 IREB2. This was identified from expression analysis in lung tissue from persons with COPD and then confirmed in three separate COPD cohorts. IREB2 is localized to the human epithelial cell surface and may play a role in protecting against epithelial damage from oxidative stress.

It is, of course, possible that a haplotype identified in large genome-wide association studies may contain multiple disease-associated genes, so each one needs individual validation. Indeed, many diseases appear to involve the interaction of multiple disease-associated alleles, each with relatively small contributions when studied individually. The chances of identifying an allele that imparts a small *relative risk* for developing a disease are improved both by increasing the numbers of cases studied (increased *power*) and by carefully selecting cases of the same phenotype. With diseases such as COPD that are likely to represent the final common pathway of many forms of lung damage, this consideration is particularly important.

The analysis of still larger numbers of patients with COPD has identified a disease-associated SNP in *FAM13A*. The role of this gene in disease is unclear, but expression has been associated with hypoxia. *FAM13A* also has been associated with lung function in a second independent study. A detailed analysis of these genes in well-characterized cohorts showed that SNPs in the α-nicotinic acetylcholine receptor are associated with smoking intensity, airflow obstruction, and emphysema, and SNPs in the hedgehog-interacting protein are associated with systemic features of COPD (low body mass index) and exacerbations, whereas SNPs in *FAM13A* are associated with airflow obstruction.

Familial clustering of asthma has also been recognized for many years, and comparisons between monozygotic and dizygotic twins suggest that 70% of asthma-related population variance is accounted for by genetic factors. Classical positional cloning using linkage analysis of large families has identified several candidates, including *ADAM33*, *CHI3L1*, *DPP10*, and *HLA*-G, and more recently, asthma-specific genome-wide association studies have identified further disease-associated loci (see Table 2-1). The first of these was in the long arm of chromosome 17 and found to contain two genes, *ORMDL3* and *GSDMB*, whose expression levels are altered in asthmatic persons. The pathways implicated by such studies can now be tested to determine what role they play in disease pathogenesis.

CELL BIOLOGY

INTRACELLULAR SIGNALS

Oxidative Stress

Cigarette smoke contains 10^{17} free radicals per puff, including superoxide ions, hydrogen peroxide, hydroxyl radicals, nitric oxides, peroxynitrite, and semiquinone. Migrating neutrophils also can release superoxide radicals in response to inflammatory stimuli, including pathogens and smoke. Alveolar macrophages from the lungs of smokers are more activated compared with controls and release more reactive oxygen species (ROS) in vitro. These toxic products can all modify proteins, lipids, and DNA during oxidative stress. Oxidized proteins can be found in lung tissue and their level increases with worsening lung disease. This damage leads directly to cell death and emphysema. When ROS react with phospholipids in the cell membrane (*lipid peroxidation*), they generate products such as F_2 isoprostanes and malondialdehyde that can trigger intracellular signaling pathways. For example, isoprostanes cause muscle constriction and induce cell growth by way of prostaglandin receptors. Other diffusible peroxides act as chemoattractants, thereby contributing to inflammation.

Normally, homeostatic mechanisms maintain the reducing environment of the cytoplasm. Glutathione (GSH) is an abundant sulfhydryl chemical that exists in the cytosol predominantly in its reduced form (GSH), with only 1% in the oxidized disulfide-bonded form (GSSG). The cell maintains the ratio of GSH to GSSG strongly in favor of the reduced form by reducing GSSG to GSH, or by excreting GSSG. However, during the adaptive response to oxidative stress, de novo synthesis of GSH also is important. Alterations in GSH metabolism have been shown to affect the sensitivity of cells to oxidative damage. For example, ROS can induce signaling by a number of stress pathways including c-Jun N-terminal kinase (JNK), extracellular signaling kinase, and p38 kinase. These are linked to signaling cascades that ultimately regulate gene transcription.

Oxidative stress is an important activator of nuclear factor κB (NFκB). This proinflammatory transcription factor is held in the cytosol in unstressed cells through binding to its inhibitor, IκB. When cell surface receptors are activated, they can trigger an IκB kinase (IKK) that phosphorylates IκB, targeting it for degradation. NFκB is thus released to migrate to the nucleus, where it transactivates genes involved in many pathways, including the inflammatory response. The precise mechanism whereby NFκB is activated by oxidative stress is not fully understood but may involve the direct activation of IKK by ROS.

ROS also modulate gene transcription by modifying chromatin, so-called *epigenetic regulation*. Chromatin structure determines the access of transcription factors to target sequences within the promoters of genes and is subject to regulation. Posttranslational modification of histones can alter DNA coiling around them. For example, the relative activities of histone acetyltransferases (HATs) and histone deacetylases (HDACs) profoundly alter histone function and consequently gene transcription. Cigarette smoke and oxidative stress can enhance histone acetylation by impairing HDAC activity resulting in altered gene expression.

A number of genes have been studied that might plausibly modify the cells' responses to cigarette smoke and ROS. These include genes involved in detoxification of toxins and genes involved in neutralization of ROS. Many toxins in cigarette smoke are subject to first-pass metabolism in the liver, and one of the enzymes involved in this is microsomal epoxide hydrolase (encoded by *EPHX1*) localized to 1q42.1, which has been studied intensely in the context of COPD (see Figure 2-2). Several *EPHX1* SNPs have been described that affect its activity. One of these leads to a 40% loss of in vitro activity (Tyr113His, the "slow" allele), whereas another increases activity by 25% (His139Arg, the "fast" allele). A recent systematic metaanalysis found homozygosity for the "slow" (Tyr113His) allele to be *protective* against COPD (odds ratio, 0.5). Analysis of the National Emphysema Treatment Trial (NETT) dataset has suggested a role for *EPHX1* polymorphism in both severity of COPD and the distribution of emphysematous changes. In addition to EPHX1, glutathione *S*-transferase (GST) comprises a large family of enzymes capable of catalyzing the conjugation of GSH to noxious compounds. The GSTs are highly polymorphic, and SNPs in *GSTP1* have been associated with COPD, the distribution of emphysema, and more rapid decline in lung function. The null mutation of *GSTM1* (localized to 1p13.1) also has been associated with COPD.

Several other proteins can loosely be considered as having antioxidant activity and thus protective against ROS. Heme oxygenase catalyzes the first step in heme degradation. Heme oxygenase 1 (encoded by *HMOX1*, localized to 22q13.1) is the inducible isoform that can be upregulated by a wide range of stresses. Bile pigments generated by heme cleavage are believed to have antioxidant properties; thus, HMOX-1 induction is protective during cellular oxidant injury, and overexpression of HMOX-1 in lung tissue protects against hyperoxia. The *HMOX1* gene 5′-flanking region contains stretches of GC repeats that are highly polymorphic in length. A higher proportion of long repeats that are associated with impaired promoter activity has been observed in patients with COPD and increased severity of disease. By contrast, superoxide dismutase (SOD) directly catalyzes the conversion of superoxide to oxygen and hydrogen peroxide. The extracellular isoform (encoded by *SOD3*, localized to 4p15) is abundant in lung parenchyma, and in the cross-sectional Copenhagen Heart Study, the R213G allele that results in higher plasma levels was associated with significantly less severe COPD in smokers.

Oxidative stress also is important in the pathogenesis of emphysema associated with α_1-antitrypsin deficiency. Free radicals released from neutrophils or cigarettes can oxidize the key P1 methionine at residue 358, which is central to the inhibitory activity of α_1-antitrypsin. This change results in a 2000-fold reduction in the association rate constant with neutrophil elastase. A reduction in the intrapulmonary concentration of α_1-antitrypsin in persons with α_1-antitrypsin deficiency means that fewer free radicals are required to have a significant impact on the inactivation of α_1-antitrypsin. In addition to Met358, methionines at positions 226, 242, and 351 and the cysteine residue at 232 in α_1-antitrypsin are similarly available for oxidation. These molecules may be considered to function as a sump to "mop up" free radicals, thereby reducing their toxicity. However, persons with α_1-antitrypsin deficiency have fewer molecules to bind free radicals. Moreover, polymer formation masks two of the four methionines, thereby further reducing the capacity of α_1-antitrypsin to detoxify these toxic species. Thus, α_1-antitrypsin from persons with Z α_1-antitrypsin deficiency is more prone to oxidative damage and less able to protect the tissues from oxidative stress as a result of both local deficiency and polymer formation.

Endoplasmic Reticulum Stress

The early steps in the biogenesis of secreted and membrane proteins occur in the lumen of the endoplasmic reticulum, where resident proteins that make up the endoplasmic reticulum machinery assist in their folding, maturation, and complex assembly (**Figure 2-3**). Variation in the load of endoplasmic reticulum client proteins and in the function of its protein-folding machinery can lead to an imbalance between the two that is referred to as *endoplasmic reticulum stress.* This imbalance triggers a cellular response, mediated by signaling pathways that restore balance between the protein-folding environment in the organelle by increasing the expression of genes that enhance most aspects of endoplasmic reticulum function and by transiently repressing the biosynthesis of new client proteins. This response has been termed the *unfolded protein response* (UPR) and is mediated by three signaling molecules, PERK, IRE1, and ATF6, located in the endoplasmic reticulum membrane (see Figure 2-3). It is now clear that the UPR plays a role in many human diseases, including many that affect the lung.

Cigarette smoke can directly induce endoplasmic reticulum stress in cells. When cultured airway epithelial cells are treated with cigarette smoke extracts, they activate the UPR. Similar responses have been observed in vivo in the lungs of cigarette smoke–exposed mice and even in the lungs of human smokers. Overexpression of the endoplasmic reticulum chaperones BiP in cultured bronchial epithelial cells protects them from smoke-induced apoptosis, supporting a role for endoplasmic reticulum stress in cigarette cytotoxicity. Precisely how smoke induces endoplasmic reticulum stress remains to be determined, but the protective effects of coadministered *N*-acetylcysteine or GSH suggest that oxidation of an unknown target is likely to be important.

The existence of IRE1β, a lung- and gut-specific IRE1 isoform, suggests that endoplasmic reticulum stress has important consequences for mucosal tissues. IRE1 signals through splicing the messenger RNA (mRNA) for the transcription factor XBP-1, which transactivates many UPR genes but it is not clear why airways and bowel require a tissue-specific IRE1 isoform. A clue may come from the *XBP1*-mutant mouse, which exhibits impaired mucosal defense against *Listeria monocytogenes* and has poorly bactericidal gut secretions. These observations suggest that the IRE1-XBP1 pathway may play an important role in host-pathogen interactions at epithelial surfaces. Endoplasmic reticulum stress can itself affect the acquired

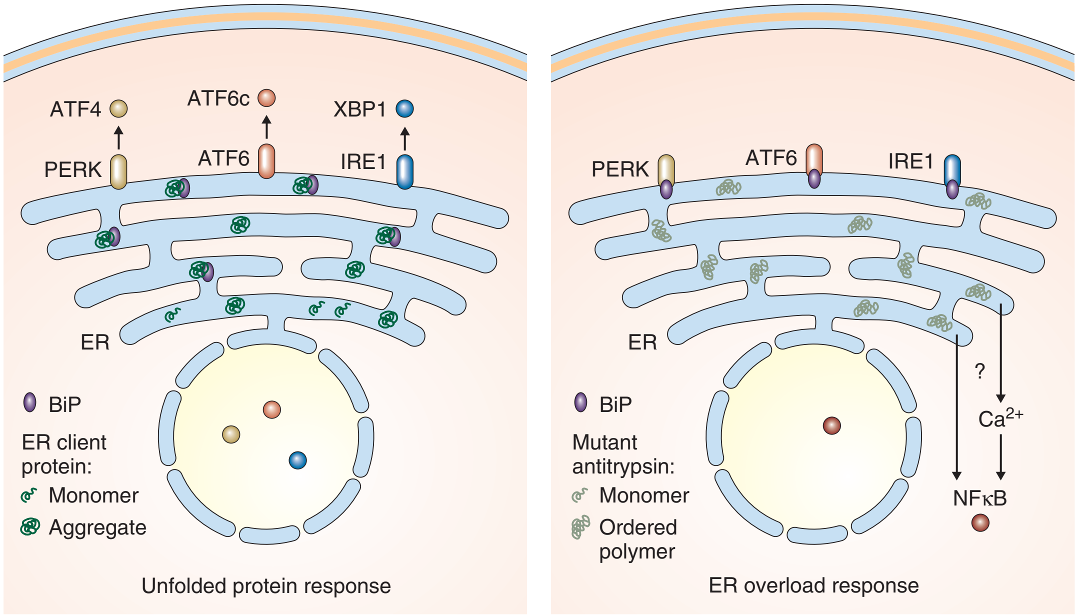

Figure 2-3 Unfolded protein response and endoplasmic reticulum (ER) overload response. *Unfolded protein response* (UPR): In the resting endoplasmic reticulum, the chaperone BiP holds the stress-signaling molecules PERK, IRE1, and ATF6 inactive. When proteins misfold in the endoplasmic reticulum, they sequester BiP (*purple*). This enables PERK, IRE1, and ATF6 to become active and signal to the cytosol. PERK phosphorylates a cytosolic translation initiation factor eIF2α, thereby halting most protein synthesis. In parallel, the translation of a subset of proteins increases. These include the transcription factor ATF4, which transactivates genes of the integrated stress response (ISR). When IRE1 is activated, it splices out an intron from the messenger RNA (mRNA) encoding the transcription factor XBP1. This causes a frameshift in the mRNA, accompanied by the translation of an activated form of XBP1, which can transactivate UPR genes. When ATF6 is released from BiP, it migrates initially to the Golgi apparatus, where it is cleaved by proteases to release a soluble fragment, ATF6c. This migrates to the nucleus, where it transactivates UPR genes. *Endoplasmic reticulum overload response* (EOR): When excess folded proteins accumulate in the endoplasmic reticulum, they cause calcium-dependent activation of nuclear factor κB (NFκB) through a poorly understood mechanism.

immune response. It is clear that the IRE1-XBP-1 pathway is crucial for differentiation programs that require expansion of the endoplasmic reticulum—for example, during the differentiation of B lymphocytes into plasma cells. This requirement can be explained by the regulation of many lipid synthetic genes by XBP-1. In addition, XBP-1–dependent processes appear to be responsible for heightened inflammatory signaling in inflamed airway epithelium. When forced to express active XBP-1, bronchial epithelial cells show elevated bradykinin-induced IL-8 release.

One of the disease-causing mutations of the surfactant protein C gene *SFTPC* is a deletion of exon 4. This change generates a protein that fails to exit the endoplasmic reticulum and induces endoplasmic reticulum stress. When expressed transiently in cultured cells, this mutant of SFTPC accumulates as large ubiquitinated inclusions and inhibits normal proteasome function, ultimately killing the cell. When cell lines that stably express this mutant are infected with respiratory syncytial virus, the cells accumulate high levels of mutant protein, activate the UPR, and show increased toxicity compared with wild type SFTPC–expressing cells. Of interest, evidence of UPR activation has been seen in a majority of cases of interstitial lung disease, both with and without SFTPC mutations. This finding may suggest an even greater role for endoplasmic reticulum stress in idiopathic pulmonary fibrosis. Very recently, it was shown that endoplasmic reticulum stress caused by a variety of insults, including mutant SFPC, can induce *epithelial to mesenchyme transition* (EMT). This is the process by which epithelia can transdifferentiate into cells of a more fibroblast-like phenotype. This mechanism has been suggested to contribute to pulmonary fibrosis and would explain why treatment strategies for idiopathic pulmonary fibrosis involving antiinflammatory drugs have been less than entirely successful. It may instead prove more beneficial to prevent EMT by ameliorating endoplasmic reticulum stress.

Cystic fibrosis is caused by *CFTR* mutations that impede protein folding. High levels of ΔF508 CFTR expression, but not of wild type protein, induce a UPR in cultured cells. However, rather than CFTR expression affecting endoplasmic reticulum stress, the clinically relevant relationship may be the converse. Recent data have suggested endoplasmic reticulum stress affects CFTR expression. In cells treated with agents that induce the UPR, levels of mature CFTR protein are markedly diminished. This involves a selective reduction of genomic CFTR expression; an effect that is not seen with recombinantly expressed CFTR or with endogenous control genes. Repression of the CFTR promoter is achieved both by selective recruitment of ATF6 and by epigenetic changes, including altered DNA methylation and histone deacetylation. This is especially unfortunate, because mucopurulent secretions from patients with cystic fibrosis are sufficient to induce endoplasmic reticulum stress in human bronchial epithelial cells, suggesting that chronic airway sepsis may actually contribute to further impairment of CFTR expression in those cases in which milder mutations allow some of the protein to reach the cell surface. This effect of endoplasmic reticulum stress on CFTR also may explain previous studies that have identified impaired CFTR expression and function in the upper airway of smokers who do not have the disease. This finding had been attributed to oxidant effects alone but now might be explained equally well as a response to smoke-induced endoplasmic reticulum stress. Whether this effect contributes to the pathologic lung changes associated with smoking is unclear, but if it does so, it would provide a novel therapeutic target.

Hypoxia is a far more common cause of protein misfolding than these single-gene disorders. The endoplasmic reticulum requires large amounts of energy to function, so it is one of the first organelles to malfunction when energy supplies are disrupted. This effect can follow nutrient deprivation or hypoxia and appears to play a role in tissue survival during ischemia. Cancers provide a good example of this mechanism. Tumors frequently outgrow their blood supply, so their cores become hypoxic. It has been found that tumors from animals with defective endoplasmic reticulum stress signaling fail to grow well, and most lung cancers show evidence of UPR activation. Consequently, modulation of endoplasmic reticulum stress may offer a target for treating thoracic malignancies. Attempts to identify antimesothelioma therapies found that proteasome inhibition with bortezomib could cause cell cycle arrest and death of cultured mesothelioma lines. The mechanism is not certain, but because bortezomib induces the UPR in several cancer models, endoplasmic reticulum stress may plausibly be involved. In some cancers, bortezomib appears to target hypoxic cells preferentially, perhaps because of their basal endoplasmic reticulum stress.

Endoplasmic Reticulum Overload

Remarkably, when Z α_1-antitrypsin polymerizes within the endoplasmic reticulum of its cell of synthesis, it fails to induce a strong UPR. Instead, the predominant signaling response appears to be activation of NFκB through a poorly understood mechanism that has variously been termed the *endoplasmic reticulum overload response* or the *ordered polymer response* (Figure 2-3). In the liver, this ultimately can lead to cirrhosis. Z α_1-antitrypsin appears also to be synthesized locally in the lung by some cell types, including bronchial and alveolar epithelial cells and macrophages. These too are likely to activate NFκB signaling cascades that would increase the production of inflammatory mediators and further amplify neutrophil recruitment and tissue damage. Chronic activation of NFκB would accelerate apoptosis within alveolar cells and thus contribute to the pathogenesis of emphysema. Because this effect would occur in all alveolar cells, it provides another explanation for the panlobular distribution of emphysema that characterizes α_1-antitrypsin deficiency. Although Z α_1-antitrypsin serves as an excellent model disease to study endoplasmic reticulum overload, it is likely that more common diseases such as some viral infections involve this form of signaling.

MAINTENANCE OF THE EXTRACELLULAR MATRIX

As in all tissues, cells of the lung communicate with one another through direct contact and by way of released diffusible and matrix molecules. This communication network is important during the inflammatory response but also is required for the maintenance of normal lung architecture. The extracellular matrix comprises a complex network of scaffolding proteins, principally elastin and collagen. The elastin filaments form from tropoelastin monomers that self-assemble into aggregates and then fuse with microfilaments. Multiple covalent cross-links between the lysines in neighboring filaments provide stability. Cutis laxa is a family of autosomal dominant, X-linked, and recessive human diseases characterized by excessively slack connective tissues. Several families with the milder autosomal dominant form show early-onset pulmonary pathology including emphysema, particularly if inherited with the Z allele of α_1-antitrypsin. Mutations have been identified within the *ELN* (elastin) gene that cause mild cutis laxa and early-onset COPD

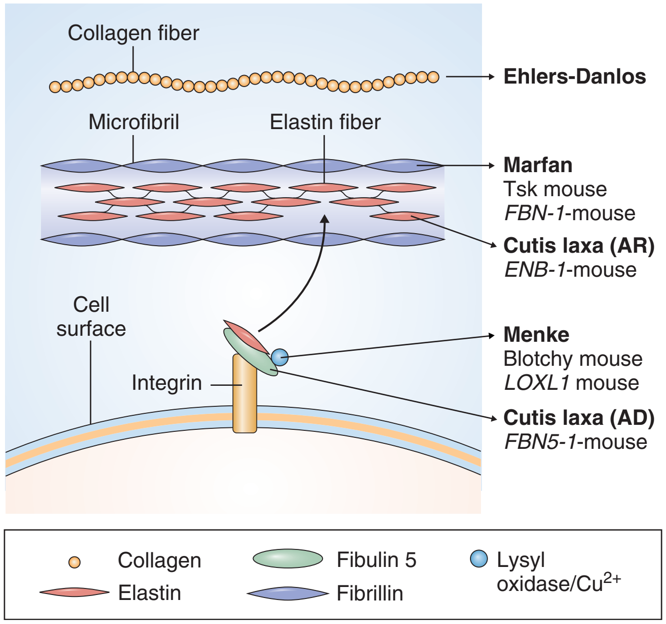

Figure 2-4 Extracellular matrix structure. The extracellular matrix of the lung is composed primarily of collagen and elastin fibers. Large fibrils of collagen assemble within the endoplasmic reticulum and traverse the Golgi apparatus, ultimately to be secreted. Elastin filaments form in association with microfilaments and integrin-anchored fibulin 5. *AD*, autosomal dominant; *AR*, autosomal recessive.

(see Table 2-1). The *ELN* gene maps to 7q11.23 in humans, but because chromosome 7 has not been identified in linkage analysis as a site associated with COPD, it is likely that *ELN* mutations are a rare cause of this disease.

Elastin fibers bind other proteins, including fibulins, which in turn bind multiple extracellular matrix components and the basement membrane (Figure 2-4). The fibulins are a family of six proteins, at least two of which (those encoded by *FBLN4*, mapped to 11q13, and *FBLN5*, on 14q32.1) are mutated in severe autosomal recessive forms of cutis laxa and whose phenotype often includes early-onset emphysema. Both pathogenic mutations are located within an epidermal growth factor–like domain of each protein, suggesting these are critical for fibulins to maintain the integrity of the extracellular matrix within the lung. Of interest, analogous mutations in fibrillin, which bares homology to the fibulins, cause Marfan syndrome. Moreover, mutations of fibrillin (encoded by *FBN1*, localized to 15q21.1) have been described in neonatal Marfan syndrome with very-early-onset emphysema.

Menkes disease, characterized by abnormal hair and specific dysmorphic features, is caused by mutations in an intracellular copper transporter (encoded by *ATP7A*, localized to Xq13.3). The clinical features are due to defective connective tissue synthesis believed to be the result of dysfunction of lysyl oxidase. This copper-dependent enzyme is required for proper cross-linking of both collagen and elastin fibers. A recent case report described a child with Menkes disease and severe bilateral panlobular emphysema who died at only 14 months of age. Gene sequencing revealed a splice-site mutation in *ATP7A*, suggesting that proper extracellular matrix cross-linking is vital for stability of the lung parenchyma.

In contrast with animal models of COPD, mutations in collagen have not been identified in humans. This difference does not appear to be due to an incompatibility of mutated collagen with survival, because numerous collagen mutations have been described that cause other human diseases. Instead, it may reflect a more important role for elastin integrity in emphysema in humans than in mice.

Noxious stimuli such as cigarette smoke that cause lung inflammation help establish chemotactic gradients of interleukin-8 (IL-8) and leukotriene B$_4$ (LTB$_4$) that encourage macrophages and neutrophils to migrate from capillaries into the small airways and alveoli. Neutrophils initially are concentrated in the centrilobular regions of the lung parenchyma where they release serine and cathepsin proteinases. These enzymes damage and degrade elastin and other structural proteins, thereby causing disease. The degraded elastin fragments themselves act as chemoattractants that recruit additional inflammatory cells. A direct correlation has been noted between the numbers of neutrophils within the interstitium and the severity of emphysema.

REPAIR

The lung comprises more than 40 specialized cell types, each with its own individual functions and distribution. Of importance, only a subset of these possesses replication potential. Those that can divide must serve as a stem cell population for the other, terminally differentiated cell types. Regeneration of the lung is a source of much debate. It appears that in humans, the primary regenerative capacity of airway epithelia comes from resident precursor cells. Limited colonization of the airway by exogenous precursors has been described in humans. For example, male epithelial cells have been identified in the lungs of women who have just given birth to a male infant, and chimerism of the bronchial epithelium has been detected in bone marrow recipients. Conversely, limited numbers of recipient-derived cells have also been detected in engrafted transplant lungs. In the absence of lung damage, however, such engraftment of non–lung-derived cells appears to be a rare event.

Alveoli are composed of capillaries and lymphatics encased in a thin epithelial layer. More than 90% of the alveolar surface is composed of *type I pneumocytes* (Figure 2-5). These are terminally differentiated, large flat squamous epithelial cells that possess a relatively simple ultrastructure. Their function is to allow gaseous exchange between the alveolar gas and the bloodstream; consequently, they require little more than a nucleus and cell membrane with a few mitochondria and a limited secretory pathway. They are unable to replicate and are susceptible to noxious insults from inhaled toxins such as cigarette smoke and therefore must be replenished by the major stem cell found within the alveolus, which is the *type II pneumocyte.* These are small cuboidal cells located predominantly at the alveolar septal junctions. Although contributing little surface area to the lung, they are abundant, making up half of the alveolar cells by number. Tight gap junctions separate their polarized apical and basolateral domains, enabling selective secretion toward their apical surface, readily identified by its many microvilli.

Type II pneumocytes have two primary functions: to secrete surfactant and to act as the sole stem cell of the alveolus. Surfactant is a complex mixture of phospholipids (mainly dipalmitoylphosphatidylcholine and phosphatidylglycerol) and surfactant proteins A to D (encoded by *SFTPA*, *SFTPB*, *SFTPC*, and *SFTPD*, respectively). Intracellular surfactant inclusions, or multilamellar bodies, give these cells their granular appearance. After exocytosis at the apical surface, these spheroid lamellar bodies form a membrane lattice called *tubular myelin* that plays

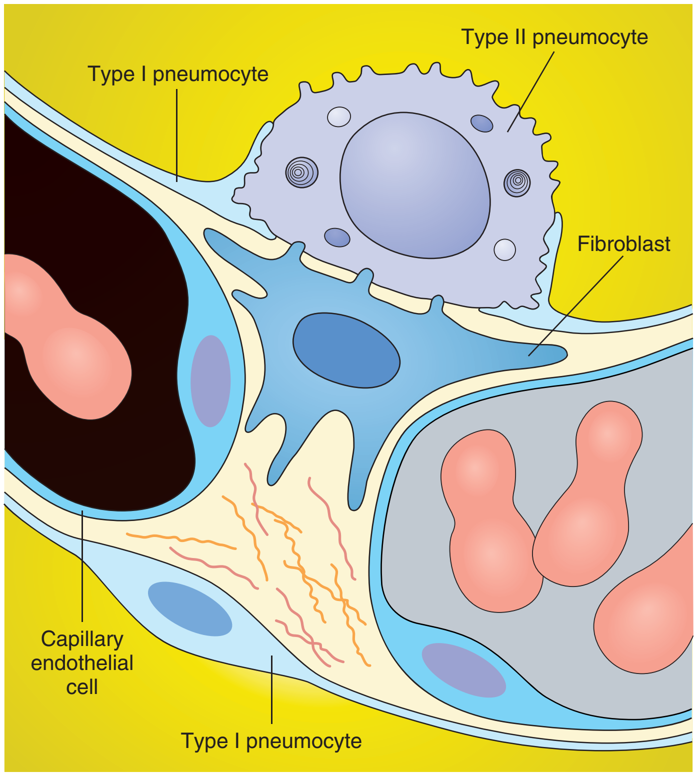

Figure 2-5 Pneumocytes. Alveoli are composed primarily of type I and type II pneumocytes. Type I pneumocytes are thin, terminally differentiated nonsecretory cells that make up 90% of the alveolar surface area. Type II pneumocytes contain lamellar bodies composed of surfactant proteins and lipids. After injury, these cells can divide and give rise to type I pneumocytes.

an important role in reducing the surface tension of the alveolar lining fluid and in host defense. Surfactant proteins A and D are members of the hydrophilic collectin family that have a carboxyl-terminal (C-terminal) lectin domain able to bind and opsonize many inhaled pathogens. In addition, they also have direct toxicity against gram-negative organisms. By contrast, surfactant proteins B and C both are small hydrophobic proteins that interact with surfactant lipids.

Because type II cells first appear in significant numbers after 24 weeks of gestation, prematurely newborn are impaired in surfactant production, which can lead to the development of respiratory distress syndrome, the most common cause of respiratory death in infants in the Western world. Those children who survive are at increased risk for respiratory disability as a result of bronchopulmonary dysplasia. Fortunately, the deficit can now be corrected by instilling surfactant into the trachea. But despite a marked improvement in survival as a result of this therapy, a significant minority (5% to 25%) nevertheless develop long-term complications. Family studies have shown clustering of disease, which suggests a genetic susceptibility to respiratory distress in infancy. The most likely causes of this susceptibility are mutations in the surfactant protein genes and some extrapulmonary gene products (such as granulocyte-macrophage colony-stimulating factor and its receptor). Mutations in the hydrophobic *SFTPB* and *SFTPC* are clearly linked to neonatal respiratory disease. The substitution of GAA for C in codon 121 in *SFTPB* gene underlies 60% of hereditary deficiency of surfactant protein B. This substitution results in a truncated protein, a lack of protein on immunohistochemical staining of lung tissue, and a *loss-of-function* phenotype, in which the homozygote experiences onset of respiratory distress within the first 12 to 24 hours of life and death by 1 to 6 months of age. A total of 27 mutations have now been described in the *SFTPB* gene, some of which have a milder effect on the production of surfactant protein B, with a later onset of respiratory failure. One family also has been described with a splice site mutation in intron 4 of the *SFTPC* gene. Infants with this mutation do not suffer neonatal respiratory distress but instead develop interstitial lung disease in the first year of life with an autosomal dominant pattern of inheritance. Furthermore, mutations within the genes encoding granulocyte-macrophage colony-stimulating factor or its receptor cause pulmonary alveolar proteinosis in children, a condition characterized by the overproduction of surfactant.

Idiopathic pulmonary fibrosis is a progressive interstitial lung disease characterized by inflammation and fibrosis of the alveolar walls. Although most cases of pulmonary fibrosis are sporadic, some rare familial cases have been described. In a number of early-onset familial cases of idiopathic pulmonary fibrosis, causative mutations have been identified in the *SFTPC* gene. This encodes a large transmembrane pro-protein that is proteolytically processed to the mature small surfactant C protein. As discussed earlier, one of its disease-causing mutants, characterized by a deletion of exon 4, misfolds to induce endoplasmic reticulum stress.

When type I cells are injured, type II cells can proliferate and differentiate into the larger type I cells. In bronchi, *intermediate and basal cells* form the pool of progenitor cells, whereas in terminal bronchioles, the *Clara cell* plays this role. These latter cells are highly metabolically active and serve to detoxify many inhaled chemicals by way of their cytochrome P-450 monooxygenase system in their smooth endoplasmic reticulum. They are able to multiply and differentiate into both ciliated and nonciliated bronchial epithelial cells. This response involves first dedifferentiation and then loss of their secretory granules and smooth endoplasmic reticulum, followed by reentry into the cell cycle. However, not all Clara cells behave identically. A variant that shows resistance to naphthalene, a toxin that targets the cytochrome P-450 isoenzyme found in Clara cells, may represent the main progenitor subtype and has been called either the *toxin-resistant variant Clara cell* or the *bronchiolar stem cell*.

Cells have been identified at the junction between terminal bronchioles and the alveoli that express markers of both Clara cells and type II pneumocytes. These have been named *bronchoalveolar stem cells* (BASCs), because when isolated and grown in vitro, they have been shown to be capable of self-renewal. At least in culture, they can differentiate into cells that express markers of bronchial epithelium, alveolar type I or type II cells. The identity of the progenitor cells of the interstitium, smooth muscle, and endothelium remains unclear. In adults, transdifferentiation of one cell type to another may be important. In disease, many examples of epithelial to mesenchymal transition have been described.

There is growing interest in the potential of stem cell technology in the treatment of lung disease. In young mice, the administration of retinoic acid derivatives can induce lung regeneration, presumably from endogenous stem cells; whether such regeneration can be induced in adult humans, however, is not clear. Instead, it may be possible to deliver exogenous stem cells to the lung. Among the potential sources for such cells, the most controversial are embryonic stem cells. When grown in vitro, these cells can be made to develop toward a type II pneumocyte–like phenotype expressing surfactant proteins that contain lamellar bodies or to form pseudoglandular structures. However, there are currently no clinical data to support their use. By contrast, mesenchymal stem cells derived from bone marrow or cord blood have been more extensively studied. In mouse models of acute lung injury and lung fibrosis, mesenchymal stem cells have yielded promising results. Moreover, in a clinical trial administering human mesenchymal stem cells to patients after acute myocardial infarction, an increase in forced expiratory volume in 1 second (FEV_1) was reported. Further trials designed specifically to test the effectiveness of such therapies in well-defined human lung disease are now required.

The major hurdle in administering exogenous cells is the potential for immune reaction and rejection. If the patient's own cells can be used, this problem can be circumvented. In one recent case involving a 10-year-old boy with congenital tracheal stenosis, a segment of trachea was grown ex vivo on a collagen scaffold from stem cells derived from his bone marrow. This was subsequently implanted to correct the stenosis. Modern technologies now enable progenitor cells to be generated from adult peripheral tissues. Induced pluripotent stem cells (iPS cells) can be derived by expressing stem cell transcriptional regulators such as SOX-2 and Oct-3 in adult cells such as skin fibroblasts. The resulting dedifferentiated cells have the potential to differentiate into many other tissues—hence their pluripotency. This technology has been used to generate hepatocyte-like cells from the skin of patients with α_1-antitrypsin deficiency. Ultimately, when such iPS cells are reprogrammed to correct the genetic defect, it is hoped that they will provide a source of autologous tissue to replace damaged or malfunctioning organs.

PITFALLS AND CONTROVERSIES

NATURE OF THE α_1-ANTITRYPSIN POLYMER

Although the "loop-sheet" model of polymerization described earlier has long been accepted as the mechanism of the retention of Z α_1-antitrypsin within cells, the field was recently revitalized by a new model for polymerization. This model was based on the finding that another serpin molecule, antithrombin, could be re-folded in vitro to form dimers linked by the swapping of a large hairpin structure rather than by the single strand of the reactive center loop. This "domain swap" model initially garnered significant support and led to revival of the molecular mechanism of α_1-antitrypsin deficiency. An important consequence of this renewed interest was the development of a novel monoclonal antibody called 2C1, which specifically recognizes α_1-antitrypsin polymers generated by heating the purified protein. This development was significant because up to that point, heating rather than refolding after chemical denaturation had been the source of most serpin polymers studied in vitro. The crucial observation that 2C1 also recognizes polymers formed within the livers of affected patients, while showing no reactivity against polymers formed by refolding in vitro, strongly supports the original loop-sheet hypothesis. However, this renewed bout of interest in serpin polymerization, while having been prompted most likely by an in vitro antithrombin artifact, has left researchers with an excellent new monoclonal antibody that will be of great use in the study (and perhaps future diagnosis) of this disease. This field remains ripe for future discoveries, and it is unlikely that the last word on serpin polymerization has yet been written.

ALVEOLAR REGENERATION IN RESPONSE TO RETINOIC ACID

In 1997 it was shown that retinoic acid could induce alveolar regeneration in rats. This observation suggested a possible future therapy for emphysema in humans. However, subsequent studies that have attempted to replicate these findings have met with mixed results, some positive and others not. This inconsistency may reflect strain-specific differences, because it has been noted that the successful studies were restricted to certain strains of mice and rats. Recent observations have demonstrated that it is not responsiveness or lack thereof to retinoic acid per se that is strain-specific, but instead that each strain differs in its sensitivity to the agent. What is not clear is if the effects can be recapitulated in animals other than rodents. A single study in humans has so far failed to show clinical improvement in indices of emphysema, although that study has been criticized for methodologic flaws including lack of power. Larger-scale, well-controlled studies are necessary to settle this important controversy.

STEM CELL BIOLOGY

As discussed earlier, the potential for regeneration of lung tissue from a stem cell pool is a research subject of considerable interest, with ongoing controversy surrounding the origins of these cells. Indeed, opinion remains split on whether to call these "stem cells," "progenitor cells," or even "reparative cells." Clearly, endogenous pulmonary cells are responsible for recovery of the lung from many insults, but it has not been established how these could be used therapeutically unless mechanisms can be found to augment their function. The use of iPS, bone marrow–derived, or even embryonic stem cells remains a controversial area but holds the potential to revolutionize therapy for emphysema.

AUTOPHAGY VERSUS ENDOPLASMIC RETICULUM–ASSOCIATED DEGRADATION IN α_1-ANTITRYPSIN DEFICIENCY

In many diseases, the accumulation of aberrant proteins in the endoplasmic reticulum directly contributes to the pathogenesis of disease, be these misfolded surfactant proteins or polymers of α_1-antitrypsin. It is a goal of several laboratories to devise ways of helping the cell dispose of these retained proteins, but a useful therapy remains elusive. For some time, it was thought that polymers within the endoplasmic reticulum were too large to be degraded by the classical endoplasmic reticulum–associated degradation (ERAD) pathway and so an alternative disposal mechanism must be involved. Indeed, a number of reports described the activation of autophagy by retained serpin polymers. Autophagy is the process by which intracellular components are engulfed by double-membraned structures called autophagosomes that ultimately "digest" their contents in what translates literally as "self-eating." However, it appears that the disposal of polymerogenic serpins shows significant cell type differences, and most in fact are degraded primarily by ERAD, with autophagy playing a secondary role. This area requires further study. An exciting recent report has described how the use of a commonly prescribed drug, carbamazepine, can stimulate both the ERAD and autophagy of polymerized α_1-antitrypsin and result in the resolution of liver disease in transgenic Z α_1-antitrypsin mice. The doses required currently are far higher than those that can safely be employed in humans, so further clinical trials are needed.

THE CANDIDATE GENE APPROACH

When hunting for a disease-associated mutation or polymorphism, it is essential to maintain a high degree of skepticism and statistical rigor. The involvement of a biologic statistician at an early stage of the study design is therefore essential. The attempt to link tumor necrosis factor (TNF)-α variants with the pathogenesis of COPD illustrates this pitfall well. The involvement of TNF-α was biologically plausible, because the levels of this multifunctional cytokine are elevated in bronchoalveolar lavage fluid, induced sputum samples, and lung biopsy specimens from patients with COPD. Moreover, well-studied promoter polymorphisms had been shown to alter expression levels and were linked with other inflammatory conditions. It was the observation of an association (with a staggering odds ratio of over 10) between a specific allele of TNF-α and "bronchitis" in Taiwanese men that ignited interest in this gene in COPD. That study was difficult to interpret, however, because a third of the men involved were "never smokers" and thus were unlikely to suffer from COPD. More than 10 subsequent studies have found little evidence that TNF-α polymorphisms are associated with, or modify the progression of, COPD. Although tempting as it may be to restrict study to a "favorite gene," it is far more fruitful to look first in an unbiased fashion for associations and only then to focus on individual genes or pathways.

FUTURE DIRECTIONS

The first human genome took a global effort of 13 years to complete. Today, genomes can be sequenced in a single laboratory in less than a week. Before very long, sequencing studies will be affordable for most research groups and may potentially even enter clinical practice, truly revolutionizing medicine. Such genomic elucidation will determine far more than whether a few disease-causing mutations are present; it will make possible individually tailored treatments like never before. Pharmacogenetics will identify the most effective therapies and avoid the worse complications. In clinical practice, experienced prognostication and risk stratification will inform the hard decisions that both patient and physician need to make. In parallel, structural and cell biologists will continue to tease apart the components that make pneumocytes work and, more important, allow them to fail. These advances can be expected to lead to a new understanding of pathology and to provide signposts to new treatments. This century promises to be one in which all physicians can look forward to an exciting role as clinician scientists.

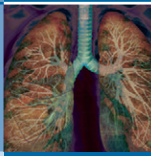
Section 1

NORMAL STRUCTURE AND FUNCTION



Chapter 3

Respiratory Mechanics

Bruce H. Culver

INTRODUCTION

This chapter describes the physical properties of the lungs and chest wall involved in the cyclic processes of ventilation supporting the metabolic needs of the body. The contribution of respiratory muscles to these processes is reviewed here; their function is described more fully in Chapter 6. Clinical measurements of some of these mechanical properties are an important part of pulmonary function testing, as discussed in Chapter 9.

STRUCTURE OF THE THORAX AND LUNGS

THORAX

The bony thorax protects the lungs, heart, and great vessels but also allows the lungs to change volume from a minimum of 1.5 to 2.0 L to a maximum of 6 to 8 L. This large expansion is made possible by the articulation of the ribs with the spine and the sternum, the arrangement of the muscles, and the motion of the diaphragm. The ribs articulate with the transverse processes of the thoracic vertebrae and have flexible cartilaginous connections with the sternum. The ribs angle down, both from back to front and from midline to side, so that as they elevate, both the anteroposterior and the transverse dimensions of the thorax increase (**Figure 3-1**). The external intercostal muscles that angle down from posterior to anterior (**Figure 3-2**) are well situated to elevate the ribs. With deep inspiratory efforts, the first and second ribs are elevated and stabilized by the accessory muscles of respiration in the neck. If the upper extremities are fixed, the pectoralis muscles also can act to raise the ribs (e.g., leaning onto a chair back or against a wall when out of breath). Expiration normally is passive, driven by the elastic recoil of the lung, but can be assisted by the internal intercostal muscles. Forced expiration or a cough requires the abdominal muscles to force the diaphragm upward.

The diaphragm is dome-shaped in its relaxed position and can be pulled flatter by muscle contraction. The diaphragm most often is described as fixed at the periphery so that its action pulls down the center of the dome, lengthening the lungs. However, if it is fixed centrally by the pressure of the abdominal contents, the peripheral attachments will lift the ribs, which swing outward when elevated, increasing the transverse diameter of the chest. In addition, the increase in abdominal pressure associated with descent of the diaphragm acts on the lower ribs in the so-called *zone of apposition* to impart an outward force. The actual action of the diaphragm is a combination of these mechanisms in a proportion that varies with position and abdominal wall tension.

The intercostal muscles are innervated from the thoracic spine at their own level, and the abdominal muscles are innervated from lower thoracic and lumbar level, but the diaphragm is served by the phrenic nerves, which originate at the cervical level (C3 to C5). Thus, the diaphragm remains functional in patients who have spinal injuries below the midcervical level. The long course of each phrenic nerve along the mediastinum, however, makes it vulnerable to both transient and permanent interruptions by disease, injury, or surgery. Occasionally, local irritation of a phrenic nerve leads to intractable singultus (i.e., hiccups). The respiratory muscles are more fully discussed in Chapter 6.

PLEURAL SPACE

The lungs are covered by a thin visceral pleura, which is invaginated into the lobar fissures. The inner aspect of each hemithorax, including the top of the diaphragm and the mediastinal surface, is lined with the parietal pleura, which joins the visceral pleura on each side at the lung hilum. The pleural space extends deeply into the posterior and lateral costophrenic recesses and is a potential space, normally containing only a few milliliters of fluid to serve a lubricating function.

The inspiratory force of the chest wall and diaphragm is transmitted to the lung by creation of a more negative pressure in this potential space. In pathologic states, pleural effusions may form and necessarily make the lung volume smaller by occupying part of the intrathoracic space. Penetration of the chest wall or rupture of the lung surface can allow air to enter the pleural space, creating a pneumothorax.

AIRWAYS

The upper respiratory passages (nasal cavities and pharynx) conduct, warm, and moisten air as it moves into the lungs. The respiratory system develops as an offshoot from the digestive system and, like the digestive system, has an absorptive function. The entire system is continuously exposed to particulate and infective agents and accordingly is protected by a well-developed lymphoid barrier and, more superficially, a mucous barrier. The upper respiratory passages contain the olfactory areas and also conduct and help shape the sounds that produce speech.

The larynx opens off the lowest part of the pharynx. During swallowing, the larynx is closed off from both the pharynx above and the esophagus posteriorly by the epiglottis. The trachea begins at the lower border of the cricoid cartilage of the larynx, at the level of the sixth cervical vertebra. The lumen of the trachea is held open by incomplete, C-shaped

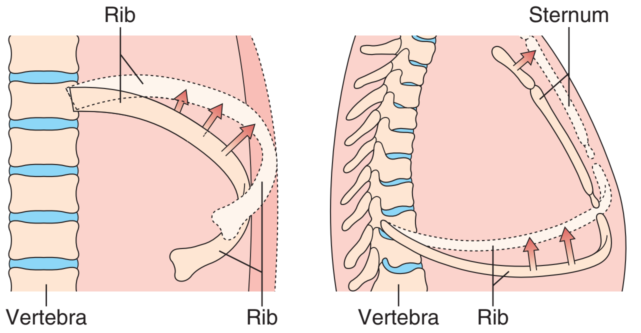


Figure 3-1 Frontal (*left*) and lateral (*right*) views of thorax movement. With rib elevation, both the transverse and anteroposterior dimensions increase.

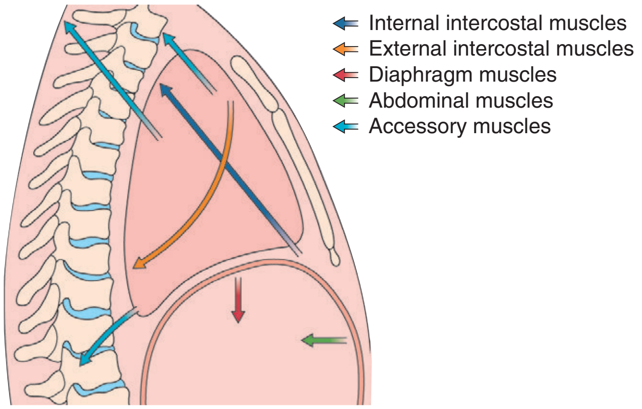

Figure 3-2 Action of the major respiratory muscle groups—intercostals, accessories, diaphragm, and abdominals.

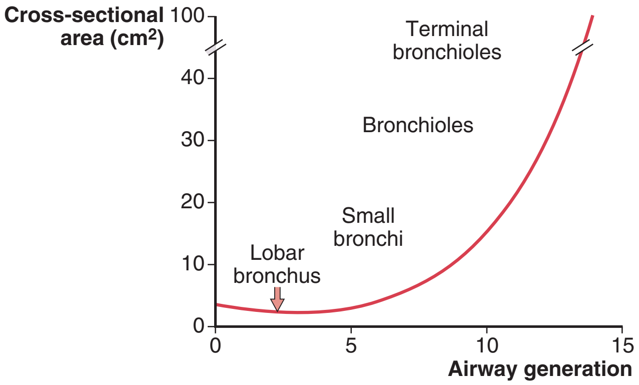

Figure 3-3 Total cross-sectional area of the airways. The aggregate luminal area increases greatly from approximately 2.5 cm^2 in the trachea and major airways to more than 100 cm^2 at the level of the terminal bronchioles. *(Modified from Culver BH, editor:* The respiratory system, *Seattle, University of Washington Publication Services, 2006; data from Weibel ER:* Morphometry of the human lung, *New York, Springer-Verlag, 1963.)*

cartilaginous rings. The posterior membranous portion contains smooth muscle. When the intrathoracic pressure exceeds the intraluminal pressure, as during a cough, the membranous portion becomes invaginated, the ends of the rings may overlap, and the lumen is greatly narrowed. Smooth muscle contraction narrows the lumen but increases its rigidity. With deep inspiration, the trachea enlarges and lengthens. The trachea bifurcates into the main bronchi, which become in turn lobar, segmental, and then subsegmental bronchi, and end in bronchioles, which lack cartilage and are approximately 1 mm in diameter. Beyond these are the respiratory bronchioles, alveolar ducts, sacs, and alveoli, which make up the respiratory zone in which gas exchange and other functions take place.

The intraparenchymal bronchi are invested with overlapping helical bands of smooth muscle wound in clockwise and counterclockwise fashion. The amount of smooth muscle increases proportionately in the smaller bronchioles to occupy approximately 20% of the wall thickness. Elastic fibers are present at every level of the respiratory system and become a rich component of the connective tissue in the smaller bronchi and bronchioles. They stretch when the lungs are expanded in inspiration, and their recoil helps to return the lungs to their end-exhalation volume. Although the smooth muscle stops at the portals of the respiratory zone, elastin and collagen contribute to the alveolar wall and form an irregular, wide-meshed net of delicate, interlacing fibers.

The number of airway generations required to reach the respiratory zone varies with pathway length, so that areas near the hilum may be reached in 15 generations, whereas those in the periphery may require 25 generations. Although the size of individual airways becomes smaller, the number of airways approximately doubles with each new generation, so that the total cross-sectional area of the combined air path increases. This is especially so in the smaller bronchi and bronchioles, where the “daughters” of each division are only slightly smaller than the “parent.” The rapidly increasing total cross-sectional area of small airways, shown diagrammatically in Figure 3-3, means that their contribution to airflow resistance in the lungs is small. Thus, diseases that affect these peripheral airways may be functionally silent until they reach an advanced state.

There is further dramatic expansion in the gas-exchanging respiratory zone as the airways terminate in an estimated 480 million alveoli with a surface area of 130 m^2.

INTERDEPENDENCE IN THE LUNG

Because the lung parenchyma is made up of interconnected alveolar walls, interstitial tissues, and fibers, any local distortion must be opposed by the surrounding tissue. That is, if a small zone of alveoli within a lobe begins to collapse, the surrounding tissue is stretched and thus tends to pull the alveoli back open. This property, termed *structural interdependence*, in concert with surfactant and the presence of collateral air pathways, helps to prevent alveolar collapse, even when small bronchioles become plugged. When collapsed areas of lung cannot expand despite distention of the surrounding alveoli, lung injury may develop as a result of extremely large stretching forces that are generated at the interface. These forces contribute to the ventilator-induced lung injury seen with mechanical ventilation at high tidal volumes and the more overt barotrauma that may result when high levels of end-expiratory pressure are applied. Because the bronchi and blood vessels travel through, and have attachments to, the lung parenchyma, they too are affected by the surrounding tissue. As the lung expands, the caliber of these channels also increases, and at low lung volumes, airway closure may occur.

RESPIRATORY MECHANICS

The properties of the lung and chest that affect and effect the movement of air into and out of the lungs are central to understanding both normal and abnormal lung function.

LUNG VOLUMES

The total gas-containing capacity of the lungs can be divided into a series of “volumes,” as shown in **Figure 3-4**, which, in combination, give lung “capacities.” The largest amount of air that can be held in the lungs at full inspiration is the total lung capacity (TLC). After a complete forced exhalation, the lungs are not empty but contain a residual volume (RV). The difference between TLC and RV—that is, the greatest volume of air that can be inhaled or exhaled—is the vital capacity (VC). The vital capacity can be affected by factors that either limit expansion of the lung (restrictive processes) or limit lung emptying (airflow obstruction).

A normal breath has a tidal volume (VT) that is only a small portion of the vital capacity (approximately 10%), and even during strenuous exercise, VT increases to only 50% to 60% of VC. Increases in VT occur by extending into the inspiratory reserve and expiratory reserve volumes as shown in Figure 3-4. At the end of a relaxed tidal exhalation, the lungs and chest wall return to a resting position, which normally is approximately 50% of TLC. The volume contained in the lungs at this end-tidal position is the functional residual capacity (FRC), and the volume that can be inhaled from this point is the inspiratory capacity (IC).

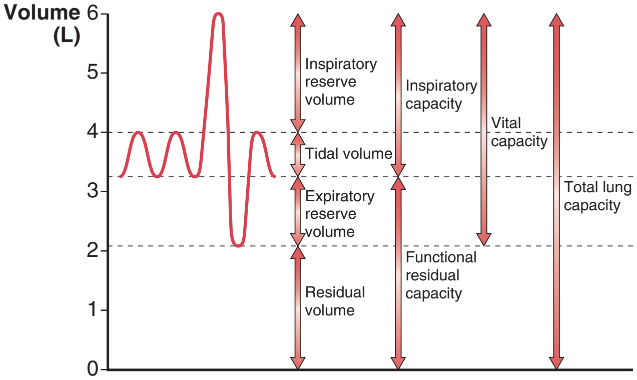

Figure 3-4 The normal spirogram and subdivisions of lung volume. By convention, *volume* is used to describe the smallest subdivisions that do not overlap (residual volume, expiratory reserve volume, tidal volume, and inspiratory reserve volume), and *capacity* is used to describe combinations of these volumes (functional residual capacity, inspiratory capacity, vital capacity, and total lung capacity). *(From Pulmonary terms and symbols: a report of the ACCP-ATS Joint Committee on Pulmonary Nomenclature*, Chest *67:583–593, 1975.)*

THE LUNG-CHEST WALL SYSTEM

To understand the process of normal breathing, special maneuvers such as coughing, and the effects of positive-pressure ventilators requires knowledge of the mechanical properties of the thorax. Three primary forces are involved:

- Elastic recoil properties of the lung
- Elastic recoil properties of the chest wall
- Muscular efforts of chest wall, diaphragm, and abdomen

In combination, these forces result in changes in lung (and thorax) volume, in alveolar pressure (PA), and in intrapleural pressure (Ppl).

VOLUMES OF ELASTIC STRUCTURES

The recoil tendency of a spring can be expressed in terms of its unstressed or resting length and its length-tension relationship. Similarly, for expandable volumetric structures, the relevant properties are the unstressed volume and the relationship between volume and the transmural pressure required to achieve that volume (**Figure 3-5**). By convention, transmural pressures are expressed as the difference between the pressure inside and the pressure outside the structure (Pin – Pout). It is convenient to think of this as the *distending pressure* required to achieve a certain volume. In addition, this distending pressure also represents the *recoil pressure*, or the tendency of the structure to return to its unstressed volume (where transmural pressure is zero). A positive recoil pressure indicates a tendency

to become smaller. A structure distorted to a volume below its unstressed volume has a negative recoil pressure, which indicates its tendency to become larger.

ELASTIC PROPERTIES OF THE LUNG

The lungs are elastic structures with a tendency to recoil to a small "unstressed volume" (usually slightly less than RV). To maintain any lung volume larger than this unstressed volume requires a force that distends the lungs; this force is the difference between the alveolar pressure (PA) and the pressure surrounding the lungs, the intrapleural pressure (Ppl). The elastic properties of the lungs and their tendency to recoil are represented by a plot of the relationship between lung volume and transmural pressure (Figure 3-6). Such graphs apply to an excised lung being inflated by a pump, an in vivo lung inflated by a ventilator, or the more physiologic normal lung inflated by expanding the chest (to create a more negative pleural pressure). In each case, the curve of volume versus the transpulmonary pressure difference (PA – Ppl) is the same.

The slope of this pressure-volume curve represents the compliance of the lungs (CL), as represented by Equation 1.

$$C_L = \Delta V/\Delta P \qquad (1)$$

The CL varies with volume, decreasing as the lungs near the limit of their distensibility at TLC. Usually, CL is measured just above FRC in the tidal breathing range. Because it normally is expressed in absolute volume units (e.g., L/cm H_2O), CL is strongly dependent on the lung size. A single lung, for example, undergoes only half the volume change that would result from the same pressure change in two lungs. A small child's normal CL is considerably lower than that of an adult. For this reason, CL often is divided by lung volume to give the volume-independent *specific compliance.*

ELASTIC PROPERTIES OF THE CHEST WALL

The chest wall has elastic properties that can be expressed in the same way as for those of the lung (Figure 3-7). The chest wall differs from many common elastic structures in that its unstressed volume (where recoil pressure = 0) normally is quite high. When expanded above its unstressed volume, it recoils inward, but if the chest wall is "distorted" to a smaller volume, its tendency is to recoil outward. Recoil pressure for the relaxed chest wall is Ppl – Patm, or simply Ppl, because Patm is taken to be zero (Figure 3-8; Table 3-1). The compliance of the chest wall is similar to that of the lungs in the midvolume range; of note, however, at TLC, the chest wall remains as distensible as it is at FRC. At low thoracic volumes, the chest wall compliance becomes very low, resisting further exhalation, and this is the mechanism determining residual volume in children and young adults. By middle age, losses in the elasticity of the tissue attachments supporting small airways cause airway closure to be the mechanism limiting further active exhalation.

Table 3-1 Recoil Pressures of the Lungs, Chest Wall, and Respiratory System, Measured as the Transmural Pressure Difference*

Locus of Measurement	Pressure Components
Lungs	Alveolar pressure (PA) − pleural pressure (Ppl)
Chest wall	Ppl − atmospheric pressure (Patm), or simply Ppl
Respiratory system	(PA − Ppl) + (Ppl − Patm) = PA − Patm

*For example, pressure inside minus pressure outside.

LUNG AND CHEST WALL: THE RESPIRATORY SYSTEM

In the intact thorax, the lungs and chest wall must move together. The muscular effort required to inspire a volume of air, or the pressure that must be developed by a ventilator to achieve the same volume change, is determined by the pressure-volume curve of the combined respiratory system, shown by the red line in Figure 3-7. The lungs and chest wall normally contain the same volume of air, so that only points at the same horizontal level in Figure 3-7 can coexist. Because both the lungs and the chest wall are expanded together, the distending pressure for the respiratory system is the sum of the distending pressures required by the lungs and chest wall. The transmural pressure for the respiratory system is PA – Patm (see Table 3-1). Figure 3-7 shows that a greater pressure change is required to add volume to the respiratory system than to either of its components alone, and thus the compliance of the respiratory system is lower than that of either lungs or chest wall at the same volume. This may at first seem paradoxical, because the tendency of the chest wall to expand might be thought to help lung expansion; however, as the system volume is increased, the outward recoil of the chest wall decreases, and this force must be replaced by additional work.

The third mechanical factor, muscle force, is not considered in Figure 3-7. Thus, the pressure difference across the lung, which has no muscle, can always be taken from its curve, but the pressure across the chest wall (and diaphragm) may reflect muscle tension and is described by this curve only during complete relaxation. Similarly, the curve for the respiratory system shows the pressure that would be measured by a manometer held tightly in the mouth after the subject has inhaled or exhaled to a particular volume and then relaxed all muscle effort.

At the resting end-tidal position of the respiratory system (FRC), no active muscular forces are applied, and PA = Patm (distending pressure = 0). The lung is distended above its low unstressed volume, and the chest wall is held below its relatively high unstressed volume. The relaxed FRC is the volume at which the opposing tendencies of the lungs to recoil inward and the chest wall to recoil outward are evenly balanced. Any change in the unstressed volume or the compliance of either lungs or chest wall results in a new FRC. For example, obesity reduces the unstressed volume of the chest wall and thus also reduces the FRC (and expiratory reserve volume) (see Chapter 62). Emphysema increases both compliance and unstressed volume of the lung, which results in a higher FRC and a "shift to the left" of the respiratory system pressure-volume curve.

The opposing forces of lung and chest wall create a subatmospheric (negative) pressure in the intrapleural space at the FRC (see Figure 3-8). Because the lungs and chest wall are not directly linked, it is actually the intrapleural pressure that opposes lung recoil and chest wall recoil. Thus, at a relaxed FRC, it must have the same magnitude as each of these recoil forces. The average pleural pressure normally is approximately −5 cm H_2O at FRC.

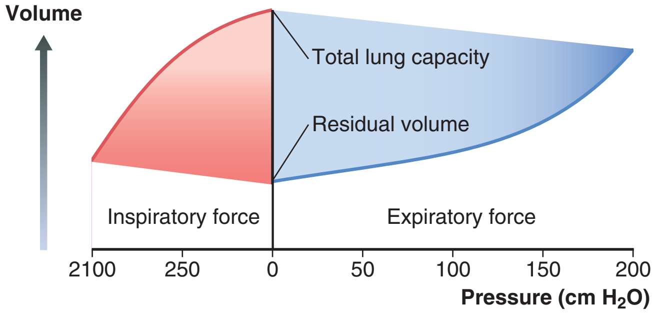

Figure 3-9 Maximum inspiratory and expiratory forces. The normal maximum force generated by inspiratory muscles is greatest at low lung volume, and the expiratory force is greatest at high lung volume. *(Modified from Culver BH, editor:* The respiratory system, *Seattle, University of Washington Publication Services, 2006.)*

EVENTS OF THE RESPIRATORY CYCLE

Inspiration is an active process. Contraction of the inspiratory muscles (primarily the intercostals and the diaphragm) tends to expand the thorax, which creates a more negative intrapleural pressure. This change increases the distending pressure applied to the lung, and the subsequent expansion causes the alveolar pressure to become negative with respect to the atmosphere, drawing air into the lungs. This process continues until the lung volume increases to a point at which its recoil pressure is increased to balance the combined muscular and elastic forces of the chest wall. At this point, alveolar pressure becomes zero, and the inspiratory flow stops, because a pressure gradient no longer exists along the airways.

During normal breathing, *expiration* is a passive process. The inspiratory muscles relax, and the balance of forces shifts so that lung recoil predominates. The alveolar pressure becomes positive, and the air moves from alveoli through the airways to the outside atmosphere until FRC conditions are reached, with the forces again balanced and the alveolar pressure zero. Of note, with a typical small VT, the chest wall volume remains below its unstressed volume, with a small outward recoil force, and pleural pressure can be negative throughout the cycle. During active expiration, this process can be assisted by contraction of the expiratory muscles (intercostal and abdominal wall muscles), which makes pleural pressure positive.

RESPIRATORY MUSCLE EFFORT

The maximum inspiratory and expiratory pressures measure the maximal efforts of the respiratory muscles (**Figure 3-9**). That is, with an inhalational effort against a closed pressure manometer, the maximum negative pressure that can be generated at the mouth is approximately 100 cm H_2O at a low lung volume. At TLC, no negative pressure can be generated, so no more air can be drawn into the chest. Maximum expiratory pressures are somewhat greater, measuring 150 to 200 cm H_2O at high lung volume, and fall to zero at RV.

SURFACE TENSION

At the surface of a liquid, the intermolecular forces are not balanced by the more widely spaced molecules of the gas phase, which creates a surface tension. The surface tension of the air-liquid interface that lines the alveoli contributes an important part of the elastic properties of the lung shown by the pressure-volume curve. If a lung is filled with liquid, surface forces are abolished, and the resultant pressure-volume curve (**Figure 3-10**) reflects only the tissue properties of the lung. This liquid-filled curve is shifted to the left, indicating that the lung can be distended with much less pressure. The air-filled lung, in addition to requiring greater pressures, demonstrates marked hysteresis; that is, the pressure-volume curve during inflation is different from that during deflation.

The air-filled deflation curve approaches the liquid-filled curve at low lung volume, indicating that the pressure from surface tension becomes small at this volume. Given no other parameters, however, the prediction would be that pressure from surface forces should *increase* as alveoli become smaller. Laplace's law relates the pressure within a sphere to wall tension (T) and radius (r), P = 2T/r, whereas for a cylinder, P = T/r. If the surface tension remains constant as "r" decreases (smaller alveoli or airway), the pressure from the surface tension should rise. This situation is avoided in the lung by the presence of a unique surface-lining material, surfactant, which not only reduces surface tension but does so in a volume-dependent manner. As lung volume and surface area decrease, the lining layer compresses, and surface tension decreases until it is nearly abolished at RV. This property has important beneficial consequences in the lung, including the following:

- The work needed to expand the lungs is greatly reduced.
- Stability of alveoli and terminal airways is maintained. (If pressure increased within an alveolus as it became smaller, the alveolus would tend to empty into interconnected, larger alveoli with lower pressure.)
- Inwardly directed forces of surface tension in the "corners" of alveoli act to draw fluid from the capillaries and interstitium into the alveoli, so lowering surface tension helps prevent alveolar edema (discussed in Chapter 4).

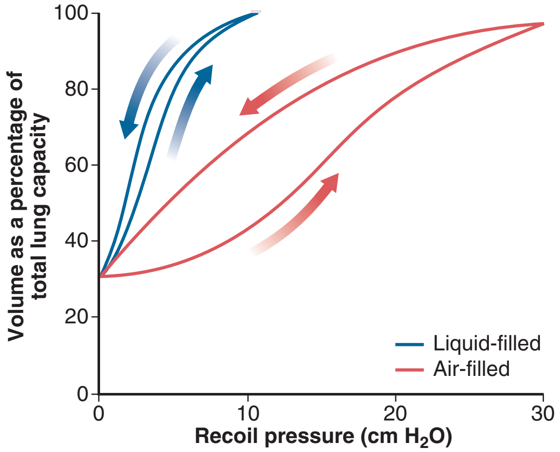

Figure 3-10 Effect of surface tension on recoil force. Pressure-volume curves obtained on inflation and deflation of a normal air-filled lung and the same lung when filled with saline. The horizontal difference between the curves reflects the effect of surface tension, which is greater on inspiration than expiration and abolished when the lung is liquid filled. *(Modified from Culver BH, editor:* The respiratory system, *Seattle, University of Washington Publication Services, 2006; data from Bachofen H, Hildebrandt J, Bachofen M: Pressure-volume curves of air- and liquid-filled excised lungs—surface tension in situ,* J Appl Physiol *29:422–431, 1970.)*

Pulmonary surfactant is produced in alveolar type II cells in the form of lamellar bodies, appears in the alveolar lining liquid as tubular myelin, and then spreads as a monolayer at the air-liquid interface. The major component, and the component that is primarily responsible for the surface tension–lowering effects, is dipalmitoyl phosphatidylcholine (DPPC). DPPC has a nonpolar end, made up of two saturated fatty acid chains, and a polar end that tends to have a positive charge. At the air-liquid interface, the molecules orient with the hydrophilic polar end in the liquid and the fatty acid chains projecting into the air (**Figure 3-11**). Both ends have similar cross-sectional area allowing them to pack closely together. The molecules may also adsorb directly to the epithelial surface, which tends to have a negative charge, in areas where a liquid subphase is absent.

FLOW RESISTANCE

Airflow between the atmosphere and alveolar gas depends on the driving pressure (i.e., alveolar − atmospheric) and the airway resistance, as shown in Equation 2.

$$\text{Flow} = \dot{V} = \frac{\Delta P}{R} = \frac{P\text{atm} - P_{\text{A}}}{\text{Raw}} \qquad (2)$$

Airflow resistance (Raw) is affected by the following factors:

- Viscosity of air
- Length of airways (Raw is directly proportional to length)
- Caliber of airways (Raw is proportional to l/r^4)

Thus, a doubling of length doubles resistance, but a halving of caliber causes a 16-fold increase in resistance. Factors affecting airway caliber include the following:

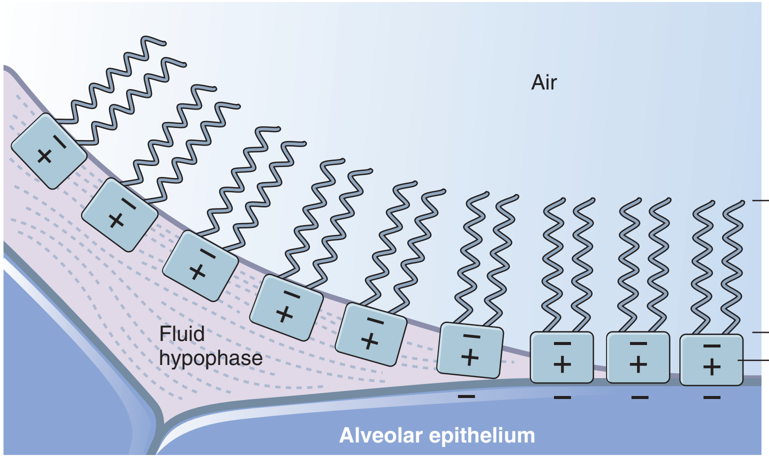

Figure 3-11 Pulmonary surfactant at the air-liquid interface in an alveolus. The nonpolar fatty acid chains project into the alveolar gas phase, whereas the hydrophilic polar end lies within the surface of the liquid phase or may be able to bond directly to the epithelium. The close arrangement of the molecules facilitates their surface tension–lowering properties. The fluid hypophase tends to fill alveolar corners and surface irregularities.

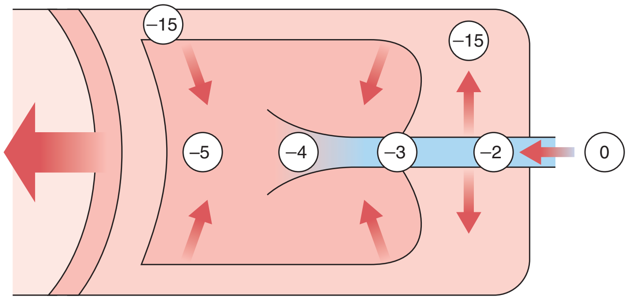
- Position of the airway in the bronchial tree
- Lung volume
- Bronchial muscle tone
- Mucous secretions
- Pressure across the airway wall

All of these factors are similar during both inspiration and expiration, except the last. During inspiration, the intrathoracic pressure that surrounds the airways is more negative than the intraluminal pressure, so airways tend to be distended (**Figure 3-12**). During passive exhalation, the magnitude of the airway distending force is lower, so airflow resistance is somewhat higher. With active expiratory efforts, the pleural pressure becomes positive, and with the addition of lung recoil, the pressure in the alveoli is even higher. However, the intraluminal pressure decreases progressively in airways mouthward of the alveoli, reflecting both frictional losses and a decrease in lateral pressure through the Bernoulli effect, because the decreasing cross-sectional area of the composite airway requires a marked increase in velocity of air movement (convective acceleration). Because their cartilaginous structure is incomplete, airways are compressed under such forces, and calculated resistance is much higher.

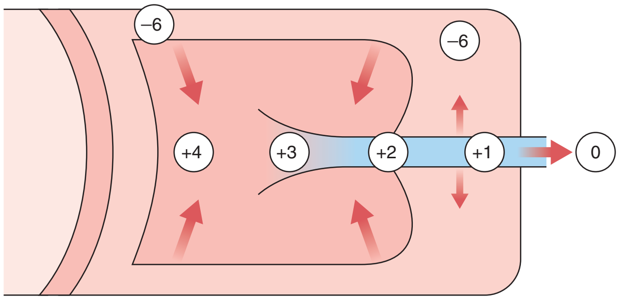
Maximum airflow rates are evaluated by having the subject take a full inspiration to TLC and blow the air out as forcefully and completely (to RV) as possible. With use of a spirometer, this forced vital capacity (FVC) is recorded as an expiratory spirogram (volume versus time), or if the flow rate is directly measured, the same information can be recorded as a maximum expiratory flow versus volume curve (**Figure 3-13**). A remarkable feature of this maneuver is that the maximum flow rate for any volume, except the higher lung volumes near the beginning of the exhalation, is achieved with submaximal effort and cannot be exceeded with further effort. This flow limitation, or "effort independence," is demonstrated in **Figure 3-14** and is a consequence of the dynamic compression noted previously. The mechanism of this flow limitation is related to the rate of propagation of a pressure wave through a compliant tube, but the result can be understood with a simpler conceptual model of dynamic compression. Because this compression begins just beyond the point at which intraairway pressure falls to equal pleural pressure, the effective pressure driving flow from the alveoli to this point becomes PA – Ppl (i.e., in Figure 3-12, for forced expiration, 30 – 20 = 10 cm H_2O). This is the same as the elastic recoil pressure of the lung and is a function of lung volume, not effort. If, in the example of Figure 3-12, a greater expiratory effort is made and the pleural pressure is raised to 40 cm H_2O at the same lung volume, the alveolar pressure becomes 50 cm H_2O and the effective driving pressure = (50 – 40) = 10 cm H_2O, so the resultant flow rate remains unchanged.

This mechanism may have its major physiologic significance in normal persons during a cough. Although overall airflow rate (L/second) out of the lungs is not increased by the high pleural pressure generated, the airflow velocity (m/second) through the narrowed major airways is greatly increased, which aids in the removal of secretions and foreign material.

Inspiration
Active diaphragm and chest wall muscles



Passive expiration
Partially relaxed muscles



Forced expiration
Active abdominal and chest wall muscles

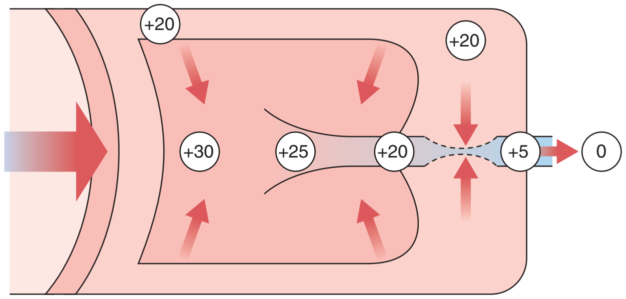


Figure 3-12 Dynamic compression. Comparison of intrathoracic and intraluminal pressures during inspiration, passive expiration, and forced expiration. In each case, the lung volume is the same, with a recoil pressure of 10 cm H_2O. During *inspiration*, the intrathoracic airways tend to be distended, which lowers airway resistance. In *passive expiration*, although intrapleural pressure may remain slightly negative, a positive alveolar pressure is generated by lung elastic recoil. Central airways are less distended than during inspiration. In *forced expiration*, high intrapleural pressure, plus lung recoil, creates a large, positive alveolar pressure to drive flow but also compresses central airways. Flow is limited once dynamic compression begins downstream from the point where intraluminal pressure falls below pleural pressure (the so-called equal pressure point). Further effort increases alveolar driving pressure but also increases compression. Airway resistance becomes high and varies with the degree of effort.

WORK OF BREATHING

The muscle effort required to raise lung volume above the FRC during inspiration is a form of work. Part of this is the *elastic* work used to stretch the tissues and the surface lining of the lung, whereas another part is the *frictional* work required to overcome airflow resistance in the airways. The elastic work stored in stretched fibers on inspiration then provides the energy needed to push air out on the subsequent passive exhalation. With active expiratory efforts, additional muscle work is done on expiration as well.

The elastic and frictional components of respiratory work are affected differently by lung volume. At low lung volume,

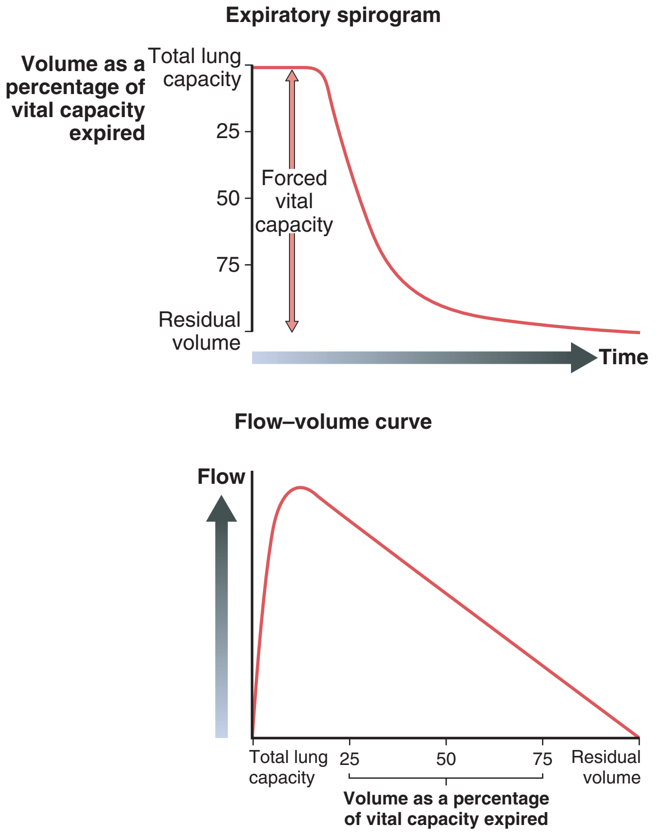

Figure 3-13 Forced vital capacity maneuver. This common breathing test can be displayed as an expiratory spirogram or as a flow-volume curve. Volume axes show percentage of vital capacity expired. *(Modified from Culver BH, editor:* The respiratory system, *Seattle, University of Washington Publication Services, 2006.)*

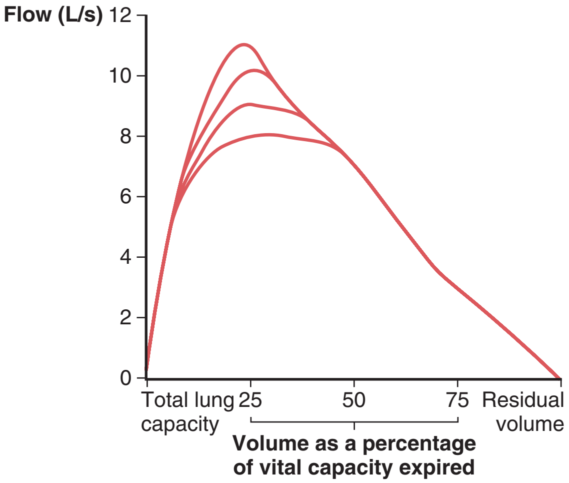

Figure 3-14 Effort-independent flow. The *top curve* represents a maximum expiratory effort, and the *lower curves* show the flow that results from progressively less effort. At lower lung volumes, the maximum flow rate is relatively independent of effort. *(Modified from Bates DV, Macklem PT, Christie RV:* Respiratory function in disease, *ed 2, Philadelphia, WB Saunders, 1971, pp 10–95.)*

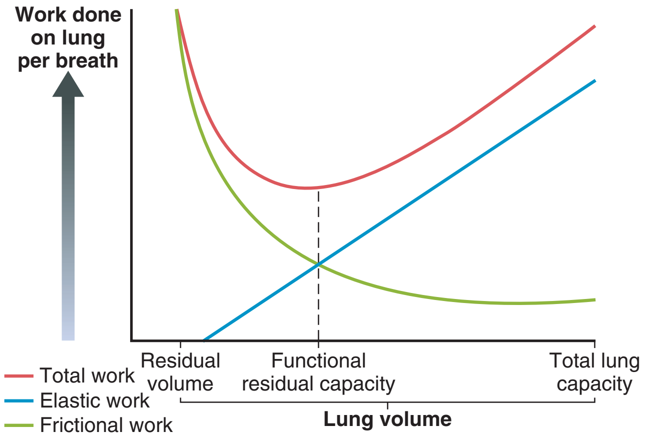

Figure 3-15 Work of breathing. The combined work of lung and chest wall expansion (elastic) and airflow resistance (frictional) is normally lowest near functional residual capacity. *(Modified from Culver BH, editor:* The respiratory system, *Seattle, University of Washington Publication Services, 2006.)*

airways are narrower, and resistance (and thus frictional work) increases rapidly (R is proportional to $1/r^4$). At higher lung volumes, the airways are larger, but muscles must do more elastic work to keep the lungs stretched. The relaxed FRC is the volume at which the static recoil forces of the lung and chest wall are balanced, but Figure 3-15 shows that FRC also is the volume at which work of breathing is least. If either the elastic or frictional contributions to work of breathing change, FRC may change rapidly or chronically.

The narrowed airways in obstructive disease increase frictional work and the volume at which work is the least increases. The accompanying shift of the tidal breathing range to a higher volume may occur quite suddenly in an asthma attack or may develop slowly with chronic obstructive disease. When airflow rates increase, frictional work becomes relatively more important, so that patients who have obstructive disease may shift to a higher end-expiratory volume during exercise or voluntary hyperventilation.

Restrictive disease processes reduce lung compliance (CL). Accordingly, the force the muscles must generate to stretch the lung increases. The elastic work required to breathe at any lung volume is higher, and this shifts the volume for least work lower. Increased CL, as with emphysema, has the opposite effect. Figure 3-7 shows that the static forces predict the same changes in FRC (greater lung recoil results in lower FRC volume and vice versa).

Normally, the energy consumed by breathing is very small. In metabolic terms, less than 1 mL/minute of oxygen consumption is required for each liter per minute of ventilation, or only a few percent of total body oxygen consumption at rest. Derangements of respiratory mechanics may increase the work of breathing significantly, contributing to the common symptom of dyspnea. With severe airflow obstruction, the energy cost of breathing becomes much higher. Increases in respiratory frequency associated with activity may cause COPD patients to shift their tidal ventilation to a higher end-expiratory lung volume whereby the increased airway caliber allows the tidal breath to be exhaled within the shorter expiratory time available. This dynamic hyperinflation places the inspiratory muscles at further mechanical disadvantage and is a major contributor to exertional dyspnea and exercise limitation. If the expiratory time does not allow the alveolar pressure to fully equilibrate to atmospheric pressure, then the residual positive end-expiratory alveolar pressure (termed auto-PEEP) must be overcome by additional inspiratory effort before inspiratory airflow can begin. The same phenomenon also is seen during mechanical ventilation of patients with airflow obstruction and may have hemodynamic consequences, as well as impairing their ability to initiate breaths.

DISTRIBUTION OF VENTILATION

The incoming air of each tidal breath is not distributed evenly to all alveoli in the lung. Pleural pressure is not the same throughout the chest but has a vertical gradient of several centimeters of water because of the effects of gravity, the configuration of the chest and diaphragm, the presence of the heart and mediastinal structures, and the need for the lung to fit within the thorax irrespective of the shape of either the lung or the thorax. At FRC measured with the patient in the upright position, −5 cm H_2O is an average value at chest midlevel; near the apices, however, the pressure outside the lung might be −8 cm H_2O, whereas near the bases it might be only −2 cm H_2O. Because alveoli throughout the lung seem to have similar maximum volume and pressure–volume relationships, and because alveolar pressure is everywhere the same, those alveoli near the top of the lung are held at larger volume (distending pressure of 8 cm H_2O) than those near the bottom (distending pressure of 2 cm H_2O). This places the lower alveoli on a steeper (more compliant) portion of their pressure-volume curve. In addition, the proximity of the basal alveoli to the motion of the diaphragm exposes them to a greater increase in distending pressure with inspiration. These two factors combine to give the lower portion of the normal lung a relatively greater proportion of the tidal ventilation than that distributed to the apices.

A second consequence of the higher (i.e., less negative) pleural pressure in the basal portions of the lung is that the distending pressure of the small airways also is less. At low lung volume, airways may close, and the dependent portions of the lung reach this “closing volume” first, whereas higher portions of the lung are still partially distended. Thus, in a patient who breathes at very low lung volumes, near residual volume (e.g., with obesity), basal airway closure may occur, with consequent poor ventilation of the lung bases.

In summary, respiratory units in the basal portion of the lung contain less gas but receive more ventilation so long as they remain open. However, they are more susceptible to airway closure and loss of ventilation at low lung volume.

SUMMARY

The mechanical properties of the lungs and chest wall are described by the interactions of volume and pressure within the thorax, and by flows and resistance during dynamic changes in lung volume. Alterations in these properties underlie many respiratory diseases and contribute to their associated symptoms. Measurement of these properties is important in elucidation of the pathophysiology of lung diseases and in diagnosis and monitoring of disease in the pulmonary function laboratory (see Chapter 9), and the increasing sophistication of modern ventilators makes an understanding of thoracic mechanics essential in the intensive care unit (see Chapter 32).

CONTROVERSIES AND PITFALLS

The principles of lung mechanics discussed in this chapter have been well established for the past 40 to 60 years, but their application in some clinical situations is less clear-cut. Inadequate understanding of lung–chest wall pressure relationships underlies the occasionally heard bedside comment that increasing positive end-expiratory pressure (PEEP) to improve hypoxemia in a mechanically ventilated patient with acute lung injury (ALI) will not affect hemodynamics “because the lungs are stiff and no added pressure will be transmitted to the pleural space.” It is true that low lung compliance will result in a lesser expansion of lung volume for any increase in alveolar pressure, with less increase in average intrapleural pressure than in a normal chest. If there is an improvement in oxygenation, however, the likely mechanism is recruitment of alveoli with an increase in end-expiratory lung volume, and this necessitates that the chest wall also must be expanded along its passive pressure-volume curve (see Figure 3-7). Because this relationship has a positive slope throughout, any increase in thoracic volume must be accompanied by at least some increase in intrapleural pressure, with its potential for a hemodynamic effect.

Since the recognition that mechanical ventilation may cause or contribute to lung injury, an ongoing issue has been the optimal tidal volume and pressures to avoid this complication. It was demonstrated in animal work many years ago that ventilation with a high tidal volume, generated by an inspiratory pressure of 40 cm H_2O, was injurious, but that this injury was greatly mitigated by a modest level of PEEP. Accordingly, in addition to concerns for the limits of lung expansion, subsequent work has focused on the stresses associated with cyclic closing and reopening of small peripheral airspaces.

It has been demonstrated that the use of a tidal volume of 6 mL/kg is associated with lower mortality in acute lung injury–acute respiratory distress syndrome (ALI-ARDS) than that with a volume of 12 mL/kg, but the relative contributions of tidal volume, end-inspiratory pressure, and PEEP remain controversial. Although it is likely to be the change in, or maximal extent of, tissue stretch due to lung volume expansion, that is the injurious force, the best bedside indicator of that force may be the airway pressure, because even a small tidal volume may overexpand the more compliant regions of an injured lung. Some clinicians feel that tidal volume reduction may be unnecessary if end-inspiratory pressure is maintained below 30 cm H_2O, but the 6 mL/kg tidal volume strategy was similarly beneficial at all levels of initial end-inspiratory pressure.

With the wide acceptance of “lung-protective ventilation,” some consideration has emerged for extending this approach to patients at risk for ALI, or even to all ventilated patients. There does appear to be a trend in this direction, with initial tidal volumes of 8 to 10 mL/kg increasingly common, and those of 10 to 12 mL/kg less so. It is difficult to know how best to prevent ventilator-induced lung injury without better understanding of its cause. Potential mechanisms include tissue failure from high stresses during lung expansion, which are magnified at the junction of atelectatic lung and adjacent expandable tissue, as well as cytokine release associated with the deformations of repetitive cycling.

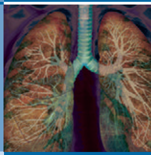
NORMAL STRUCTURE AND FUNCTION



Chapter 4

Pulmonary Circulation

Bruce H. Culver • Robb W. Glenny

The lungs are served by two circulations—the pulmonary circulation, which accommodates the entire cardiac output from the right side of the heart through a low-pressure circulation, and the bronchial circulation, which arises from branches of the aorta with systemic pressure and usually carries less than 1% of the cardiac output.

CIRCULATORY STRUCTURE

PULMONARY CIRCULATION

The pulmonary arteries lie near and branch in unison with the airways in the bronchovascular bundle. They are much thinner than systemic arteries and have proportionately more elastic tissue in their walls. The walls of the arterioles, with a diameter less than 100 μm, are so thin relative to those of their systemic counterparts that fluid and gas can move across them. Within the gas-exchanging zone, the arterioles give rise to a network of pulmonary capillaries in the alveolar walls that is continuous throughout the lungs. They are so numerous that, when distended, blood flows almost as an unbroken sheet between the air spaces (**Figure 4-1**). "Sheet flow" reduces vascular resistance and optimizes gas exchange by creating a very large surface area, estimated at over 100 m^2. When the transmural pressure difference between the inside and outside of the vessels is low, many of the capillary segments are closed, but flow switches among segments frequently as some open and others close. Nonflowing segments are rapidly recruited into the pulmonary vascular bed as needed to accommodate increased flow and may be further distended by an increase in transmural pressure. Both recruitment and distention of the pulmonary capillary bed reduce resistance to blood flow and help to maintain a low pressure in the face of increased blood flow. This low pressure allows the capillary-alveolar membrane to be very thin (approximately 1 μm), facilitating diffusion of respiratory gases between blood and alveoli. A red cell that follows a capillary path from the pulmonary artery to a vein may cross several alveoli, with the average transit time through the vessels engaged in gas exchange calculated to be approximately 0.75 second. The capillaries unite to form larger alveolar microvessels, which become venules and then veins that run between the lobules toward the hila, where upper and lower pulmonary veins from each lung empty into the left atrium.

BRONCHIAL CIRCULATION

The bronchial arteries arise directly from the aorta or from intercostal arteries to supply the walls of the trachea and bronchi and also to nourish the major pulmonary vessels, nerves, interstitium, and pleura. Extensive small-vessel anastomoses occur between these (systemic) vessels and both the precapillary and postcapillary pulmonary vasculature. The bronchial veins from the larger airways and hilar region drain through the systemic veins (particularly the azygos system) into the right atrium. However, bronchial flow to the intrapulmonary structures connects to the pulmonary circulation and drains through the pulmonary veins into the left atrium. This small aliquot of desaturated blood contributes to the normal (2% to 5%) right-to-left shunt, which may increase when the bronchial circulation hypertrophies to supply inflammatory or neoplastic lesions. The bronchial circulation has a role in the regulation of temperature and humidity in the airways and supplies the fluid for secretion through the airway mucosa.

LYMPHATIC CIRCULATION

Pulmonary lymphatics are not found in alveolar walls but originate in interstitial spaces at the level of the respiratory bronchioles and at the pleural surface, then follow the bronchovascular bundles to the hila. The lymph flows through the right lymphatic duct and the thoracic duct into the right and left brachiocephalic veins. The total flow from the lungs is quite low under normal conditions (less than 0.5 mL/minute in experimental animals) but can increase many-fold with pulmonary edema. The lymphatics have valves to prevent backflow and can generate sufficient pressures to maintain flow when systemic venous pressure is as high as 20 cm H_2O.

CIRCULATORY PHYSIOLOGY

The pulmonary circulation conducts the entire cardiac output with a remarkably low driving pressure from the pulmonary artery (mean Ppa of 15 to 20 mm Hg) to the left atrium (Pla of 7 to 12 mm Hg). As in the airways, the branching pattern of vessels leads to an increase in total cross-sectional area as the alveolar vessels are approached, but unlike in the airways, this increase is not associated with a decrease in resistance. Total cross-sectional area increases at a branching point if the number of daughter branches (n) is greater than the ratio of the parent to daughter radii squared, $(a/b)^2$, but resistance decreases only if n is greater than $(a/b)^4$. The latter case occurs in the peripheral airways but not in the vessels, so although small peripheral airways contribute little to normal airflow resistance, pulmonary microvessels make up a substantial portion of vascular resistance. Efforts to partition the pressure drop longitudinally suggest that approximately 20% to 30% is in the arterial portion (including arterioles), 40% to 60% in the microvascular portion, and the remainder in the veins. With increases in flow,

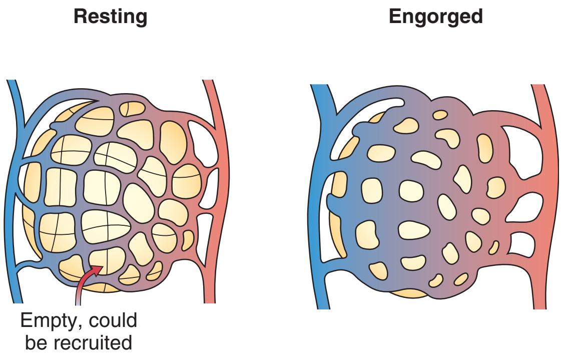


Figure 4-1 Alveolar capillaries. The normal cardiac output requires only a portion of the sheet of capillaries; any remaining vessels can be recruited when cardiac output rises during exercise. *(Modified with permission from Butler J: The circulation of the lung. In Culver BH, editor:* The respiratory system, *Seattle, 2006, University of Washington Publication Services, p 8.2.)*

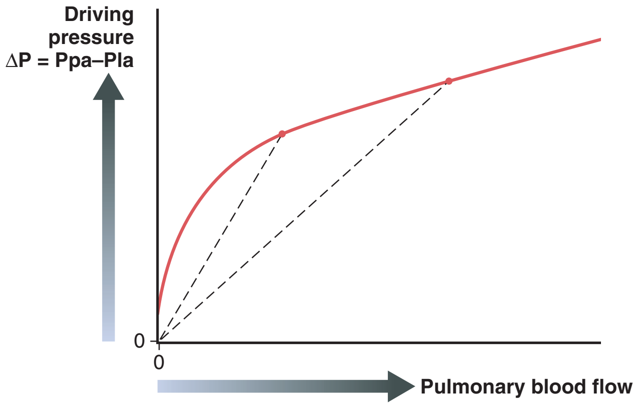

Figure 4-2 Driving pressure across the pulmonary circulation. Mean pulmonary artery pressure (Ppa) minus mean left atrial pressure (Pla) increases nonlinearly with cardiac output. Resistance, represented by the slope from the origin to any point on the line, decreases with increased pulmonary blood flow, which reflects recruitment and distention of vessels.

recruitment occurs mainly at the level of microvascular vessels, so their relative contribution to resistance becomes less.

The pulmonary circulation is a network of segmental resistors that share common upstream (i.e., Ppa) and downstream (i.e., Pla) pressures. Flow is distributed to the various segments in proportion to the reciprocal of the total serial resistance through any segment. The benefit of having the highest resistance at the microvascular level is that the control of blood flow distribution can occur at a finer level, allowing active mechanisms of flow regulation (see further on) to adjust blood flow to relatively small lung regions.

The pulmonary vascular resistance, PVR, is calculated as transvascular driving pressure, ΔP (mean upstream Ppa minus mean downstream Pla), divided by the flow: PVR = ΔP/Q. The calculated resistance must be interpreted in the context of flow, because the relationship of driving pressure to flow usually is not linear and its plotted curve does not pass through zero. As shown in Figure 4-2, pulmonary vascular resistance decreases as flow and pressure increase with the attendant recruitment and distention of vessels.

The resistance to flow through a vessel increases with its length, with the viscosity of the fluid, and, most important, with the inverse of the radius to the fourth power. In addition to muscle activity in the wall, the caliber of a distensible vessel depends passively on the transmural pressure difference between intravascular and extravascular pressures. This mechanism is particularly important in the lungs, where the vessels are embedded in expandable parenchyma. It is convenient to consider separately the effect of lung expansion on the extraalveolar arterial and venous vessels, which differs from the effect on the microvessels of the alveolar zone. With lung volume increase, extraalveolar vessels are distended as the pressure is lowered in the expanding perivascular space around them (Figure 4-3), and they are elongated as the lung expands.

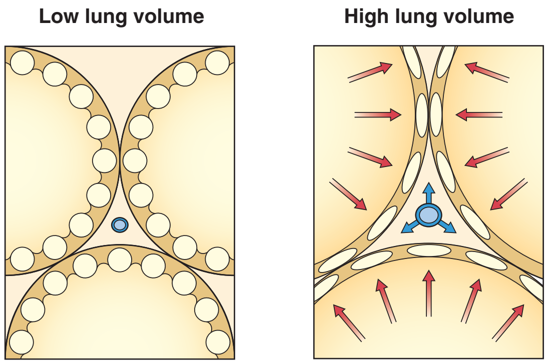

Figure 4-3 Lung volume affects alveolar and extraalveolar vessels differently. At high lung volumes, alveolar microvessels are stretched and compressed as vascular pressures fall relative to alveolar pressure. Extraalveolar vessels, however, tend to be expanded as the pressure surrounding them decreases. *(Modified with permission from Butler J: The circulation of the lung. In Culver BH, editor:* The respiratory system, *Seattle, 2006, University of Washington Publication Services, p 8.4.)*

By contrast, the alveolar microvessels in the alveolar walls are elongated but partially collapsed by lung inflation, because the alveolar pressure that surrounds them tends to increase relative to the intravascular pressure. This effect is easy to recognize with positive-pressure ventilation, but it also occurs with spontaneous inspiration, because intravascular pressures fall relative to atmospheric and alveolar pressure. The sheets of capillaries in the alveolar walls are protected from the full compressive force of the alveolar pressure by the surface tension of the fluid that lines curved portions of the alveolar surface. Microvessels in the "corners" where alveolar walls meet are more fully protected from compression by the sharper curvature of the surface film and perhaps by local distending forces, analogous to the situation with extraalveolar vessels (Figure 4-4). The pulmonary vascular resistance is the sum of that through alveolar and extraalveolar vessels and thus has a complex relationship with lung volume. It is lowest at approximately the normal resting lung volume (functional residual capacity) but increases at higher and lower volumes.

BLOOD FLOW DISTRIBUTION

Both vascular geometry and gravity influence the distribution of blood flow within the lung. If the upright lung is viewed as a stacked series of slices, a vertical gradient occurs in which the average flow per slice rises progressively down the lung, consistent with the influence of gravity. Within each slice, however, a marked variability of blood flow is found among regions, with high-flow areas distributed dorsally. The tendency of blood flow to be higher in dorsal and basal regions is largely preserved even when the gravitational direction is reversed, which indicates

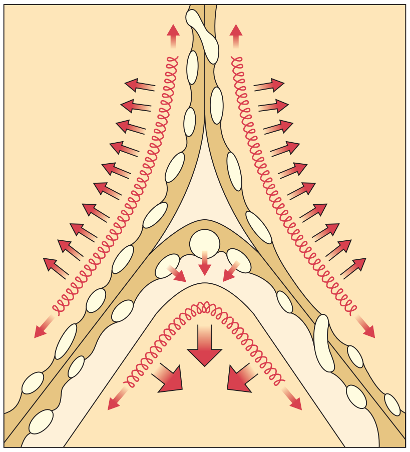

Figure 4-4 Alveolar “corner” at the junction of three alveolar walls. Surface tension (depicted by “springs”) holds vessels open, particularly in corners, and promotes fluid transudation by lowering the pressure around vessels. *(Modified with permission from Butler J: The circulation of the lung. In Culver BH, editor:* The respiratory system, *Seattle, 2006, University of Washington Publication Services, p 8.5.)*

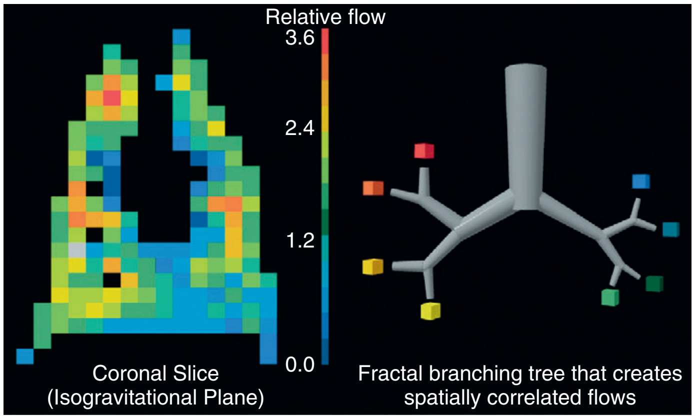

Figure 4-6 Blood flow distribution. The *left half* of the figure shows an isogravitational coronal plane of a canine lung divided into cubes of tissue 1.2 cm on a side. The color scale shows the relative blood flow, indicated by the number of flow-directed microspheres trapped in each cube. Note that low flow (*blue*) cubes tend to cluster together, as do high flow (*yellow-red*) cubes. The *right half* shows how the geometry of shared, more proximal vessel segments can account for this spatial correlation further downstream.

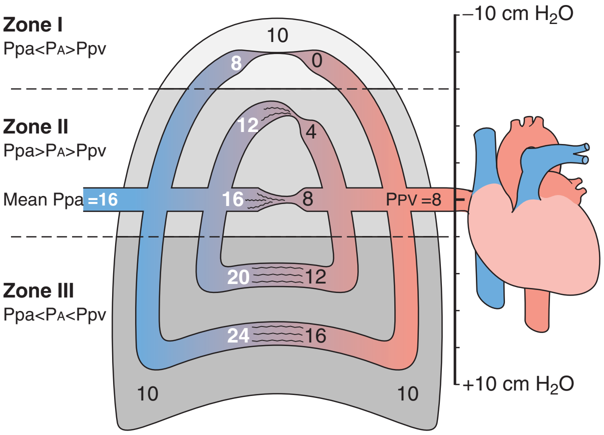

Figure 4-5 Perfusion in the lungs is influenced by the relationship of pulmonary arterial and venous pressures (Ppa and Ppv) to alveolar pressure (PA). In this example, the alveolar pressure is 10 cm H_2O, as might be found in a patient who receives positive-pressure ventilation. *(Modified with permission from Culver BH: Hemodynamic monitoring: physiologic problems in interpretation. In Fallat RJ, Luce JM, editors:* Cardiopulmonary critical care, *Edinburgh, 1988, Churchill Livingstone.)*

that anatomic branching patterns are a major determinant of flow distribution.

The gravitational effect has been conceptualized by dividing the lung into four zones, one above another, on the basis of the relationship of vascular and alveolar pressures (Figure 4-5). Intravascular pressures are higher at the bottom of the lung than at the top by an amount equal to a vertical hydrostatic column as high as the lung. Near the lung apex, *zone I*, the pressure in the alveoli (PA) exceeds that in both the pulmonary arteries (Ppa) and pulmonary vein (Ppv) and collapses the alveolar vessels, except those in the alveolar corners, which remain patent and allow some flow to continue. Below this, in *zone II*, Ppa exceeds PA, but PA is greater than Ppv, so flow depends on the pressure difference between Ppa and PA. The vessels remain open but are critically narrowed at the downstream end, where venous pressure is lower than alveolar pressure. This condition creates independence of flow from the downstream venous pressure, analogous to a waterfall in which a stream that flows over a precipice is unaffected by a rising level in the pool below until it rises above the level of the lip. In the middle to lower portion of the lung, *zone III*, both Ppa and Ppv exceed PA, the vessels are distended, and blood flow is the highest. *Zone IV* is restricted to a small area in the most dependent region, where flow diminishes. It has been postulated that this reduction is the result of increased vascular resistance secondary to low lung volume or perivascular edema in this area.

Although the gravitational effect expressed in the vertical zone concept contributes to the average increase in flow down the lung, it does not explain the observed large variability in flow within an isogravitational slice, which implies that other anatomic or vasoregulatory factors are important at this level. More recent studies have determined that the heterogeneous distribution of blood flow within horizontal (isogravitational) planes is due to asymmetric branching geometries (and hence resistances) of the vascular tree. Because the vascular tree is largely a dichotomous branching structure, differences in resistances between daughter branches cause flow to be distributed unevenly between the branches. With differences in resistances occurring at every bifurcation in the vascular tree, blood flow becomes progressively more heterogeneous, resulting in a broad distribution of flows at the terminal branches. Owing to the shared heritage up the vascular tree, neighboring lung regions have similar magnitudes of flow, with high-flow regions near other high-flow regions and low-flow regions neighboring other low-flow regions. Hence, the spatial distribution of pulmonary blood flow is not random but rather exhibits a clear pattern of high and low flows (Figure 4-6). Studies have demonstrated that the pattern of perfusion distribution is very stable over time and with growth, and that the pattern is genetically determined. These insights provide a new perspective on blood flow distribution in the lung. The traditional model of vertically stacked zones needs to be replaced by one in which the multiple zones can exist within horizontal planes. In addition, the large degree of heterogeneity within isogravitational planes suggests that mechanisms other than gravity must be responsible for the tight matching between regional ventilation and blood flow.

REGULATION OF PULMONARY BLOOD FLOW

Besides their responses to passive mechanisms (anatomy, gravity, lung volume, alveolar pressure), the pulmonary vessels exhibit vasomotor activity regulated by both neural and non-neural factors. Motor efferents from three autonomic networks are in anatomic proximity to the vasculature: sympathetic, parasympathetic, and nonadrenergic noncholinergic fibers. The *sympathetic* efferents have a vasoconstrictor effect, whereas *parasympathetic* stimulation dilates constricted vessels. Although acetylcholine is a potent pulmonary vasodilator, there is little cholinergic innervation of the pulmonary resistance vessels. The *nonadrenergic noncholinergic* system is inhibitory, constantly releasing small vasodilatory peptides at the ganglia and postganglionic ends of its unique network. This vasodilator function is augmented with exercise.

Pulmonary arteries demonstrate an intrinsically low tone as they remain relaxed when isolated from the lung. This state reflects a balance between effects of endothelium-derived vasoconstrictor and vasodilator substances. Although their relative roles are yet to be clarified, many vasoactive peptides are found in the lung. Those exerting vasoconstrictor activity on the pulmonary circulation include angiotensin II, arginine vasopressin, endothelin 1, peptide tyrosine Y, and substance P. Vasodilatory peptides include adrenomedullin, atrial natriuretic peptide, calcitonin gene–related peptide, endothelin 3, somatostatin, and vasoactive intestinal peptide.

Nitric oxide is produced in endothelial cells in the pulmonary circulation and elsewhere and is now recognized as an important mediator of vasodilatation. The oxidation of a nitrogen from L-arginine is catalyzed by nitric oxide synthase, present in both a constitutive form and a form that is inducible by products of inflammation. Nitric oxide activates guanylate cyclase, which increases cyclic guanosine monophosphate (cGMP) within vascular smooth muscle cells. This in turn reduces intracellular Ca^{++} by several mechanisms, leading to vascular relaxation. Nitric oxide also is abundantly produced in the nasal sinuses, providing an intriguing mechanism whereby inhaled nitric oxide may enhance blood flow to the best-ventilated areas of lung.

Although the role of nasal nitric oxide in ventilation-perfusion matching is still speculative, the role of alveolar hypoxia in vasoregulation has been recognized for more than 50 years, but the mechanisms involved are still uncertain. Pulmonary arterioles constrict when the P_{O_2} in the alveoli they serve falls, and additional vasoconstriction results if alveolar P_{CO_2} rises (Figure 4-7). Thus, when ventilation is decreased by an obstructed airway or other injury, local hypoxic pulmonary vasoregulation decreases blood flow to the affected region, which tends to restore the local ventilation-perfusion ratio ($\dot{V}/\dot{Q}$) toward normal and thereby improve the P_{O_2} of the blood flowing through that area. The diverted blood flow can be directed to better-ventilated regions, which further contributes to an improvement in overall matching. This hypoxic vasoconstriction seems to be a response to a low P_{O_2} in the air spaces, rather than in the intraluminal blood, which normally is desaturated in these prealveolar vessels. The effector cell is thought to be pulmonary artery smooth muscle located at the entrance to the acinus, and the sensor may be the oxygen-consuming mitochondria within these cells. Several candidate signaling pathways to generate the increase in intracellular calcium necessary for muscle contraction are under investigation.

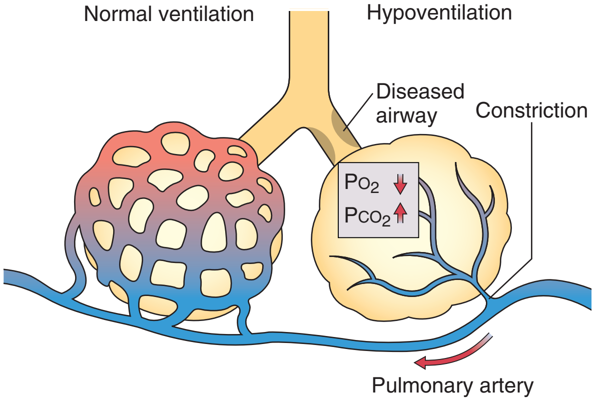

Figure 4-7 Hypoxic vasoconstriction reduces blood flow to poorly ventilated areas. This adaptation improves ventilation-perfusion matching and oxygenation but, if generalized, contributes to pulmonary hypertension. *(Modified with permission from Butler J: The circulation of the lung. In Culver BH, editor:* The respiratory system, *Seattle, 2006, University of Washington Publication Services, p 8.7.)*

Considerable individual variability is found in the hypoxic vasoconstrictor response, and it may be diminished by vasodilating drugs. Diversion of blood flow is most effective in atelectatic areas of lung, in which hypoxic vasoconstriction is unopposed by the radial traction of surrounding expanded lung tissue. A reciprocal reflex in the airways also contributes to better matching: Small airways constrict when intraluminal P_{CO_2} falls and dilate when it rises. Hypoxic vasoconstriction is a helpful, adaptive response to local or regional lung abnormalities, but when alveolar hypoxia is generalized (e.g., hypoventilation or altitude), the increased resistance can lead to pulmonary hypertension.

NONRESPIRATORY FUNCTIONS OF THE PULMONARY CIRCULATION

FILTERING

Aggregates of blood elements and emboli of various types (e.g., fat, air, particulate matter) carried in the systemic venous return are continually filtered out, dissolved, or engulfed by the cells of the pulmonary capillary bed. This process provides vital protection for the cerebral, coronary, and other systemic vascular beds and is a benefit of the entire cardiac output from the right side of the heart passing through the lungs. Emboli that bypass the pulmonary circulation through anatomic shunts are called "paradoxical emboli" and are the most common cause of strokes in young persons. Larger emboli have the potential to cause ischemia in affected regions of the pulmonary vascular bed, but this may be countered in part by limited perfusion from the bronchial circulation through bronchopulmonary anastomoses and by exposure to oxygenated pulmonary venous blood that backflows into the occluded region during tidal lung volume changes. Thus, ischemic damage to the alveoli is prevented while a thrombus is lysed and the pulmonary flow restored.

Large numbers of white cells, mainly polymorphonuclear leukocytes, are sequestered in the small vessels of the pulmonary bed. The numbers of leukocytes sequestered in the lung increases markedly if the pulmonary endothelium expresses ligands that cause these cells to adhere and then traverse the vascular wall into the interstitial and alveolar spaces. Many reticuloendothelial cells are found in the lung, and some evidence suggests that the vascular endothelial cell itself can be phagocytic when stimulated.

MODIFICATION OF MEDIATORS

Some mediators in the blood that have regulatory functions throughout the body are secreted, taken up, or inactivated through specific receptors and enzyme systems in the pulmonary endothelial cells. Best-known is angiotensin-converting enzyme, which converts inactive angiotensin 1 into the systemic vasoconstrictor angiotensin 2. Histamine, bradykinin, serotonin, and acetylcholine are largely inactivated by the pulmonary endothelium in one pass through the lungs.

COAGULATION

When local injury is present, pulmonary endothelial cells can be a source of thromboplastin and tissue plasminogen activator. Despite vascular stasis and closure of vessels when flow decreases, clots do not form in pulmonary vessels because of the structure of the endothelial surface and because the secretion of anticlotting substances bathes the surface and prevents the adherence of platelets and cells. Nitric oxide, produced by the pulmonary endothelium, is a potent inhibitor of platelet aggregation. Embolic thrombi are dissolved remarkably quickly by local thrombolytic secretions.

FLUID EXCHANGE IN THE PULMONARY CIRCULATION

The fluid flux across the pulmonary vascular endothelium is influenced by the same pressure relationship as in the systemic capillaries, summarized in the modified Starling equation presented in Table 4-1. The hydrostatic pressure in the pulmonary microvessels (Pmv) exceeds the interstitial hydrostatic pressure outside the microvessels, i.e., the perimicrovascular pressure (Ppmv). This effect favors filtration. The interstitial tissue fluid protein osmotic pressure is approximately two thirds that in the vessel; thus, the net osmotic force is absorptive and inward. The components of this equation make it convenient to categorize abnormal fluid flux into the lung into two broad types: *hydrostatic* edema, when the primary abnormality is an increase in Pmv minus Ppmv, and *permeability* edema, when endothelial injury increases fluid conductivity across the membrane (incorporated into the permeability factor) and decreases the osmotic reflection coefficient and osmotic gradient. The terms *cardiogenic* and *noncardiogenic* also are commonly used for these two mechanisms of edema formation.

Table 4-1 **Modified Starling Equation**

$F = K_f\,[(Pmv - Ppmv) - \sigma(pv - pt)]$

Symbol	Description
F	Net fluid flux out of vessels
K_f	Permeability factor (constant)
σ	Reflection coefficient for oncotic agents
Pmv	Pressure in microvessels
Ppmv	Perimicrovascular pressure
pv	Osmotic pressure in vessels
pt	Osmotic pressure of tissues

Fluid flux is sensitive to small intravascular or perivascular pressure changes. Intravascular pressure rises may originate downstream (as with a failing left ventricle) or may follow overall vascular volume increments (as in overhydration) or displacement of blood from the systemic to the pulmonary vessels. The pulmonary capillary endothelium is much less permeable than that of systemic capillaries, and the interstitial space around alveolar microvessels is tightly restricted by the collagen network between the alveolar walls, forming an inexpansible space, so leakage at this site is limited. The extraalveolar arterioles and venules, which are not so confined and are more permeable, appear to constitute an additional important site of fluid leakage and reabsorption in the lungs.

Surface tension in the fluid film that lines the alveoli opposes alveolar pressure and tends to lower the interstitial pressure around pulmonary microvessels, particularly in corner areas (see Figure 4-4). An increase in surface tension may contribute to edema when surfactant is lost in an injured lung. Interstitial pressure around the extraalveolar vessels is close to intrathoracic (pleural) pressure and falls as the lungs are distended, which favors relatively more leakage from them at high rather than low lung volumes (see Figure 4-3).

INTERSTITIAL EDEMA

Several factors tend to keep the lung from becoming edematous. Normally, a net outflow of fluid from the upstream arterioles and capillaries is reabsorbed into the downstream capillaries and venules, where the intravascular pressure is lower. Fluid leakage causes local perivascular pressures to rise, particularly in the restricted space between the alveolar walls, which reduces the outward fluid flux. It also may compress the vessels, thereby reducing the total surface available for leakage. Because the fluid that leaks through intact endothelium is largely protein-free, it dilutes and washes out the interstitial protein. This alteration reduces the perivascular osmotic pressure of tissues and thus increases the inward osmotic pressure difference and reduces the local fluid leak. If excess leakage does occur, the fluid moves from the alveolar walls, where it could interfere with gas exchange, into the low-pressure interstitial zones around the bronchovascular bundles, where it forms relatively innocuous venous, arterial, and peribronchial cuffs. This fluid may be absorbed in part by the rich bronchial vascular network and by the many lymphatics in the adventitia of the airways and vessels. Edema fluid also may reach the pleural space, where it is absorbed by the pleural lymphatic and blood vessels. Finally, experimental data suggest that all the blood perfusing the capillaries in alveolar walls must first pass through capillaries located in alveolar corners and that the negative interstitial pressure surrounding these corner capillaries is critically dependent on alveolar surface tension. When surface tension is eliminated by alveolar flooding, interstitial pressure around these vessels increases, thus serving to compress the corner vessels and diminish flow through the capillaries in the alveolar wall of these flooded alveoli. This mechanism provides for much more precise control of perfusion, virtually on an alveolus-to-alveolus basis, compared with the effects of alveolar hypoxia, which are directed to much more proximal vessels.

When the capillary endothelium is injured, locally or through the effect of circulating mediators, the vascular permeability to fluids and solutes is increased; consequently, even a modest outward pressure gradient causes a large fluid leak. The ability to retain large molecules is lost, protein-rich plasma leaks out, and the osmotic pressure in tissues approaches that in vessels, so that the osmotic force opposing intravascular hydrostatic pressure is lost. This high-permeability or "leaky capillary" edema can be a fulminant process that leads to severe abnormalities in gas exchange.

ALVEOLAR EDEMA

The epithelial cells that line the air spaces have tight junctions along their apical surface, so this membrane normally is even less permeable than the endothelial membrane, protecting alveolar spaces as interstitial edema increases. After total lung water has increased by approximately 50%, the edema fluid appears in the alveoli. A structural failure, at the epithelial cell junctions or elsewhere, is suspected, because there is no protein gradient between interstitial and alveolar edema fluid. Fluid initially is seen only in the corners of the alveoli, where surface tension causes the pressure below the curved fluid film to be lowest. As more fluid accumulates, the alveoli rapidly become completely filled, again because of surface tension effects. As alveoli fill, the radius of the curvature of the meniscus of the fluid becomes shorter, and the effect of surface tension becomes greater (Laplace's law), which pulls fluid in more strongly (Figure 4-8). Thus, the sequence of edema development progresses from the perimicrovascular interstitium to peribronchovascular "sump" to patchy alveolar flooding.

Fluid and ions normally exchange across the bronchial and alveolar epithelial surfaces to regulate the character of the mucous blanket and maintain the subphase film beneath the surfactant that lines the alveoli. Alveolar edema can be cleared by an active process of sodium reabsorption with water following osmotic transport. The type II epithelial cells take in sodium through channels on their apical surface and move it by active Na^+,K^+-ATPase pumping on the basolateral surfaces into the interstitium. The type I cells seem to have similar, though less prominent, apparatus and, because they cover about 90% of the alveolar surface, might have a significant role. Fluid removal also may occur in distal airways, where epithelial and Clara cells actively transport sodium. These active mechanisms also are crucial in the initial clearance of fetal lung fluid at birth. In experimental models, fluid clearance from air spaces is enhanced by β_2-agonists and blocked by antagonists such as propranolol.

HIGH-ALTITUDE PULMONARY EDEMA

Some persons traveling or climbing to high altitudes develop pulmonary edema that may be severe and life-threatening. The mechanisms are becoming better understood and seem to involve both hydrostatic and permeability factors. The underlying abnormality in people who are susceptible to high-altitude pulmonary edema (HAPE) and who are subject to repeated episodes with repeated exposures is an exaggerated elevation of pulmonary artery pressure in response to hypoxia. Susceptible persons may experience only slight elevations in Ppa at rest or during routine activities when breathing air at sea level but demonstrate a greater increase in response to exercise than that observed in control subjects. In response to a hypoxic challenge, HAPE-susceptible subjects experience a rise in Ppa that is three- to four-fold higher than that in control subjects. At altitude, typically greater than 3000 m above sea level, Ppa in susceptible persons would be expected to rise rapidly in response to alveolar hypoxia and to increase further with the exertion that is common to mountaineering activities. Symptomatic edema develops after 24 hours up to a few days later but rarely arises after 5 days at altitude. The few hemodynamic measurements made under these circumstances have shown marked elevation of pulmonary artery systolic pressure, as high as 80 to 100 mm Hg, but usually normal or only modestly elevated pulmonary artery occlusion pressure. Thus, although high hydrostatic forces are involved, this is not a typical cardiogenic mechanism, with elevation of left atrial pressure reflected into the pulmonary microvasculature. The site of hypoxic vasoconstriction is in small pulmonary arteries and arterioles, although some venoconstriction also occurs, which could contribute to a pressure increase at the capillary level. It has been hypothesized that a heterogeneous distribution of the increased pulmonary vascular resistance might divert relatively high blood flow to low-resistance arterioles, thereby increasing local microvascular pressure sufficiently to cause the patchy edema pattern typically seen on lung radiographs of patients with HAPE. Because some persons with a similarly exaggerated hypoxic vasoconstrictor response do not develop edema, it is suggested that a defect in alveolar epithelial fluid clearance also may contribute to HAPE.

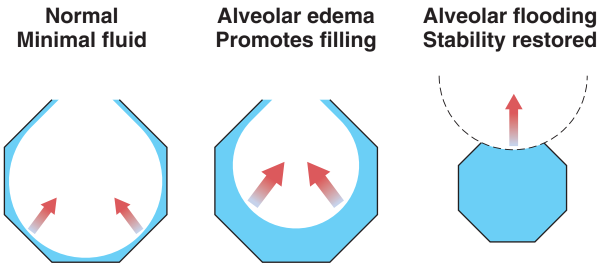

Figure 4-8 Alveoli tend to fill with fluid in an "all-or-none" fashion. In the normal alveolus, a small amount of fluid rounds off the corners. Alveolar edema decreases the radius, which increases the inward force of surface tension and pulls in more fluid. When the alveolus is filled, the radius of the surface increases, so stability is regained. *(Modified with permission from Butler J: The circulation of the lung. In Culver BH, editor:* The respiratory system, *Seattle, 2006, University of Washington Publication Services, p 8.11.)*

Of interest, bronchoalveolar lavage fluid obtained from climbers on Mt. McKinley and elsewhere with symptomatic HAPE has shown high levels of protein, which is consistent with increased vascular permeability, and red cells, suggesting further loss of barrier function. Because granulocytes and inflammatory markers are seen in only modest quantities and tend to appear later in the course, the underlying mechanism is believed to be a noninflammatory permeability change. This may be explained by the stretching of pores under hydrostatic forces or, in more severe cases, by overt capillary stress failure with endothelial, epithelial, and basement membrane disruption, as described in experiments in rabbit lungs subjected to high intravascular pressure. Although the cellular mechanisms responsible for the exaggerated pulmonary vascular response are yet to be explained, a plausible sequence of events leading to pulmonary edema in HAPE-susceptible persons has now emerged, and pulmonary vasodilators have been shown to be protective.

RESPIRATORY-CIRCULATORY INTERACTIONS

SPONTANEOUS BREATHING

The phasic changes of intrathoracic pressure and lung volume of the respiratory cycle alter the preload and afterload of the right and left sides of the heart, which interact to vary cardiac output and blood pressure with the respiratory cycle. The changes are modest during normal tidal breathing, when intrathoracic pressure swings are small, but can be more notable in pathologic states. During inhalation, the decrease in intrathoracic pressure enhances systemic venous return to the chest. The right atrium and ventricle fill, and right heart output to the pulmonary vessels increases as the alveoli fill with air. Lung expansion dilates the extraalveolar pulmonary arterial vessels, which reduces their resistance and helps to accommodate the increased flow. Ppa stays almost constant relative to alveolar pressure. The increase in right ventricular volume tends to stiffen or compress the left ventricle within the common pericardium, but the surge of pulmonary flow reaches the left heart after two or three beats, so that systemic output and blood pressure begin to rise in late inspiration or early expiration. This preload effect normally is dominant, but the inspiratory drop in intrathoracic pressure also can add effective afterload to the left ventricle. When the pressure surrounding the heart is lower, the myocardium would have to generate a greater transmural pressure difference to maintain the same stroke volume and systemic arterial pressure. Accordingly, systemic blood pressure falls a few millimeters of mercury coincident with inspiration and rises a few millimeters of mercury during exhalation. Depending on the respiratory rate, this direct pressure effect may be enhanced or countered by the arrival at the left ventricle of the inspiratory surge of venous return.

When intrathoracic pressure swings are exaggerated, as occurs during an asthma attack or an exacerbation of chronic obstructive pulmonary disease, the inspiratory drop in blood pressure can be 20 to 30 mm Hg, creating the clinical observation of pulsus paradoxus. Of interest, such markedly negative inspiratory pressures do not generate a proportionate increase in systemic venous return because of a flow-limiting, or waterfall, mechanism in the central veins. When the intraluminal pressure falls in these intrathoracic veins, the vessels collapse at the point where they are first exposed to atmospheric pressure, in the neck, axilla, and abdomen, and their flow becomes independent of the increasingly negative downstream right atrial pressure.

When the pericardial space is limited (e.g., pericardial effusion, constrictive pericarditis, enlarged heart), the interaction between the two ventricles is more prominent. Inspiratory filling of the right side of the heart limits the diastolic expansion of the left side of the heart. This ventricular interaction contributes to an inspiratory decrease in systemic outflow and blood pressure and allows both to increase when the right side of the heart is less full during expiration.

POSITIVE-PRESSURE VENTILATION

When patients are mechanically ventilated with positive inspiratory pressure, the same mechanisms seen in spontaneous breathing are involved, but the pressure effects shift phase in the tidal cycle. For example, the pressure outside the left ventricle rises during inspiration, so the same contraction yields a higher blood pressure early in the inspiratory phase. This increase may be augmented by blood pushed out of the capillaries by the positive alveolar pressure (see Figure 4-3). During late inspiration or early expiration, the blood pressure decreases as the effect of an inspiratory decrease in venous return to the right heart reaches the left side. If the expiratory phase is long enough, the blood pressure will begin to rise, reflecting enhanced venous return to the right heart earlier in expiration.

In addition to the cyclic changes, overall effects on cardiac output are seen when spontaneous breathing is replaced by positive-pressure ventilation, particularly when positive end-expiratory pressure (PEEP) is added. The mean airway pressure and the mean intrathoracic pressure both are high, and the latter is reflected in the pressure outside the right heart. This in turn causes the right atrial pressure to be higher, which may decrease the pressure difference driving venous flow from the systemic capacitance vessels. In addition, the increase in lung volume may partially compress the inferior vena cava as it runs through the lung just above the diaphragm, thereby increasing resistance to venous return. A resultant decrease in cardiac output typically is seen, accompanied by a decrease in right atrial transmural pressure and a decrease in right ventricular end-diastolic volume, particularly if intravascular volume is low. This effect may be opposed by a rise in abdominal pressure as thoracic volume increases and by increased venous tone to help restore the driving pressure for venous return.

When an increase in end-expiratory lung volume is recruited by PEEP, the chest wall also must be passively expanded, and its pressure-volume relationship (see Chapter 3, Figure 3-7) would predict at least a modest increase in pleural pressure. As shown by direct measurement with suitable flat devices, however, when the lungs are distended with PEEP, the pressure in the cardiac fossa may rise more than that measured by an esophageal balloon, and the pressure in the pericardium may be still higher. Bedside measurements of a decreased cardiac output accompanied by a higher pulmonary arterial occlusion pressure may suggest a decrease in cardiac function or contractility, but when accurate measurements of juxtacardiac pressure or left ventricular end-diastolic volume are made, the ventricle is seen to be operating at a lower preload on the same function curve. The same phenomenon may be seen when patients with severe airflow obstruction develop dynamic hyperinflation with an associated increase in cardiac fossa pressure.

High levels of PEEP and of end-inspiratory alveolar pressure compress alveolar septal capillaries, outweighing any distention of extraalveolar vessels with the lung volume increase, and thus increase pulmonary vascular resistance and right ventricular afterload. If this effect becomes dominant, a decrease in cardiac output may be associated with an increase in right ventricular end-diastolic volume.

The increase in juxtacardiac pressure with PEEP decreases the stroke work the left ventricle must do to maintain any given systemic blood pressure, thus effectively decreasing left ventricular afterload. In most circumstances, the preload effect previously described dominates, but a failing ventricle is quite sensitive to afterload, and this effect becomes more important in patients with severe heart disease. In such patients, the benefit of continuous positive airway pressure (CPAP) may be more hemodynamic than ventilatory.

CONTROVERSIES AND PITFALLS

The “classic” three- (or four-) zone model of lung blood flow distribution with its emphasis on gravitational effects has evolved to a more complete understanding of this distribution, as discussed earlier in this chapter. No real controversy clouds the accuracy of either the earlier data or more recent work, but the role of gravity has been so extensively taught that some misconceptions persist. Studies measuring blood flow with radioactive tags and relatively large counters placed over the upper, middle, and lower thorax clearly demonstrated a vertical gradient of flow increasing toward the base. The effect of alveolar and intravascular pressures on blood flow, with the latter decreasing with vertical height due to gravitational hydrostatic force, provided a plausible explanation for this finding. More recent data measuring regional flow by various techniques confirm this vertical gradient in upright lungs, but studies of inverted lungs do not show the reversal expected of a gravitational effect, and studies in zero or increased gravity show less-than-expected redistribution of regional flow. With the development of techniques to measure regional flow on increasingly smaller anatomic scales, wide variation in local blood flow is observed within an isogravitational plane, whereas flow in a specific region remains consistent despite different gravitational states. These data indicate that the distribution of blood flow is dominated by the arrangement of serial vascular resistances, due to anatomic development and largely under genetic control, with a relatively small superimposed effect of gravity. The influences of alveolar and intravascular pressures described in the zone model remain important but should not be tied to a stacked vertical alignment, because the physiology of different zones may coexist at the same height in the lung. The measurement techniques used to measure flow on a small anatomic scale require subsequent lung excision and destructive sampling, so they have been applied only to animals, including primates; whatever controversy remains, therefore, is related to the less-substantiated proof in human lungs and continuing debate over the relative importance of vascular structure and hydrostatic gradients in determining regional blood flow.

Failure to appreciate this newer description of blood flow distribution in the lung can lead to misunderstanding of clinical events. For example, considerable interest has emerged in the improved oxygenation that commonly occurs with prone positioning in acute lung injury. The gravitational model would suggest that the improved ventilation-perfusion distribution could be attributed to a shift in perfusion, but available data show that it is predominantly the ventilation that shifts to better match the maintained higher perfusion of the dorsal-caudal regions of lung.

Section 1
NORMAL STRUCTURE AND FUNCTION

Chapter 5
Gas Exchange

Peter D. Wagner

The primary function of the lungs is to exchange gases between the blood and the external air. Mostly, of course, it is only O_2 and CO_2 that undergo exchange, but during gaseous anesthesia, the anesthetic gas is taken up by the lungs during induction or eliminated by the lungs during recovery. In addition, when a person is exposed to foreign gases in the air, these gases can be inhaled and may undergo exchange as well. Furthermore, gases with selected physical and chemical properties are sometimes used in cardiorespiratory research or even clinical care. For example, acetylene as a moderately soluble gas can be used to measure pulmonary blood flow; carbon monoxide (in very low concentrations) is routinely used to measure the lung diffusing capacity or transfer factor.

Fortunately, all such gases behave in accordance with the same basic physical principles underlying gas transport and exchange—mass conservation—explained in some detail further on. Although different gases appear to behave differently, this reflects their different physicochemical properties related to how they are transported in blood, and not differences in conforming to the mass conservation principles of exchange. Moreover, gas uptake from air into blood obeys the same rules as for gas elimination from the blood to the air. Thus, the topic of gas exchange can be treated as a general process applicable to all gases, whether taken up or eliminated. Subsequent applications can be made for individual gases in accord with their blood transport properties. In this chapter, the focus is primarily on the respiratory gases O_2 and, to a lesser extent, CO_2.

THE BASIS OF GAS EXCHANGE: VENTILATION, DIFFUSION, AND PERFUSION

The lungs conduct gas exchange through three interacting processes: ventilation, diffusion, and perfusion (or blood flow). Ventilation brings O_2 from the air to the alveoli (and simultaneously eliminates CO_2, transferred from the blood, to the air). Diffusion is the process by which O_2 in the alveoli passes across the alveolar wall into the pulmonary capillary. Perfusion moves the blood through the pulmonary circulation and allows continuously flowing red cells to take on O_2. Ventilation and perfusion are mostly convective processes that require energy expenditure by the organism. Ventilation is an alternating, bidirectional process of inspiration and expiration, while perfusion is unidirectional from right ventricle to left atrium. Inspiration is accomplished by the respiratory muscles (diaphragm and external intercostal muscles mostly), which on contraction expand the thoracic cage, thus reducing the intrapleural pressure around the lungs, resulting in passive lung expansion. Expiration generally is passive and occurs as the respiratory muscles relax and allow the elastic recoil of the lung to expel air. Diffusion is passive and does not require the organism to expend energy. It simply reflects random molecular motion that over time tends to equalize molecular concentrations in space.

RELATIONSHIPS BETWEEN LUNG STRUCTURE AND FUNCTION

The evolutionary "decision" to conduct gas exchange by passive diffusion (rather than by energy-requiring active transport) was a profound one that dictated the basic structure of the lungs. The laws of diffusion show that diffusive mass transfer rates are directly proportional to the surface area available for diffusion and are inversely proportional to the distance the molecule must diffuse. The fundamental unit of structure in the lung is the alveolus, small and roughly spherical in shape, with an average radius of 150 micrometers (μm). There are about 300 million alveoli in the human lung. Each is supplied with air that must pass through the branching bronchial tree (conducting airways). The wall of each alveolus, shared by adjacent alveoli, is packed with capillaries. The tissue separating alveolar gas from the blood in the capillaries consists of the capillary endothelium, interstitial matrix, alveolar epithelium, and a thin layer of fluid. The entire wall is less than 0.5 μm in thickness.

These dimensions imply a total alveolar surface area of about 80 m^2, yet a gas volume of only 4 L (small enough to fit within the chest cavity). Thus, the actual lung can conduct diffusive exchange efficiently because of the large surface area and small diffusion distance. By contrast, if the lungs consisted of just a single large sphere of the same 4-L volume, its surface area would be only $\frac{1}{8}$ m^2 (640-fold less). Moreover, if the same mass of 0.5-μm-thick alveolar wall tissue covering all 300 million alveoli were spread around this one sphere, its thickness would be over 300 μm, also about 600 times greater than in the actual lung. Because diffusion rates depend on the ratio of area to thickness, the real lung is about 640 × 600, or 400,000 times better at diffusive transport than would be a single sphere of the same volume and mass. The message is that by dividing up the lung into a very large number of very small structures, diffusion becomes a feasible and energy-efficient method of gas exchange, circumventing the need for active transport.

This picture of the lungs is similar in some ways to a bunch of grapes in which each grape is an alveolus, the skin is the alveolar wall (containing the capillaries) and the pulp inside is the alveolar air space. The stalks connecting each grape to its cluster depict the conducting airways and blood vessels. A major shortcoming to the grape analogy, however, is that each grape in a bunch is physically detached from all others in the bunch. However, all alveoli are connected, sharing common alveolar walls, much like the cells of a honeycomb. This connectivity means that the alveoli are mechanically interdependent—they pull on each other, forming a self-stabilizing three-dimensional network.

CHALLENGES TO LUNG FUNCTION CAUSED BY ITS STRUCTURE

Lung structure may be optimized for diffusion, but it results in several potentially life-threatening challenges:

Inequality of ventilation and blood flow: Because the lungs are ventilated through a single main airway (trachea), yet air must reach all 300 million alveoli, there must be a substantial branching airway system. Indeed, some 23 orders of largely dichotomous branching are recognized, resulting in a very large number of very small airways arranged in parallel with each other—much like tree branches emanating and serially dividing from a single trunk. It is impossible to imagine that inhaled air can be distributed homogeneously to all 300 million alveoli, and nonuniform ventilation distribution is well known to occur. Similarly, blood flow reaches the lungs from the main pulmonary artery by a corresponding branching system, and it also is known that perfusion is nonuniform. Nonuniform distribution of ventilation and blood flow are important for gas exchange efficiency as will be shown later.

Wasted ventilation (dead space): The first 17 or so generations of the airways are conducting airways—plumbing whose walls are unable to perform any gas exchange. Their total volume is about 150 mL. This means that with every single breath, 150 mL of inhaled air never reaches the alveoli yet must be moved by muscle contraction. Normally, each breath is about 500 mL in total volume, so about 30% of each breath represents wasted effort. This is not important in health, but in some lung diseases, the effort of breathing is so high that this wasted ventilation, called *dead space*, leads to insufficient ventilation of fresh gas to the alveoli.

Alveolar collapse: A very large number of very small collapsible structures is potentially physically unstable, due to surface tension forces. The laws of physics show that the pressure inside a soap bubble caused by surface tension is inversely proportional to the bubble radius. To the extent that the soap bubble analogy applies to the alveoli, which simply are not all exactly equal in size, surface tension forces will therefore tend to empty small alveoli into larger alveoli. Unchecked, this progression would lead to massive alveolar collapse with loss of gas exchange surface area and could prove fatal. In fact, the neonatal respiratory distress syndrome is considered to represent an example of just this phenomenon. The body has solved this problem by generating, in normal full-term newborns, a surfactant that lines each alveolus. It reduces surface tension by about an order of magnitude, greatly mitigating the risk of alveolar collapse. What also helps prevent collapse is the aforementioned interdependence whereby adjacent alveoli share common alveolar walls, creating a mesh or network that is inherently self-stabilizing.

Particle deposition: An array of about 20 orders of dichotomous branching leads to a very large (2^{20} in this case) number of small peripheral airways. Although individually each is very small, there are so many of them that their total cross-sectional area becomes very large. With this arrangement, the forward velocity of the air in each small airway is reduced as air is inhaled, which in turn increases the chance that an inhaled dust (or other) particle will settle out and deposit on the small airway wall (compared with larger, more proximal airways, in which the velocity of air flow is much greater). If such a particle is physically, chemically, or biologically dangerous, disease may result, often starting in those small peripheral airways—as is the case for emphysema caused by inhalation of tobacco smoke.

Airway obstruction by mucus: Although the airways have developed a sophisticated particle clearance mechanism using mucociliary transport, the mucus that traps the particles may itself occlude small airways, impairing distal ventilation of the alveoli.

Capillary stress failure: The pulmonary microcirculation is at risk from the inherent structure of the lungs. With capillaries poorly supported in very thin alveolar walls (good for diffusion), they risk rupture into the alveolar space when intravascular pressures rise even modestly. Such alveolar hemorrhage occurs in several conditions, and especially in racehorses, whose lungs are relatively small, leading to high vascular pressures, which in this setting can be fatal.

Pulmonary hypertension: Because all of the cardiac output has to pass through the lungs (compare the systemic circulation, for which flow is divided among all of the body's other tissues and organs), the potential for high vascular pressures is considerable. The twin processes of capillary distention and recruitment mitigate increases in pressure when perfusion is increased, as in exercise.

In sum, many life-threatening challenges may be associated with a lung built for diffusion, affecting the airways, alveoli, and blood vessels. In the normal lung, defenses against them are satisfactory, but in lung disease, they often are inadequate, with sometimes fatal outcomes.

GAS EXCHANGE IN THE HOMOGENEOUS LUNG: VENTILATION, DIFFUSION, AND PERFUSION

Because gas exchange obeys mass conservation rules and occurs by passive diffusion, the exchange of gases can be understood and predicted quite accurately in a quantitative sense. In fact, quantitative discussion is essential to understanding of not just the principles but also the clinically very important differences in behavior of O_2, CO_2, and other gases. It is best to start with a perfectly homogeneous lung—one in which every alveolus is assumed to be identical and to receive an equal share of both ventilation and blood flow. Although an obvious oversimplification, this assumption allows the establishment of the basic principles, which can then be readily applied to lungs in which differences in ventilation and blood flow exist among alveoli.

Ventilation

For ventilation, *mass conservation* means that the amount of O_2 diffusing into the pulmonary capillary blood from the alveolar gas in a given period (say, 1 minute—i.e., $\dot{V}O_2$) can be expressed as the difference between how much O_2 was inhaled and how much was exhaled (over that minute). This relation holds because inhaled O_2 has only two fates—diffusing into the blood or being exhaled. The amount inhaled is the product of minute ventilation and the concentration of O_2 in inhaled air; the amount exhaled is the product of minute ventilation and the concentration of O_2 in the exhaled gas. Because O_2 concentration is constantly changing during the course of an exhalation, it is appropriate to use the mean concentration over exhalation. Minute ventilation is the product of the volume of each breath (L/breath) and the frequency of breathing (breaths/minute). Although the volumes inhaled and exhaled might be expected to be the same (or the lungs would either blow up or collapse), exhaled volume usually is 1% less than that inhaled because the amount of O_2 absorbed into the blood is a little more than the amount of CO_2 eliminated from the blood. This small difference can be neglected in most circumstances, as is the case in the following discussion. The mass conservation equation that then describes O_2 uptake as a function of ventilation is

$$\dot{V}O_2 = \dot{V}E \times FIO_2 - \dot{V}E \times FEO_2 \tag{1}$$

where $\dot{V}O_2$ is the volume of O_2 taken up into the blood per minute, and $\dot{V}E$ is the minute ventilation, both expressed in L/minute. FIO_2 and FEO_2 are, respectively, the inhaled and exhaled mean O_2 fractional concentrations. $\dot{V}E$ commonly is about 7 L/minute. Because about 21 of every 100 molecules in air are O_2 molecules (the rest being mostly nitrogen), FIO_2 is 0.21. FEO_2 at rest is about 0.17; this difference shows that $\dot{V}O_2$ is about 0.3 L/minute. Because the conducting airways that feed the alveoli do not exchange O_2 or CO_2, it has become conventional to subtract the volume of gas left in the conducting airways each breath—the so-called *anatomic dead space*—from the total breath volume before multiplying by respiratory frequency to calculate ventilation, resulting in a variable known as *alveolar ventilation* ($\dot{V}A$). Equation 1 then becomes

$$\dot{V}O_2 = \dot{V}A \times FIO_2 - \dot{V}A \times FAO_2 \tag{2}$$

where FAO_2 is now the mean alveolar O_2 concentration. FAO_2 is higher than FEO_2 because the latter combines the inhaled air from the dead space with the alveolar gas, which is lower because of O_2 transfer into the blood.

The tendency is to use partial pressure (PIO_2, inhaled; PAO_2, alveolar) rather than fractional concentration (FIO_2, FAO_2) in describing these relationships: From Dalton's law of partial pressure, $PO_2 = FO_2 \times$ (barometric pressure − water vapor pressure). Allowing for proper units, Equation 2 can then be rewritten as

$$\dot{V}O_2 = 1.159 \times \dot{V}A \times (PIO_2 - PAO_2) \tag{3}$$

$\dot{V}O_2$ is now expressed in mL/minute, $\dot{V}A$ in L/minute, and P in mm Hg.

$\dot{V}O_2$ is the whole-body metabolic rate and as such is dictated by the body tissues, not the lungs. Because PIO_2 is a constant, Equation 2 can be used to demonstrate the dependence of alveolar PO_2 on alveolar ventilation for a given value of $\dot{V}O_2$ (**Figure 5-1**). The same concepts apply to CO_2, for which it is simpler, because CO_2 is essentially absent from inhaled air. The corresponding equation is

$$\dot{V}CO_2 = 1.159 \times \dot{V}A \times PACO_2 \tag{4}$$

How ventilation affects $PACO_2$ also is shown in Figure 5-1. It is evident that a relatively small reduction in ventilation will reduce PAO_2 and increase $PACO_2$—both substantially.

Dividing Equation 4 by Equation 3 gives

$$\dot{V}CO_2 / \dot{V}O_2 = R = PACO_2 / (PIO_2 - PAO_2) \tag{5}$$

which can be rearranged into what is called the *alveolar gas equation*:

$$PAO_2 = PIO_2 - PACO_2 / R \tag{6}$$

This equation, which relates alveolar PO_2 to alveolar PCO_2 for a given respiratory exchange ratio R, is very useful at the bedside, as discussed later on.

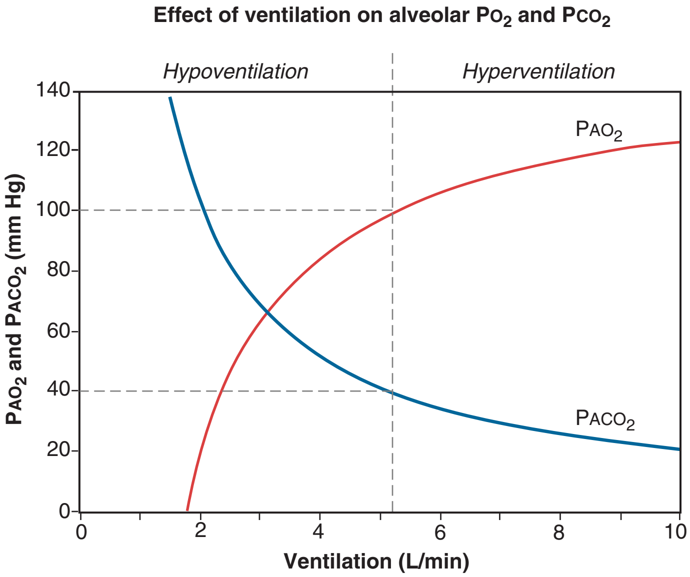

Figure 5-1 Relationship between alveolar PO_2/PCO_2 and alveolar ventilation when metabolic rate is held constant. *Dashed lines* indicate normal ventilation, PO_2 and PCO_2. Note that as ventilation is reduced, even moderately, PO_2 falls sharply and PCO_2 rises similarly.

Diffusion

The laws of diffusion dictate that the rate at which a gas diffuses between two points is the product of the diffusion coefficient for the gas and the partial pressure difference between the two points. In the lungs, the diffusion coefficient, measured as the diffusing capacity, is determined by surface area and distance of the diffusion pathway (see earlier). When a red cell leaves the pulmonary arteries and enters the pulmonary capillary, it arrives with a reduced level of O_2, because the tissues visited by that red cell took O_2 from the red cell for the tissue's metabolic needs. The PO_2 in the red cell in this blood commonly is about 40 mm Hg. Alveolar PO_2, on the other hand, usually is about 100 mm Hg. The large PO_2 difference ("driving gradient") of 60 mm Hg leads to rapid diffusion of O_2 from the alveolar gas into the capillary blood. Consequently, however, the blood PO_2 increases, reducing the driving gradient, and O_2 diffusion slows down as the red cell progresses along the lung capillary network. With modeling of this process, again using mass conservation principles, PO_2 is seen to rise approximately exponentially as the red cell moves along the lung capillary until PO_2 in the red cell has reached the alveolar value, indicating that diffusion equilibration has occurred. This process is shown in **Figure 5-2**. Note that for O_2, equilibration occurred in about 0.25 second. On average, each red cell takes about 0.75 second to move through the alveolar capillary system, so that diffusion equilibration is complete already a third of the way along the capillary, and thus well before its end. As might be expected, during exercise, time available for a red cell to pick up O_2 in the lung is reduced, because blood flow rate is increased, and at very high exercise intensity, there may not be sufficient time for PO_2 in the red cell to reach the alveolar value. Accordingly, PO_2 in the systemic arterial blood will be lower than that in the alveolus—a situation referred to as hypoxemia caused by diffusion limitation. This effect is seen commonly in exceptional athletes exercising heavily at sea level, and in all subjects exercising at altitude.

While CO_2 moves from blood to gas, the principle is the same as for O_2. Here, the red cell enters the alveolar capillary

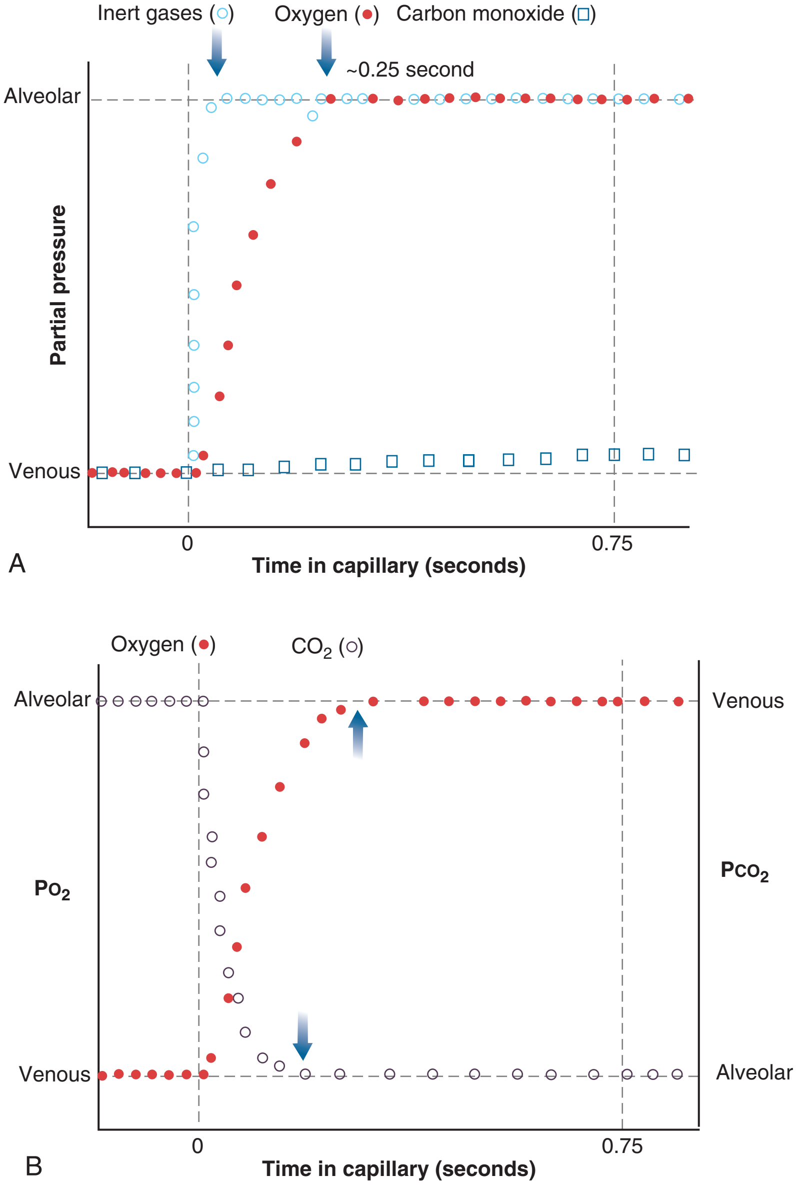

Figure 5-2 **A,** Rate of rise in gas partial pressure along the capillary. Inert gases equilibrate very rapidly, and O_2 more slowly, but CO fails to equilibrate. **B,** Rate of fall in CO_2 partial pressure along the capillary. CO_2 equilibrates about twice as rapidly as does O_2.

with a high P_{CO_2} (because of addition of waste CO_2 from tissues visited by the red cell), whereas alveolar P_{CO_2} is lower. Thus, diffusion will move CO_2 from red cell to alveolar gas, and red cell P_{CO_2} will fall toward the alveolar value in mirror image to the rise in P_{O_2} described earlier (see Figure 5-2). The speed of equilibration for CO_2 is about twice that for O_2, so it takes about half the time to reach equilibration. In practice, CO_2 is never diffusion-limited. Gases carried in blood only in physical solution (i.e., inert and anesthetic gases) equilibrate even faster—about 10 times as quickly as for O_2 (see Figure 5-2). This rule holds true for gases of any solubility.

In the remainder of this chapter, diffusion equilibration is assumed to be complete for all gases discussed. What this means is that the alveolar (A) and end-of-the-capillary (ec) P_{O_2} values are the same for any one gas. Thus, for O_2, $P_{AO_2} = P_{ecO_2}$.

Perfusion

From the preceding, it is clear that O_2 brought to the alveoli by ventilation then diffuses into the flowing blood in lung capillaries. O_2 uptake into the blood can be described using mass conservation principles, just as for ventilation. Thus, the amount of O_2 taken up into the flowing blood per minute ($\dot{V}_{O_2}$) is the amount of O_2 in the blood leaving the lungs each minute heading for the left atrium, minus the amount that had entered the lungs in the pulmonary arterial blood. These amounts are the product of the concentration of O_2 in each site and the blood flow rate. If Ce_{CO_2} is the concentration of O_2 in the end-capillary blood, Cv_{O_2} is the concentration of O_2 in the capillary blood as it enters the lung capillaries, and $\dot{Q}$ is the blood flow rate through the lungs, mass conservation gives

$$\dot{V}_{O_2} = \dot{Q} \times Ce_{O_2} - \dot{Q} \times Cv_{O_2} \tag{7}$$

Because O_2 concentration in end-capillary blood is virtually unchanged between the end of the capillary and the systemic arterial circulation, end-capillary O_2 concentration can be replaced with arterial Ca_{O_2}, giving

$$\dot{V}_{O_2} = \dot{Q} \times (Ca_{O_2} - Cv_{O_2}) \tag{8}$$

This relationship is known as the *Fick principle.* For CO_2, the corresponding equation is

$$\dot{V}_{CO_2} = \dot{Q} \times (Cv_{CO_2} - Ca_{CO_2}) \tag{9}$$

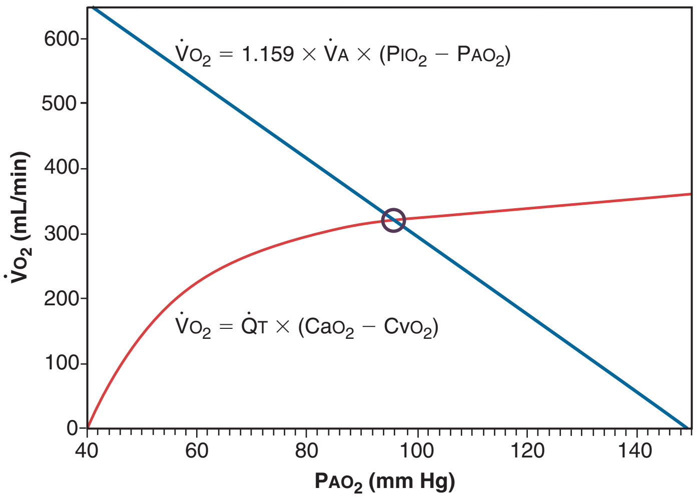

Figure 5-3 The two mass conservation equations for calculating O_2 transfer rate ($\dot{V}O_2$): one as a function of ventilation ($\dot{V}A$, *straight line*) and the other based on blood flow ($\dot{Q}T$, *curved line*), as alveolar PO_2 (PAO_2) varies. Inspired and mixed venous O_2 levels are held constant, as are $\dot{V}A$ and $\dot{Q}T$. The point of intersection (*open circle*) is the only combination of $\dot{V}O_2$ and PAO_2 for which mass of O_2 is conserved and indicates the PAO_2 that must exist for the given values of $\dot{V}A$ and $\dot{Q}T$.

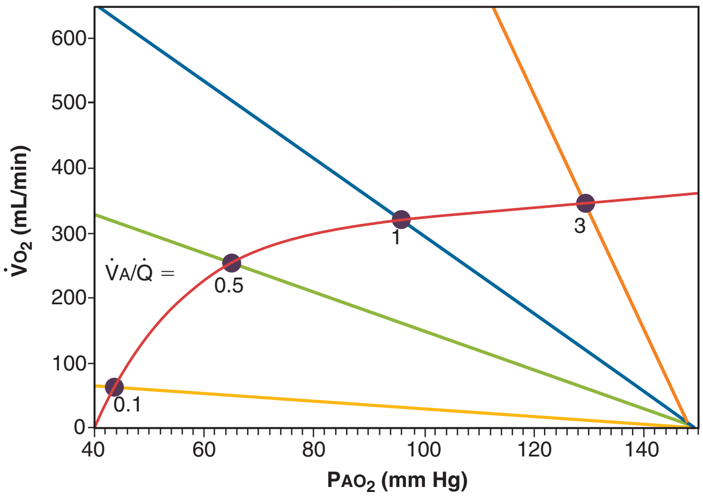

Figure 5-4 Same analysis as in Figure 5-3, with the *four straight lines* reflecting four values of ventilation, $\dot{V}A$, but only one value of blood flow, $\dot{Q}T$ (and thus yielding four values of their ratio, $\dot{V}A/\dot{Q}$). PAO_2 increases with $\dot{V}A/\dot{Q}$, as shown by the *four filled circles.*

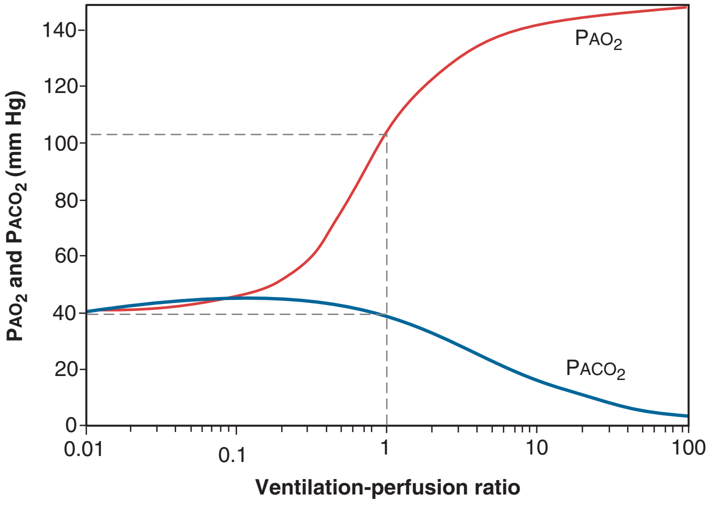

Figure 5-5 How alveolar PO_2 (and PCO_2) vary with ventilation-perfusion ratio ($\dot{V}A/\dot{Q}$), based on the analysis of Figures 5-3 and 5-4. *Dashed lines* show normal values for a $\dot{V}A/\dot{Q}$ of 1. Normal conditions are assumed: inspired PO_2 = 150 mm Hg, PCO_2 = 0 mm Hg, mixed venous PO_2 = 40 mm Hg, PCO_2 = 45 mm Hg. PAO_2 and $PACO_2$ approach mixed venous values as $\dot{V}A/\dot{Q}$ approaches zero and inspired values as $\dot{V}A/\dot{Q}$ approaches infinity.

GAS EXCHANGE

Focusing on O_2, Equations 3 and 8 should now be considered together. They both embody mass conservation but express it differently, with Equation 3 reflecting alveolar loss of O_2 into blood and Equation 8, red cell gain of O_2 into blood. **Figure 5-3** shows how, for given constant values of $\dot{V}A$ and $\dot{Q}$, and for designated values of inspired PO_2 (PIO_2) and inflowing pulmonary arterial O_2 concentration (CvO_2), $\dot{V}O_2$ would have to vary with alveolar PO_2 (to satisfy both these equations) when determined by each of the two equations independently. Because each molecule of O_2 that leaves the alveolus by crossing the blood gas barrier appears in the capillary blood, the $\dot{V}O_2$ calculated from the two equations must be the same—again, conservation of mass. Thus, only a single value of PAO_2 can exist—that at the point of intersection of the two relationships in Figure 5-3. If the calculations in Figure 5-3 were repeated for different values of $\dot{V}A$, and thus $\dot{V}A/\dot{Q}$ (in this example, keeping $\dot{Q}$ the same), the lines and their point of intersection would change as in **Figure 5-4**. This figure shows that alveolar PO_2 (x axis) and the amount of O_2 that can be taken up ($\dot{V}O_2$, y axis) both depend on $\dot{V}A$ and $\dot{Q}$. Commonly, Equations 3 and 8 are combined, because $\dot{V}O_2$ must be the same when calculated from either equation. This yields the ventilation-perfusion equation:

$$\dot{V}O_2 = 1.159 \times \dot{V}A \times (PIO_2 - PAO_2) = \dot{Q} \times (CaO_2 - CvO_2)$$

or

$$\dot{V}A/\dot{Q} = 0.863\,(CaO_2 - CvO_2)/(PIO_2 - PAO_2) \qquad (10)$$

and the equivalent for CO_2:

$$\dot{V}A/\dot{Q} = 0.863\,(CvCO_2 - CaO_2)/PACO_2 \qquad (11)$$

These equations say that it is the *ratio* of $\dot{V}A$ to $\dot{Q}$ that determines the alveolar PO_2 and PCO_2 in any region of the lungs.

Figure 5-5 shows how alveolar PO_2 and PCO_2 vary with $\dot{V}A/\dot{Q}$ when inspired PO_2 is that of room air and the pulmonary arterial (mixed venous) PO_2 is normal (i.e., 40 mm Hg). Important conclusions to be drawn from this figure are that as $\dot{V}A/\dot{Q}$ falls, PO_2 falls, approaching the mixed venous value at low $\dot{V}A/\dot{Q}$ values, and conversely, PCO_2 rises. Also, as $\dot{V}A/\dot{Q}$ rises, PO_2 approaches the inspired value, while PCO_2 falls. The dashed lines show that at the normal value for the $\dot{V}A/\dot{Q}$ ratio of about 1, PO_2 is about 100 mm Hg, and PCO_2 is about 40 mm Hg.

Although the behavior of the two gases is qualitatively similar (even if opposite in direction), their quantitative behaviors are different. Most of the variance in PO_2 occurs over the $\dot{V}A/\dot{Q}$ range 0.3 to 3, whereas for CO_2, most of its change is seen in the $\dot{V}A/\dot{Q}$ range 2 to 20, almost a decade higher. The gases obey the very same conservation of mass rules in their exchange, so their quantitative differences are due to differences in their transport properties in blood.

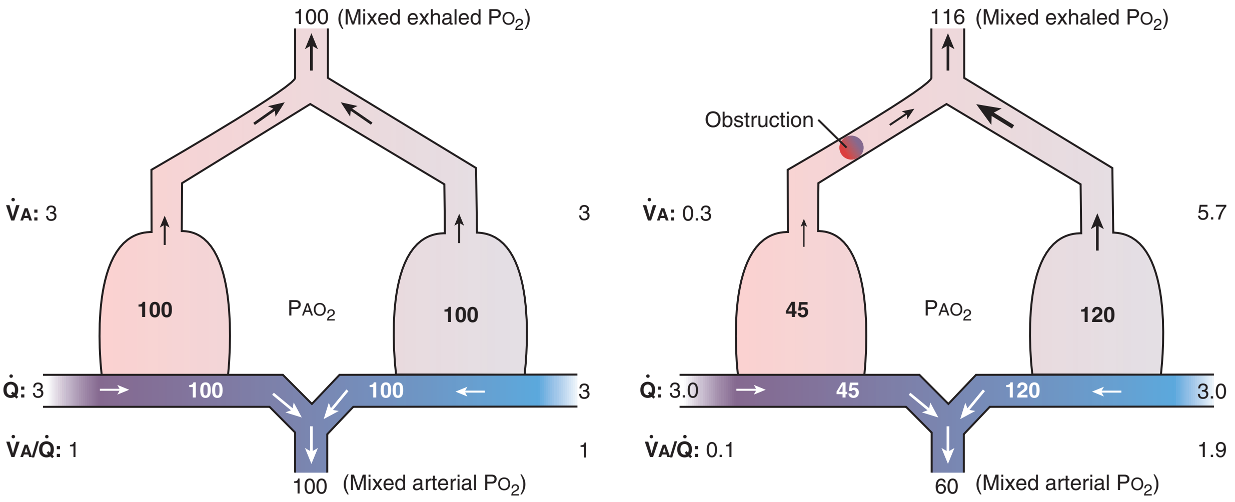

Figure 5-6 A two-compartment representation of ventilation-perfusion distribution showing how maldistribution interferes with gas exchange. **Left,** The homogeneous example in which each compartment having the same $\dot{V}A/\dot{Q}$ also must have the same PAO_2. When exhaled air and end-capillary blood from the two compartments mix, the mixed exhaled gas and mixed arterial blood have the same PO_2. **Right,** Effects of altered distribution of ventilation due to airway obstruction on the left side, reducing ventilation and thus $\dot{V}A/\dot{Q}$ each 10-fold. Mixed exhaled PO_2 is higher and mixed arterial PO_2 is lower than in the homogeneous case, and total O_2 uptake is reduced—all as total ventilation and total blood flow are held constant.

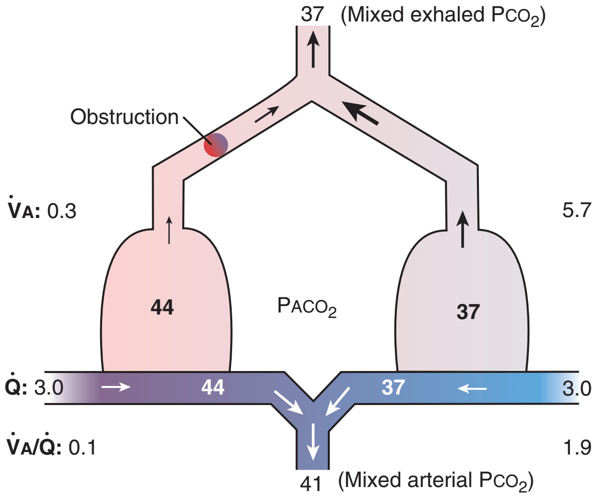

Figure 5-7 Corresponding calculations for CO_2 in the same model as in Figure 5-6, *right*. CO_2 output is impaired, whereas arterial PCO_2 is increased and exhaled PCO_2 is decreased, although the changes are less than for O_2.

VENTILATION-PERFUSION INEQUALITY AND GAS EXCHANGE

The preceding analysis accounts for gas exchange in the intact, homogeneous lung, in which a single value is taken for $\dot{V}A/\dot{Q}$ (equal to the ratio of total alveolar ventilation to total pulmonary blood flow). In real life, not all alveoli enjoy the same $\dot{V}A$ to $\dot{Q}$ ratio. In fact, even in healthy young humans there is about a 10-fold difference between the lowest and highest values, from a low of about 0.3 to a high of about 3. This difference is due to both gravitational influences (higher $\dot{V}A/\dot{Q}$ in nondependent than in dependent regions) and nongravitational factors such as variation in length and diameter of airways and blood vessels. Alveoli with different $\dot{V}A/\dot{Q}$ ratios are connected in parallel: Mixed venous blood reaches them all, and then the end-capillary blood from each flows into the pulmonary veins, much like tributaries joining a river. In lung diseases, variation in $\dot{V}A/\dot{Q}$ (also called $\dot{V}A/\dot{Q}$ inequality) can be extreme and even fatal. Thus, it is essential to consider how such inequality affects the ability of the lungs to take up O_2 and eliminate CO_2.

This analysis can be done by comparing a homogeneous lung to one with the simplest degree of inequality—a lung imagined to have two "alveoli" of different $\dot{V}A/\dot{Q}$ ratios. This schema is illustrated in **Figure 5-6**. In the left panel, the homogeneous case, with a total ventilation of 6 L/minute and a total blood flow also of 6 L/minute, both equally divided between two identical "alveoli," PO_2 and PCO_2 values can be read off Figure 5-5 for the resulting $\dot{V}A/\dot{Q}$ ratio of 1.0. In the case of inequality, the example in the right panel shows the effect of severe but incomplete airway obstruction, causing 90% reduction in ventilation of the left "alveolus," with corresponding redistribution of ventilation to the right "alveolus" (that is, total ventilation and blood flow are assumed to be unaltered by the airway obstruction). The PO_2 values are again read from Figure 5-5 and are now 45 and 120 mm Hg, respectively. As the two "alveoli" exhale, their gas streams mix in proportion to the relative gas flow rates, resulting in a mixed exhaled PO_2 of 116 mm Hg. Similarly, the blood leaving each "alveolus" has the same PO_2 as in the respective alveolar gas, as shown, and these two blood streams mix again in proportion to their blood flows. Here the computation is performed using the concentrations, not partial pressures, and when this is done, the mixed arterial PO_2 is reduced to only 60 mm Hg.

Thus, what this simple calculation shows is that when the $\dot{V}A/\dot{Q}$ ratio is not everywhere the same, gas exchange suffers: Arterial PO_2 falls, and the amount of O_2 taken up by the whole lung also falls (which can be deduced from the *increase* in mixed exhaled PO_2, which means that because more O_2 was exhaled, less O_2 was transferred into the blood).

The same occurs for PCO_2, but in the opposite direction: $\dot{V}A/\dot{Q}$ inequality increases arterial PCO_2, reduces mixed exhaled PCO_2, and thus also reduces the amount of CO_2 eliminated. **Figure 5-7** shows the values for CO_2 for the same case as in Figure 5-6. What is seen, however, is a quantitatively larger negative effect on O_2 than on CO_2, in terms of both the arterial partial pressures and total amounts of gas transferred.

That O_2 is more affected than CO_2 in this instance reflects the nature of the example: The obstructed "alveolus" has a very low $\dot{V}_A/\dot{Q}$ ratio. With modeling of exactly the same problem but this time reducing blood flow in one "alveolus" by 90%, rather than reducing ventilation as in Figures 5-6 and 5-7, $\dot{V}_A/\dot{Q}$ inequality would still be present and both gases would be affected, but because the abnormal "alveolus" has a high and not low $\dot{V}_A/\dot{Q}$ ratio, the quantitative effects are different: CO_2 is affected more than is O_2.

This result points out that the effects of $\dot{V}_A/\dot{Q}$ inequality are always to impair gas exchange for all gases, but the degree to which any one gas is affected depends on the exact pattern of distribution of ventilation and blood flow. The basic reason why O_2 and CO_2 are differently affected in any given pattern is found in the differences in their dissociation curves in blood. That for O_2 is quite nonlinear; that for CO_2 is almost linear and also is much steeper. In sum, O_2 is affected more when low $\dot{V}_A/\dot{Q}$ regions dominate; CO_2 is more affected when high $\dot{V}_A/\dot{Q}$ regions dominate.

SHUNT

Shunt refers to blood that crosses from the right to the left side of the heart without encountering any alveolar gas. This pathophysiologic entity can be due to ventricular or atrial septal defects and other intracardiac anomalies, or to lung lesions such as complete airway obstruction, atelectasis, pneumothorax, pulmonary edema, pneumonic consolidation, and large arteriovenous intrapulmonary vascular malformations. Referring back to Figure 5-6, which illustrates partial airway obstruction, a shunt could be modeled by assigning zero ventilation to the left "alveolus" and all the ventilation to the right side. The effects would be slightly more severe than those illustrated for partial obstruction, but the point is that a shunt can be thought of as an extreme of $\dot{V}_A/\dot{Q}$ inequality: a region with $\dot{V}_A/\dot{Q} = 0$, because ventilation is absent.

There is, however, a special feature of shunt that merits discussion: response to inhalation of 100% O_2. When $\dot{V}_A/\dot{Q}$ inequality is present, and 100% O_2 is inhaled, all alveolar nitrogen that had been present in the lungs of a subject breathing room air will eventually wash out, and the only gases in the alveoli will be O_2 and CO_2. P_{O_2} in all alveoli will be above about 600 mm Hg, no matter what the $\dot{V}_A/\dot{Q}$ ratio is for each alveolus. Accordingly, on 100% O_2, a lung with $\dot{V}_A/\dot{Q}$ inequality will exchange O_2 normally. In the presence of shunt, however, the shunted blood is never exposed to 100% O_2, and its P_{O_2} remains low (at P_{O_2} in the inflowing pulmonary arterial blood). This, using the same principles as in Figure 5-6, causes the mixed arterial P_{O_2} to be abnormally low even as 100% O_2 is inhaled.

THE FOUR CAUSES OF HYPOXEMIA

As characterized in the preceding discussion, arterial hypoxemia (defined as a subnormal value of arterial P_{O_2}) has four different causes:

1. Hypoventilation (see Figure 5-1)
2. Diffusion limitation (not illustrated but discussed earlier)
3. $\dot{V}_A/\dot{Q}$ inequality (see Figure 5-6)
4. Shunt, as discussed previously

The alveolar gas equation derived earlier (Equation 6) is useful in separating hypoxemia from these various insults: For hypoventilation alone, the equation predicts exactly how much arterial P_{O_2} will fall for any given increase in arterial P_{CO_2}, because the alveolar P_{O_2} and the arterial P_{O_2} remain equal. However, as shown in Figure 5-6, for $\dot{V}_A/\dot{Q}$ inequality, the exhaled alveolar P_{O_2} increases while the arterial P_{O_2} falls. Equation 6 is used to compute alveolar P_{O_2} by inserting arterial P_{CO_2} into the equation, and when this is done and the arterial P_{O_2} is subtracted from it, one has what is called the alveolar-arterial P_{O_2} difference $P_{O_2}(A–a)$. The typical patterns of arterial P_{O_2}, P_{CO_2}, and $P_{O_2}(A–a)$ are illustrated in **Table 5-1** for each cause of hypoxemia, together with the response to 100% O_2 breathing mentioned earlier. In Table 5-1, it is specifically assumed that the body has not reacted to the hypoxemia by any of the compensatory mechanisms normally available to it, as discussed next. In life, such compensatory reactions are the rule, unless special circumstances such as trauma, heart disease, or narcotic overdose also are present.

COMPENSATORY MECHANISMS

When hypoxemia develops for any reason, three principal compensatory mechanisms are invoked:

1. *Greater O_2 extraction from blood by the tissues.* When arterial P_{O_2} falls, the initial response of the body is to extract more O_2 from the flowing blood. In this way, $\dot{V}_{O_2}$ can be restored passively, both rapidly and effectively. It does result in a lower P_{O_2} in the venous blood returning to the lungs, which may further impair arterial oxygenation, thereby worsening the hypoxemia, but metabolism is protected. The same occurs in reverse for CO_2: More CO_2 is added to the tissue venous blood, raising the CO_2 level in the blood reaching the lungs. If ventilation remains unchanged, arterial P_{CO_2} must rise as a result.
2. *Hyperventilation.* Within seconds of the emergence of hypoxemia, chemoreceptors are stimulated, and reflex increase in ventilation occurs. This response usually is very effective in reducing an elevated arterial P_{CO_2} to normal but often is less

Table 5-1 **Effects of Different Causes of Hypoxemia on Gas Exchange**

Cause of Hypoxemia	Arterial P_{O_2}	Arterial P_{CO_2}	$P_{O_2}(A–a)$	Arterial P_{O_2} on 100% O_2
Hypoventilation	Reduced	Increased	Normal	Normal
Diffusion limitation	Reduced	Normal	Increased	Normal
$\dot{V}_A/\dot{Q}$ inequality	Reduced	Increased	Increased	Normal
Shunt	Reduced	Normal	Increased	Reduced

$P_{O_2}(A–a)$, alveolar-arterial P_{O_2} difference; P_{CO_2}, partial pressure of carbon dioxide; P_{O_2}, partial pressure of oxygen; $\dot{V}_A/\dot{Q}$, alveolar ventilation-perfusion ratio.

effective in restoring arterial P_{O_2}. Indeed, in an attempt to normalize P_{O_2}, ventilation commonly is increased to the point of causing arterial hypocapnia despite gas exchange abnormalities that in themselves impair CO_2 exchange. Hyperventilation is not especially effective in restoring arterial P_{O_2} in conditions associated with very low $\dot{V}_A/\dot{Q}$ ratios, such as asthma, pneumonia, and acute lung injury. It is much more effective in diseases in which high $\dot{V}_A/\dot{Q}$ ratios are the principal pulmonary abnormality—especially pulmonary thromboembolic disease.

3. *Increased cardiac output*. The sympathetic stimulation resulting from hypoxemia and other factors in many lung diseases may result in tachycardia and an elevated cardiac output. The increased output allows less fractional extraction of O_2 in the tissues, which has the effect of increasing the P_{O_2} of the venous blood returning to the heart, which in turn elevates and partly restores arterial P_{O_2}. This clinical situation commonly is seen in asthmatic patients during acute episodes, especially when β-sympathetic agonists have been taken in large doses, but is unusual in chronic, stable disease states.

These mechanisms act to restore the mass flow of O_2 and CO_2 across the lungs, returning $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ to levels necessary to sustain tissue metabolism. Failure to invoke these mechanisms leads to tissue death and can be fatal.

CLINICAL ASSESSMENT OF GAS EXCHANGE BASED ON PHYSIOLOGIC PRINCIPLES

The entire preceding discussion has provided a physiologic basis for clinical tools to assess pulmonary gas exchange. All of these tools are based on measurement of P_{O_2} and P_{CO_2} in an arterial blood sample. Because measuring the entire distribution of ventilation and of blood flow is complex and time-consuming, several simplified methods of gas exchange analysis have been proposed.

Alveolar-Arterial P_{O_2} Difference: $P_{O_2}(A–a)$

As noted earlier, Equation 6, derived previously, is called the *alveolar gas equation*.

$$P_{AO_2} = P_{IO_2} - P_{ACO_2}/R$$

If an arterial blood gas sample is taken, arterial P_{O_2} (P_{aO_2}) and arterial P_{CO_2} (P_{aCO_2}) are available. P_{aO_2} as measured can then be subtracted from P_{AO_2} as calculated from Equation 6, to get $P_{O_2}(A–a)$:

$$P_{O_2}(A\text{–}a) = P_{AO_2} - P_{aO_2} = P_{IO_2} - P_{aCO_2}/R - P_{aO_2} \qquad (12)$$

In a perfect lung, $P_{O_2}(A–a)$ would be zero. In a normal lung in a young, healthy subject, $P_{O_2}(A–a)$ is about 4 to 10 mm Hg. It can increase to as much as 60 mm Hg in severe lung disease.

Shunt: $\dot{Q}s/\dot{Q}t$

Even if the lung is complex in disease, it can always be modeled as consisting of two "compartments": one normal and one completely unventilated (i.e., in which all the blood flow is shunted). As described previously, shunted blood takes on no O_2, so that the blood leaving has the same low O_2 level as that entering in the mixed venous blood. The objective is to calculate that fraction of the cardiac output ($\dot{Q}s/\dot{Q}t$) necessary to flow through the "shunt" compartment to explain the measured arterial P_{O_2}. This calculation is done using the shunt equation, as follows:

$$C_{aO_2} \times \dot{Q}t = \dot{Q}s \times C_{vO_2} + (\dot{Q}t - \dot{Q}s) \times C_{ecO_2} \qquad (13)$$

This is a *conservation of mass* or *mixing* equation that states that the arterial O_2 concentration (C_{aO_2}) is the blood flow–weighted average of the concentrations of O_2 coming from the shunt ($\dot{Q}s$, shunt flow; C_{vO_2}, mixed venous O_2 concentration) and the normal compartment ($\dot{Q}t - \dot{Q}s$, nonshunt blood flow; C_{ecO_2}, end-capillary O_2 concentration). $\dot{Q}t$ is total blood flow, or cardiac output. Equation 13 can be rearranged as follows:

$$\dot{Q}s/\dot{Q}t = (C_{ecO_2} - C_{aO_2})/(C_{ecO_2} - C_{vO_2}) \qquad (14)$$

This is called the *shunt equation*. To use it, C_{ecO_2} is calculated using the oxygen-hemoglobin dissociation curve, and the P_{AO_2} as calculated from Equation 6; C_{aO_2} is determined from an arterial blood gas sample, and C_{vO_2} is either assumed or measured from a mixed venous blood sample. If C_{vO_2} is assumed to have a specific value, the calculated value of shunt fraction ($\dot{Q}s/\dot{Q}t$) is only as accurate as the assumed value of C_{vO_2}.

If data for this equation were collected with the patient breathing 100% O_2, a true value of shunt would be found. Recall that, as explained previously, when the subject is breathing 100% O_2, even low $\dot{V}_A/\dot{Q}$ alveoli have very high P_{AO_2} values, exceeding 600 mm Hg, and thus would not contribute to a discernible reduction in C_{aO_2}, because the alveolar blood is fully O_2-saturated. If, however, the data came from a patient breathing less than 100% O_2, the value for $\dot{Q}s/\dot{Q}t$ would in general be larger, because when less than pure O_2 is breathed, areas of low ventilation-perfusion ratio contribute numerically to what appears as $\dot{Q}s/\dot{Q}t$, because they show less than full O_2 saturation of hemoglobin.

Physiologic Dead Space: Vd/Vt

In a conceptual mirror-image formulation, total dead space can be calculated as another parameter of abnormal gas exchange. Conventionally, CO_2 has been used as the marker gas for this, not O_2. The basis is again conservation of mass, and the concept makes use of another two-compartment model. This time, while one compartment remains normal, the other is given an infinitely high ratio of $\dot{V}_A/\dot{Q}$—that is, it is ventilated ($\dot{V}_A > 0$) but unperfused ($\dot{Q} = 0$). No gas exchange occurs because there is no blood flow. This compartment therefore wastes any ventilation it gets. Its alveolar P_{CO_2} is thus that of inspired gas, namely, zero. The objective is to explain the P_{CO_2} in mixed exhaled gas (P_{ECO_2}) as a ventilation-weighted average of the P_{CO_2} coming from each compartment—alveolar P_{CO_2} (P_{ACO_2}) from the normal compartment and zero from the dead space compartment. The mass conservation equation parallels that for shunt, as follows:

$$P_{ECO_2} \times Vt \times f = P_{ACO_2} \times (Vt - Vd) \times f + 0 \times Vd \times f \qquad (15)$$

Here f is respiratory frequency, Vd is the volume of air inhaled per breath by the unperfused compartment, and Vt is total inhaled volume of air per breath. Rearranging this equation gives

$$Vd/Vt = (P_{ACO_2} - P_{ECO_2})/P_{ACO_2} \qquad (16)$$

Usually, alveolar P_{CO_2} (P_{ACO_2}) is replaced by arterial P_{CO_2} (P_{aCO_2}) from an arterial blood sample, to arrive at

$$Vd/Vt = (P_{aCO_2} - P_{ECO_2})/P_{aCO_2} \qquad (17)$$

This dead space equation needs as input arterial P_{CO_2} as well as P_{CO_2} measured in mixed exhaled gas.

The foregoing discussion makes it clear that taking an arterial blood sample is critical for estimating all three parameters of gas exchange. For accurate results, an arterial blood sample is not sufficient. Mixed exhaled gas is required to determine R ($\dot{V}CO_2/\dot{V}O_2$) in Equation 12 and for measuring mixed exhaled PCO_2 ($P\bar{E}CO_2$) as used in Equation 17. Moreover, Equation 14 requires an estimate of mixed venous O_2 concentration.

ACID-BASE RELATIONSHIPS

For the body to function, hydrogen ion concentration must be kept within narrow limits. Expressed as pH (negative log of $[H^+]$ in moles per liter), normal acidity in circulating blood is 7.40 (40 nanomoles of free H^+ per liter). About the lowest pH that can be survived is 6.8; what is the highest survivable value is unclear (probably about 7.9). A pH of 6.8 corresponds to about 160 nmol/L, whereas a pH of 7.9 corresponds to 13 nmol/L.

It is not surprising that the body has several mechanisms available to maintain pH within this very narrow range. There are in essence three homeostatic mechanisms that together work toward keeping pH normal. The first is chemical buffering by weak acids or bases. The second is renal excretion or retention of H^+, and the third is the process of ventilation.

BUFFERING

When blood is examined, several weak acids and bases are present in solution in plasma, red cells, or both. The major concept here is that they are all in chemical equilibrium with the existing $[H^+]$. Should the concentration of H^+ ions (i.e., protons) increase for any reason (that is, should *acidosis* develop), positively charged protons can react with the negatively charged ionic form of the weak acid to form the combined, nonionic species. In this way, protons are removed from solution, thus raising the pH back toward normal. This sequence is evident when the chemical equation for this process is displayed:

$$H^+ + A^- \rightarrow HA \qquad (18)$$

The ionic form of the weak acid A (i.e., A^-) combines with a proton (H^+) to form the associated nonionic form HA, thus reducing free $[H^+]$ and thereby raising pH.

Should the opposite condition exist—a reduction in free $[H^+]$ (known as *alkalosis*), the reaction shown in Equation 18 can run from right to left, thereby increasing H^+ ion levels and lowering pH back toward normal.

Important buffers in blood include plasma proteins, especially albumin, phosphate ions, and, inside the red cell, hemoglobin. These buffers form the body's first line of defense against an alteration in pH. They are immediately available and work instantly. Once deployed, however, they can be of little further use until new molecules are synthesized. Thus, they are of limited long-term value for modulating acid-base disturbances and have limited quantitative effect.

THE KIDNEYS

The kidneys can retain or excrete H^+ and bicarbonate ions (HCO_3^-) to preserve their levels in the blood and thus play a major role in controlling pH changes arising from acid-base disturbances. The details of renal function are beyond the scope of this discussion, and further information is available in any of several texts on the subject.

Two important aspects of the renal contribution to acid-base disturbances are as follows: First, the kidneys are slow to react noticeably to an alteration in pH. Somewhat akin to a freight train starting from a dead stop, renal action may begin as soon as pH is changed, but it takes hours to "get up to speed" and affect pH. Second, just as normal kidneys can play a major homeostatic role in restoring pH toward normal, when renal disease develops, the ability to excrete a normally acid urine may be compromised, resulting in accumulation of H^+ ions, with consequent development of acidosis. The kidneys can therefore be a cause of acidosis when they themselves are abnormal, owing to failure of H^+-excreting mechanisms that are invoked to deal with excess H^+ in normal kidneys.

THE LUNGS

Just as the kidneys can counteract either an acidosis or an alkalosis, the lungs have the ability to do likewise. The lungs contribute to regulation of blood pH through changes in PCO_2 brought about by changes in ventilation. In sum, an increase in $[H^+]$ in the blood stimulates both central (ventral medullary) and peripheral (carotid body) chemoreceptors, which send neural signals to the respiratory control areas of the brain, which in turn direct the respiratory muscles to produce an increase in ventilation, thereby decreasing PCO_2 (refer to Equation 4). A decrease in $[H^+]$ does the opposite. This effect is achieved through the buffering principle, as described, with carbonic acid (H_2CO_3) as the weak acid, as follows. The reaction is greatly accelerated by carbonic anhydrase:

$$H^+ + HCO_3^- \rightarrow H_2CO_3 \rightarrow H_2O + CO_2 \qquad (19)$$

Thus, if acidosis develops, the entire reaction proceeds rightward, removing H^+ ions, raising pH, and producing more CO_2 that can (usually) be easily eliminated by a (usually) modest increase in ventilation. Conversely, should alkalosis develop, the reaction proceeds leftward, liberating H^+ ions to restore pH. The source of the CO_2 necessary to "feed" this backward reaction is a reduction in ventilation. In sum, changes in ventilation affect changes in PCO_2, which then cause the chemical reaction in Equation 19 to proceed rightward when there is acidosis (increased ventilation and lowering PCO_2) or leftward when there is alkalosis (lowering ventilation and raising PCO_2).

By writing the equilibrium version of Equation 19, the concentrations of H^+, HCO_3^-, and CO_2 can be related as follows:

$$K = [H^+] \times [HCO_3^-]/[CO_2] \qquad (20)$$

or

$$K = [H^+] \times [HCO_3^-]/[0.03 \times PCO_2] \qquad (21)$$

where 0.03 is the solubility of CO_2 in plasma (water) in mmoles per liter per mm Hg unit. Taking logarithms of equation 21 and rearranging K and $[H^+]$ gives:

$$-\log [H^+] = -\log K + \log ([HCO_3^-]/[0.03 \times PCO_2]) \qquad (22)$$

or

$$pH = pK + \log ([HCO_3^-]/[0.03 \times PCO_2]) \qquad (23)$$

where pK is the negative logarithm of the equilibrium constant for the reaction in Equation 19 and equals 6.1. This equation is known as the *Henderson-Hasselbalch equation* and is widely used in describing acid-base disturbances. As can be seen, it relates pH to $[HCO_3^-]$ and PCO_2.

Because this equation contains three variables, their relationship should be expressed in three dimensions, which is difficult. Several ways of working with the equation to surmount this problem have been devised, and they are in essence graphical.

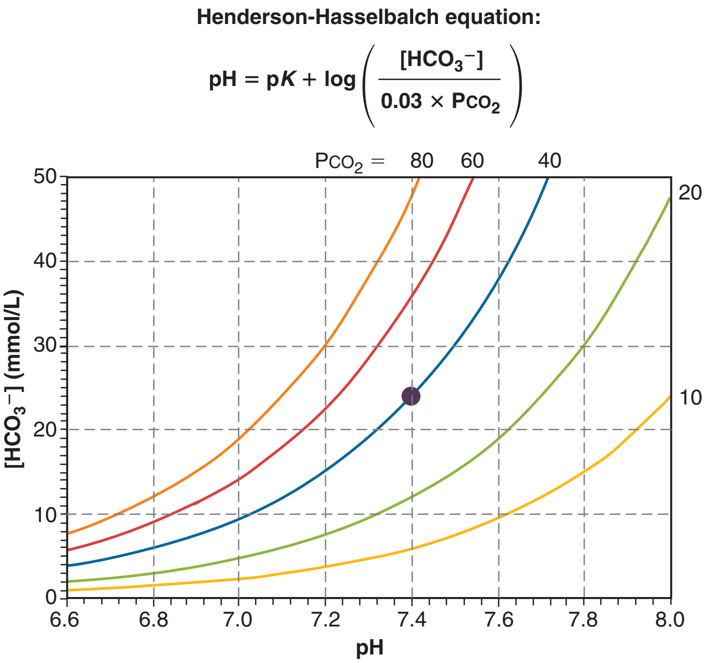

Figure 5-8 The Davenport diagram: Representation of the Henderson-Hasselbalch equation relating pH, $[\mathrm{HCO_3^-}]$, and $P\mathrm{CO_2}$. Each *curved line* shows the unique relationship between $[\mathrm{HCO_3^-}]$ and pH for each single value of $P\mathrm{CO_2}$ shown on the graph. The *filled circle* is the point corresponding to normal arterial blood.

Perhaps the most intuitive and widely used is the *Davenport diagram*, which plots $[\mathrm{HCO_3^-}]$ on the ordinate and pH on the abscissa and uses isopleths of $P\mathrm{CO_2}$ to allow consideration of variation in that variable. For example, if $P\mathrm{CO_2}$ is held constant at its normal value of 40 mm Hg, the equation simplifies to

$$\mathrm{pH} = 6.1 + \log\left([\mathrm{HCO_3^-}]/[0.03 \times 40]\right) \qquad (24)$$

In this way, the value of $[\mathrm{HCO_3^-}]$ for any given pH can be calculated, forming a single line on which each point satisfies Equation 24 for the same value of $P\mathrm{CO_2}$—in this example, 40 mm Hg. Figure 5-8 shows this line on a Davenport diagram for a $P\mathrm{CO_2}$ of 40 mm Hg and also for several other fixed $P\mathrm{CO_2}$ values, as indicated. This set of $P\mathrm{CO_2}$ isopleths then forms the framework for considering acid-base relationships, both normal and abnormal. The value in normal arterial blood is shown in this figure by the solid circle located at $P\mathrm{CO_2}$ of 40 mm Hg, pH of 7.40, and $[\mathrm{HCO_3^-}]$ of 24 mmol/L.

Figure 5-9 plots as a series of solid circles the relationship between pH and $[\mathrm{HCO_3^-}]$ when the same *normal* blood sample is exposed to and equilibrated with gases of different $P\mathrm{CO_2}$ values (one at a time), after which pH and $[\mathrm{HCO_3^-}]$ are measured. From Equation 23, the Henderson-Hasselbalch equation, it is evident that as the applied $P\mathrm{CO_2}$ is raised above normal, pH must fall to below normal, and as $P\mathrm{CO_2}$ falls below normal, pH rises above normal, as shown. The pH/$[\mathrm{HCO_3^-}]$ relationship turns out to be almost straight, as the figure indicates. The steeper the line, the less is the change in pH for a given $P\mathrm{CO_2}$. That is, the steeper the line, the more effectively $[\mathrm{H^+}]$ is kept from changing. Because these results pertain to a single blood sample in vitro, no renal intervention is possible, and the line can be said to represent the buffering ability of the blood sample. Indeed, it is called the *blood buffer line*. The higher the plasma and red cell buffer levels, the steeper will be the buffer line.

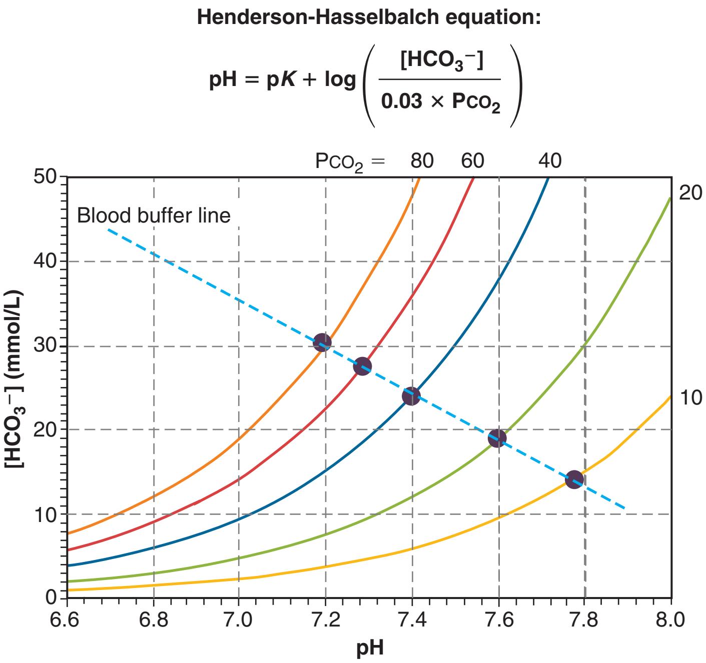

Figure 5-9 The blood buffer line on the Davenport diagram. It is the line relating pH to $[\mathrm{HCO_3^-}]$ as $P\mathrm{CO_2}$ is varied in a given blood sample. See text for details.

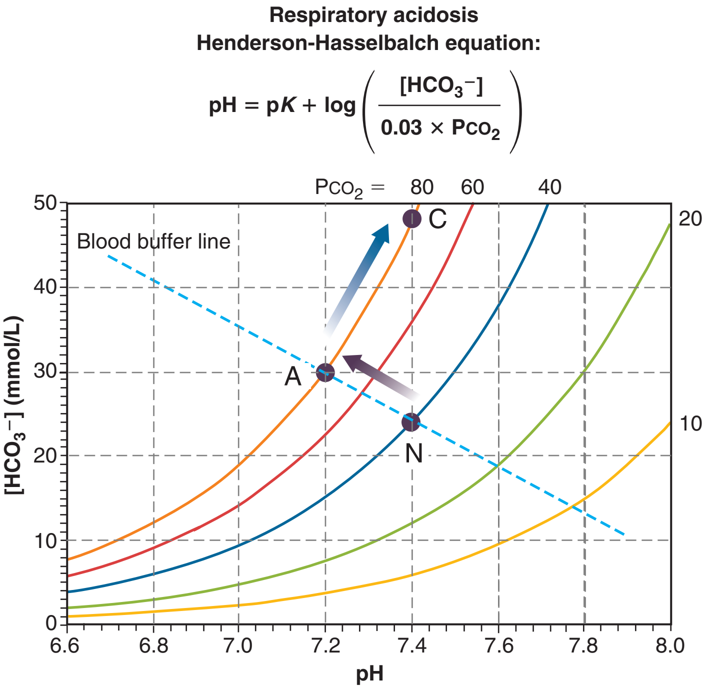

Figure 5-10 The Davenport diagram for respiratory acidosis. An acute increase in $P\mathrm{CO_2}$ moves blood pH from the normal position (N) to point A—that is, movement up the normal blood buffer line. Over several hours to days, renal compensation slowly restores pH through $\mathrm{HCO_3^-}$ retention, moving blood to point C.

Use of the Davenport diagram to describe acid-base disturbances is illustrated in Figures 5-10 through 5-13. Each figure depicts the consequences of one of the four possible types of acid-base disturbance—respiratory acidosis, respiratory alkalosis, metabolic acidosis, and metabolic alkalosis. In each, the $\mathrm{CO_2}$ isopleths and normal blood buffer line are shown, along with the normal point, N. These diagrams often are very useful at

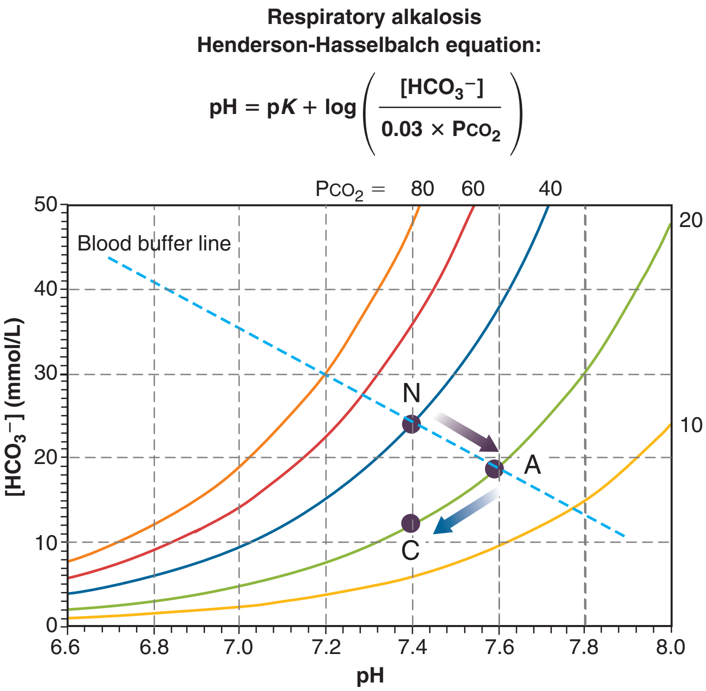

Figure 5-11 The Davenport diagram for respiratory alkalosis. An acute decrease in P_{CO_2} moves blood pH from the normal position (N) to point A—that is, down the normal blood buffer line. Over several hours to days, renal compensation slowly restores pH through HCO_3^- excretion, moving blood to point C.

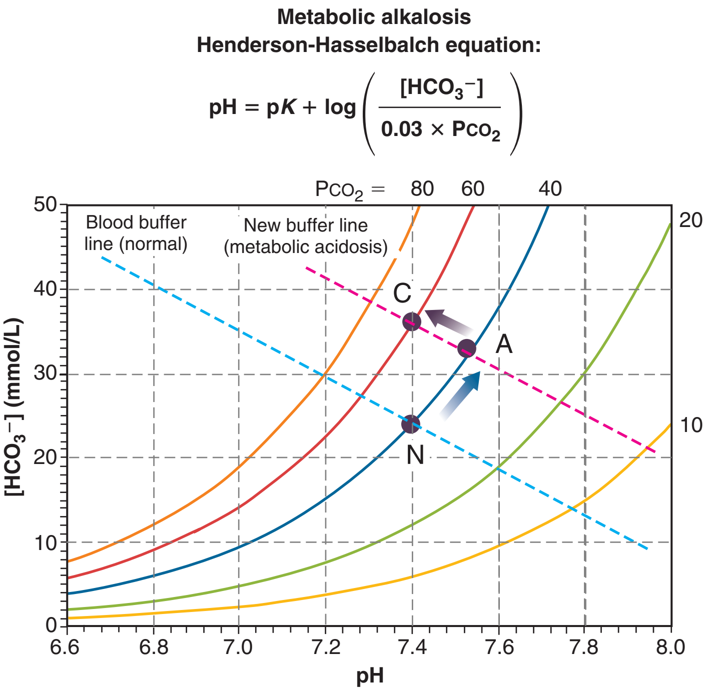

Figure 5-13 The Davenport diagram for metabolic alkalosis. An acute decrease in [H$^+$] moves blood pH from the normal position (N) to point A—that is, up the line for normal P_{CO_2}. Over seconds to minutes, ventilatory compensation quickly restores pH through hypoventilation, thereby increasing P_{CO_2}, and moving blood to point C.

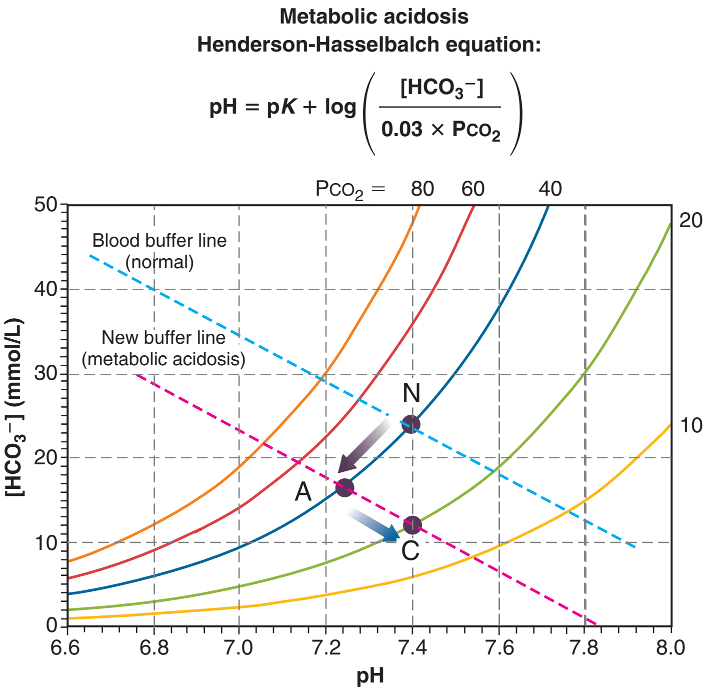

Figure 5-12 The Davenport diagram for metabolic acidosis. An acute increase in [H$^+$] moves blood pH from the normal position (N) to point A—that is, down the line for normal P_{CO_2}. Over seconds to minutes, ventilatory compensation quickly restores pH through hyperventilation, thereby reducing P_{CO_2}, and moving blood to point C.

the bedside because they allow the caregiver to visually assess, diagnose, understand, and quantify the sometimes complex acid-base states encountered in clinical practice.

Figure 5-10 presents a Davenport diagram for *respiratory acidosis.* As the name implies, it is the result of insufficient ventilation to keep P_{CO_2} normal at 40 mm Hg for the given rate of metabolic production of CO_2. It is the necessary consequence of mass conservation as expressed in Equation 4. From the Henderson-Hasselbalch equation, a rise in P_{CO_2} due to insufficient ventilation causes a fall in pH. When changes in ventilation or metabolic rate occur rapidly (minutes), the movement of P_{CO_2} is along the blood buffer line (from N to A in the particular example in Figure 5-10), because the kidneys have not had time to affect pH. This early situation is called *acute* respiratory acidosis. How far up the buffer line the value moves will depend on the degree to which ventilation is insufficient to maintain P_{CO_2}. In the example of Figure 5-10, the point has moved from the P_{CO_2} = 40 mm Hg isopleth to the P_{CO_2} = 80 mm Hg isopleth. Using Equation 4, it becomes evident that doubling P_{CO_2} from 40 to 80 mm Hg must have happened because either ventilation was, for some reason, cut in half while maintaining metabolic rate or metabolic rate doubled while ventilation did not change (or a combination of these two). If the acute respiratory acidosis is not treated but persists, the kidneys will start to retain HCO_3^-, excreting acid until after a day or so, the pH, from Equation 23, is (almost) restored to normal (point C in Figure 5-10). The situation is now termed *compensated* respiratory acidosis. As can be seen from Figure 5-10 and the Henderson-Hasselbalch equation, doubling [HCO_3^-] will return the ratio of [HCO_3^-] to P_{CO_2} to normal, and therefore also restore pH to 7.40. In real life, renal compensation (as this process is called) is rarely complete, and so as long as P_{CO_2} remains elevated (in this example, at 80 mm Hg), the point labeled C will be at a lower pH and lower [HCO_3^-] than depicted but must still lie on the isopleth for P_{CO_2} = 80 mm Hg.

Common clinical causes of respiratory acidosis are central nervous respiratory depression from drugs, brain injury, phrenic nerve damage, neuromuscular diseases, chest wall trauma, and lung diseases causing ventilation-perfusion inequality such as chronic obstructive pulmonary disease (COPD).

Figure 5-11 depicts the mechanism of *respiratory alkalosis*, which is the exact mirror image of respiratory acidosis as just described. It occurs when ventilation is increased in relation to metabolic rate, lowering both P_{CO_2} and lowering $[HCO_3^-]$, and increasing pH. Acute (point A, no renal compensation due to short duration) and fully renally compensated (C) points are indicated along with the normal (N) values. Again, complete compensation usually is not seen, so that point C is a little above and to the right of where it is shown in Figure 5-11 (but still on the same isopleth for CO_2).

A common cause of respiratory alkalosis is hyperventilation, either in intact awake persons, usually due to anxiety, or in ventilated patients, as in the ICU or during anesthesia. Additional causes are high-altitude exposure, leading to hypoxic stimulation of respiration, and lung diseases such as asthma, COPD, and interstitial pulmonary fibrosis, as evidenced by a P_{CO_2} lower than normal.

Figure 5-12 depicts the third type of acid-base disturbance, called *metabolic acidosis*. In contrast with respiratory acidosis (in which the high P_{CO_2} was the primary disturbance, which then led to a lower pH), metabolic acidosis achieves a low pH through generation of protons from some metabolic or external source. Referring to the Henderson-Hasselbalch equation, addition of protons must reduce $[HCO_3^-]$ as they combine with HCO_3^- to produce H_2CO_3. Although the chemoreceptors will react to the low pH rapidly (seconds), thus raising ventilation, it is useful to depict what would happen before that compensatory action takes place. In Figure 5-12, point A represents acute respiratory acidosis without change in ventilation (or, therefore, in P_{CO_2}). The more severe the disturbance, the further down and to the left will be point A, but before ventilatory compensation, it must lie on the normal $P_{CO_2} = 40$ isopleth. Point C shows normalization of pH, achieved by hyperventilation, which lowers P_{CO_2} and allows pH to be restored. This is called respiratory compensation and usually is also incomplete.

In contrast with respiratory acidosis, the data point (A) lies well off (i.e., below) the normal blood buffer line, even before compensation, as Figure 5-12 shows. The vertical drop between the two essentially parallel buffer lines (in this instance, about 11 units) is termed the *base deficit*. It signifies how much base must be added to the blood to fully compensate for the acidosis and restore pH—in this case, 11 mmol of base/L of blood.

Common causes of metabolic acidosis include lactic acidosis (as with exercise or in multiple organ failure) and diabetic ketoacidosis.

Finally, Figure 5-13 depicts the mirror image of metabolic acidosis: *metabolic alkalosis*. The acute response is an increase in pH and $[HCO_3^-]$, from point N to A. Depression of ventilation may ensue, causing P_{CO_2} to rise and pH to normalize. This is a much weaker response than the converse (i.e., hyperventilation in acidosis), but if it occurs, normalization to point C results if compensation is complete.

Common causes of metabolic alkalosis are overdosing on (alkaline) antacid medications, persistent vomiting (of acid gastric fluid) secondary to a duodenal obstruction such as a scar from a previous ulcerative lesion or from cancer, and continuing use of some diuretics.

An important observation with this depiction of acid-base disturbances is that the Davenport diagrams for respiratory acidosis and metabolic alkalosis look similar after compensation—normal pH, high $[HCO_3^-]$, and high P_{CO_2}. In principle, then, it is impossible to tell by which pathway the patient arrived at the compensated state, and therefore which abnormality was primary and which was the secondary, compensating process. The patient profiles usually are very different, however, and in practice, confusion is uncommon. Exactly the same issue arises for respiratory alkalosis and metabolic acidosis, and again, the clinical situations usually are very different.

CONTROVERSIES AND PITFALLS

The subject of pulmonary gas exchange is well established and is grounded in the fundamental and irrefutable principle of mass conservation. Accordingly, few real controversies remain among researchers who study the topic. Where pitfalls arise is in clinical application of the methods used to assess gas exchange.

Some pitfalls are methodologic, especially the well-known difficulty in accurately measuring arterial P_{O_2} in patients breathing 100% O_2. Here, essentially all errors cause the value provided by the laboratory to be erroneously low. To minimize this effect, samples should be completely free of air bubbles, immediately placed on ice, and measured within a few minutes. Although this admonition should be respected for all blood samples, it is especially key when F_{IO_2} is high.

Other pitfalls are conceptual. Clinicians understandably desire to simplify gas exchange tests by assuming values for key variables that are hard to measure. Important here is the respiratory exchange ratio (R), which is necessary in calculation of the alveolar-arterial P_{O_2} difference (P_{O_2}(A–a); see Equation 12). Uncertainty in R can cause substantial errors in P_{O_2}(A–a). Furthermore, with its basis in mass conservation principles, appropriate use of this equation is limited to the steady state. If the patient's gas exchange condition is not in a steady state but rather actively in flux, P_{O_2}(A–a) is likely to be uninterpretable.

Similarly, the shunt equation (Equation 14) requires knowledge of mixed venous (i.e., pulmonary arterial) O_2 concentration, $C\bar{v}_{O_2}$. Without a direct measurement of this entity using a pulmonary arterial catheter, the value of $C\bar{v}_{O_2}$ must be assumed, and especially in critically ill patients, this is problematic, causing potentially large errors in calculated shunt. However, using the Fick principle (see Equation 8), $C\bar{v}_{O_2}$ can be calculated if $\dot{V}_{O_2}$ (oxygen uptake), $\dot{Q}$ (cardiac output), and Ca_{O_2} (arterial oxygen concentration) all are measured, considerably improving the reliability of the calculated shunt value.

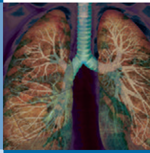
Section 1

NORMAL STRUCTURE AND FUNCTION



Chapter 6

Control of Ventilation and Respiratory Muscles

Theodoros Vassilakopoulos

The respiratory muscles are the only muscles, along with the heart, that must work continuously, although intermittently, to sustain life. They have to repetitively move a rather complex elastic structure, the thorax, to achieve the entry of air into the lungs and thence effect gas exchange. The presence of multiple muscle groups in this system mandates that these muscles interact properly to perform their task despite their differences in anatomic location, geometric orientation, and motor innervation. They also should be able to adapt to a variety of working conditions and respond to many different chemical and neural stimuli.

This chapter describes some aspects of respiratory muscle function that are relevant to current understanding of the way these muscles accomplish the action of breathing and how their function is controlled by the respiratory centers located in the central nervous system.

THE RESPIRATORY CENTERS

Early studies of the neural control of breathing involved the section and ablation of various brain stem structures. From these studies emerged the classical description of the neural control of breathing that required centers in the medulla for the rhythmic generation of ventilatory drive plus additional areas in the pons (traditionally known as the pneumotaxic and apneustic centers) that modulated and regulated the basic rhythm. Nowadays, the very complex and inadequately explored and understood respiratory center structure and function can be summarized as follows (Figure 6-1):

- Primary centers responsible for the generation of respiratory rhythm are located in the medulla. Within the medulla, there are two bilateral aggregations of neurons having respiratory related activity.
    - The *dorsal respiratory group* (DRG) neurons are primarily inspiratory (firing on inspiration) and are located in the nucleus tractus solitarius (NTS). These neurons project contralaterally to the phrenic and intercostal motor neurons in the spinal cord and provide the primary stimulus for respiration. In addition, this region is the recipient of important afferent stimuli, most notably from peripheral and central chemoreceptors and from receptors in the lung. Many connections are present between the dorsal and ventral groups of neurons.
    - The *ventral respiratory group* (VRG) consists of a long column of respiratory neurons, some of which are inspiratory (firing on inspiration) and some of which are expiratory (firng on expiration). It contains the nucleus ambiguus, which contains primarily inspiratory neurons that project to the larynx, pharynx, and tongue. Stimulation of these neurons causes dilation of the upper airways, which minimizes airway resistance during inspiration. The VRG connects polysynaptically, with inspiratory motor neurons in the thorax at T1 to T12 that transmit the drive to external intercostal muscles, and polysynaptically, with expiratory motor neurons in the thorax and abdomen that supply expiratory muscles such as the internal intercostal and abdominal muscles.
- An area of the ventrolateral medulla next to the nucleus ambiguus, the pre-Bötzinger complex, is hypothesized to be a critical site for respiratory rhythmogenesis. Current theory proposes that a group of pacemaker neurons depolarize, fire, and repolarize in a rhythmic fashion. This endogenous oscillatory activity can be modulated by afferent inputs, generating an efferent output that is translated into the respiratory drive. Apart from the pre-Bötzinger complex principally involved in controlling inspiratory motor activity, the retrotrapezoid-parafacial respiratory group (RTN/pFRG) appears to play at least a modulatory role and may be a conditional oscillator that controls active expiration.
- An additional mechanism is voluntary control of the respiratory muscles, signals for which originate in the motor cortex and pass directly to the spinal motor neurons by way of the corticospinal tracts. The medullary respiratory control center is bypassed. The voluntary control competes with automatic control at the level of the spinal motor neuron.

AFFERENT INPUTS TO THE RESPIRATORY CENTERS

The respiratory controller receives information from a variety of sources. Some of these involve the relatively straightforward chemoreceptor signals that provide closed-loop information on the gas exchange functions of the lung. These signals arise mainly from the central and peripheral chemoreceptors that mediate the response to hypoxia, hypercapnia, and acidemia. In addition, at any given time, many other inputs from the upper airways, the lung, the respiratory muscles, and the thoracic cage may be important in determining ventilatory drive (Figure 6-2). The states of cortical arousal, sleep, and emotion play important roles in the level of ventilation and the response to other stimuli.

Figure 6-2 Input to the respiratory centers. The respiratory centers receive afferent information from the central and peripheral chemoreceptors, and from various receptors located in the respiratory system and other parts of the body, and input from higher brain centers.

CENTRAL CHEMORECEPTORS

Central chemoreception involves neurons (and glial cells) at many sites within the hindbrain, including, but not limited to, the retrotrapezoid nucleus (glutaminergic neurons), the medullary raphe (serotoninergic neurons), the locus ceruleus (noradrenergic neurons), the nucleus tractus solitarius, the lateral hypothalamus (orexin neurons), and the caudal ventrolateral medulla. Central chemoreception also has an important nonadditive interaction with afferent information arising at the peripheral chemoreceptors (carotid body). The exact role of each area and its relative importance may vary depending on the condition (e.g., sleep versus wakefulness) and is currently not definitely established. The central chemoreceptors respond to either local increases in CO_2 or decreases in pH. However, because the chemoreceptors are located on the brain side of the blood-brain barrier and H^+ ions do not readily cross this barrier, the central chemoreceptors are much more sensitive to increases in Pa_{CO_2} than to decreases in blood pH. The central chemoreceptors are not sensitive to blood P_{O_2}.

PERIPHERAL CHEMORECEPTORS

The peripheral chemoreceptors include the carotid bodies and the aortic bodies. The carotid bodies are much more important than the aortic bodies in humans. The peripheral chemoreceptors are sensitive to both hypoxia and hypercapnia or acidosis. The site of chemoreception in the carotid body is the type I glomus cells; the type II cells play more of a supporting role, similar to that of glial cells. The hypoxic response causes a sharp increase in firing rate of the carotid sinus nerve when the Pa_{O_2} is lowered below 60 mm Hg. Signal transduction involves the depolarization of the type I cells (by closing a potassium channel that normally is open at resting membrane potential). After the transduction in the type I cells, the signal is transmitted to the carotid sinus nerve endings. Rather than there being a single neurotransmitter, multiple inhibitory and excitatory neurochemicals function both as classical neurotransmitters and also as neuromodulators. Dopamine is abundant in type I cells but seems to be an inhibitory neurotransmitter. Adenosine triphosphate (ATP), by contrast, functions as the primary excitatory neurotransmitter, perhaps coreleased with acetylcholine.

The Hypercapnic Ventilatory Response

CO_2 is the most important factor in the control of ventilation under normal circumstances. The Pa_{CO_2} is held very close to 40 mm Hg, during the course of daily activity with periods of rest and exercise. During sleep, it may vary a little more. Increasing Pa_{CO_2} acts through a negative feedback loop to increase alveolar ventilation.

Both the central and peripheral chemoreceptors respond to hypercapnia. The carotid body provides about 20% to 30% of the total hypercapnic response. This response is fast, with a time constant of 10 to 30 seconds. The central chemoreceptor response accounts for about 70% to 80% of the total hypercapnic response but is slower, with a time constant in the range of 60 to 150 seconds. This slow central response requires 5 to 6 minutes of hypercapnia to reach steady-state ventilation. Steady-state ventilation has an apparently linear relationship to increasing Pa_{CO_2} (normal values for the hypercapnic ventilatory response slope range between 1 and 2 L/minute/mm Hg of P_{CO_2}). Hypoxia augments the hypercapnic response by shifting the CO_2 response curve to the left and increasing its slope. A number of factors can influence the response to CO_2 (e.g., drugs, sleep-wakefulness).

The Hypoxic Ventilatory Response

The hypoxic ventilatory response is due almost solely to the carotid bodies. Very little ventilatory response occurs until the arterial oxygen is lowered below 60 mm Hg, and then there is a sharp increase, just as in the firing rate of the carotid sinus nerve. Hypercapnia greatly augments the hypoxic response. Hypoxia and hypercapnia interact at the level of the carotid body, and their combination is an extremely powerful stimulus to ventilation.

UPPER AND LOWER RESPIRATORY TRACT RECEPTORS

Important receptors in the lung and the upper respiratory tract provide afferent information to the respiratory centers. This information is used in normal ventilation as well as to initiate maneuvers such as sneezing and coughing that need to override the gas exchanging role of the ventilatory system.

Reflexes from all along the respiratory tract provide information to the respiratory centers that will modify or sometimes even block the respiratory drive. Many of the reflexes of the airway are involved in protection, either through trying to clear the airway of foreign material through sneezing or coughing, or in preventing aspiration by closing the larynx during the swallowing of emesis. *Irritant receptors* are found in the nose and upper airways. They are triggered by nonspecific irritants, and their stimulation leads to reflex apnea. Pharyngeal reflexes are important in maintaining a patent airway. During inspiration, the pressure in the airway is negative, and because no intrinsic structures are present to hold the pharyngeal airway open (as with the tracheal cartilages), muscle tone must provide the counterforces to maintain an open airway. Receptors in the pharynx sense this negative pressure and signal the need for increased drive to the upper airway muscles during inspiration. In obstructive sleep apnea, this reflex may not be sufficient to overcome the forces that collapse the airway during inspiration.

Reflexes in the lower airway (tracheobronchial tree) also are involved in both shaping the ventilatory pattern and protecting the airway. *Rapidly adapting pulmonary stretch receptors* are so named because during constant stimulation they initially fire very rapidly but then soon decrease their firing rate. These receptors are located between airway epithelial cells and are found in abundance throughout the carina and at subsequent bronchial bifurcations. These locales are where contaminants in the inspired air (particles) are most likely to impact because of their mass. They are stimulated by irritant gases, histamine, and rapid or extreme lung inflation. They mediate reflex cough, bronchoconstriction, and hyperpnea. The *slowly adapting pulmonary stretch receptors* are located in airway smooth muscle and carry impulses in the vagus nerve by way of large myelinated fibers. They are activated by high lung volume or bronchoconstriction and mediate the Hering-Breuer reflex (early termination of inspiration, which in humans becomes active at an inspired volume of about 1 to 1.5 L). The *J receptors*, whose impulses are carried in small unmyelinated C fibers of the vagus nerve, have been so called because the nerve endings are found near ("juxta") the alveolus in the walls of pulmonary capillaries or interstitium. They respond to mechanical deformation (e.g., pulmonary edema). Activation of these receptors causes rapid, shallow breathing and dyspnea.

RESPIRATORY MUSCLE-THORACIC CAGE RECEPTORS

Receptors in the respiratory muscles themselves also are very important: tendon organs that sense changes in tension, muscle spindles that sense changes in muscle length, and unmyelinated small afferent fibers that sense metabolic-inflammatory products. These somatic receptors provide information on the length-tension relationship of the respiratory muscles and make essential contributions to control the work of breathing and respiratory loads. In addition to somatic receptors located in the intercostal muscles, rib joints, accessory muscles, and tendons, the output of receptors in other parts of the body, including skeletal muscles, can influence the respiratory pattern. At the onset of exercise, an increase in ventilation occurs that precedes the increase in $P\text{CO}_2$ that would be required for chemoreceptor signals. It is believed that the observed increase in ventilation is mediated by other mechanisms. For example, passively moving the limbs causes an increase in ventilation. The aforementioned somatic receptors presumably account for these observations. The control of ventilation during exercise and with changes in metabolic rate also involves afferent information from temperature and nociceptive receptors.

THE EFFERENT LIMB: THE RESPIRATORY MUSCLES

FUNCTIONAL ANATOMY

The Intercostal Muscles

The intercostal muscles are two thin layers of muscle fibers occupying each of the intercostal spaces. They are termed external and internal because of their surface relations, the external being superficial to the internal. The muscle fibers of the two layers run at approximately right angles to each other. The *external intercostals* extend from the tubercles of the ribs dorsally to the costochondral junctions ventrally, and their fibers are oriented obliquely, downward, and forward, from the rib above to the rib below. The *internal intercostals* begin posteriorly as the posterior intercostal membrane on the inner aspect of the external intercostal muscles. From approximately the angle of the rib, the internal intercostal muscles run obliquely, upward, and forward from the superior border of the rib and costal cartilage below to the floor of the subcostal groove of the rib and the edge of the costal cartilage above, ending at the sternocostal junctions. All of the intercostal muscles are innervated by the intercostal nerves.

The external intercostal muscles have an inspiratory action on the rib cage, whereas the internal intercostal muscles are expiratory. An illustrative clinical example of the “isolated” inspiratory action of the intercostal muscles is offered by *bilateral diaphragmatic paralysis.* In patients with this deficit, inspiration is accomplished solely by the rib cage muscles. As a result, the rib cage expands during inspiration, and the pleural pressure falls. Because the diaphragm is flaccid and no transdiaphragmatic pressure can be developed, the fall in pleural pressure is transmitted to the abdomen, causing an equal fall in the abdominal pressure. Hence, the abdomen moves paradoxically inward during inspiration, opposing the inflation of the lung (Figure 6-3). This paradoxical motion is the cardinal sign of diaphragmatic paralysis on clinical examination and is invariably present in the supine posture, during which the abdominal muscles usually remain relaxed during the entire respiratory cycle. However, this sign may be absent in the erect posture.

The Diaphragm

The floor of the thoracic cavity is closed by a thin musculotendinous sheet, the diaphragm—the most important inspiratory muscle, accounting for approximately 70% of minute ventilation in normal subjects. The diaphragm is anatomically unique among the skeletal muscles in that its fibers radiate from a central tendinous structure (the central tendon) to insert peripherally into skeletal structures. The muscle of the diaphragm has two main components as defined at its point of origin: the crural (vertebral) part and the costal (sternocostal) part. The *crural* part arises from the crura (strong, tapering tendons attached vertically to the anterolateral aspects of the bodies and intervertebral disks of the first three lumbar vertebrae on the right and two on the left) and the three aponeurotic arcuate ligaments. The *costal* part of the diaphragm arises from the xiphoid process and the lower end of the sternum and the costal cartilages of the lower six ribs. These costal fibers run cranially so that they are directly apposed to the inner aspect of lower rib cage, creating a *zone of apposition.*

The shape of the relaxed diaphragm at the end of a normal expiration (at functional residual capacity [FRC]) is that of two domes joined by a “saddle” that runs from the sternum to the

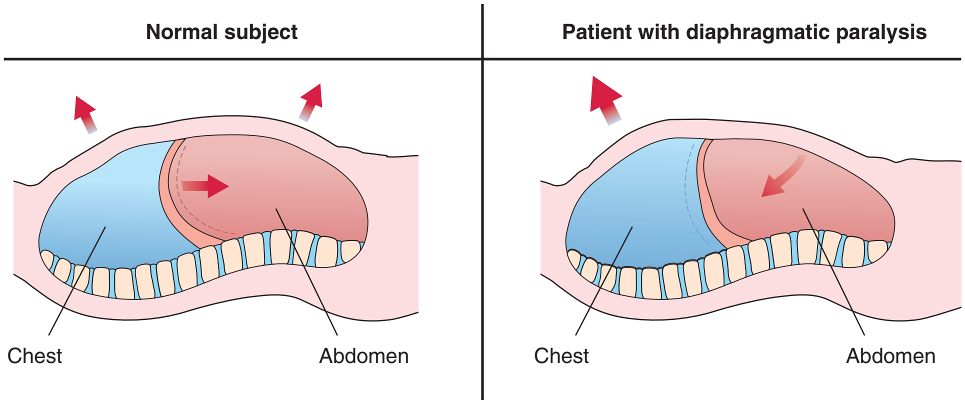

Figure 6-3 Schematic demonstration of normal abdominal and rib cage movement (*left panel*) and the paradoxical abdominal motion of isolated diaphragmatic paralysis (*right panel*). The diaphragm at resting end expiration is shown as a *solid line* and after inspiration as a *dashed line.* In the normal subject, the diaphragm moves caudally, and in the patient with diaphragmatic paralysis, the diaphragm moves in a cephalic direction. The anterior abdominal wall moves inward instead of outward.

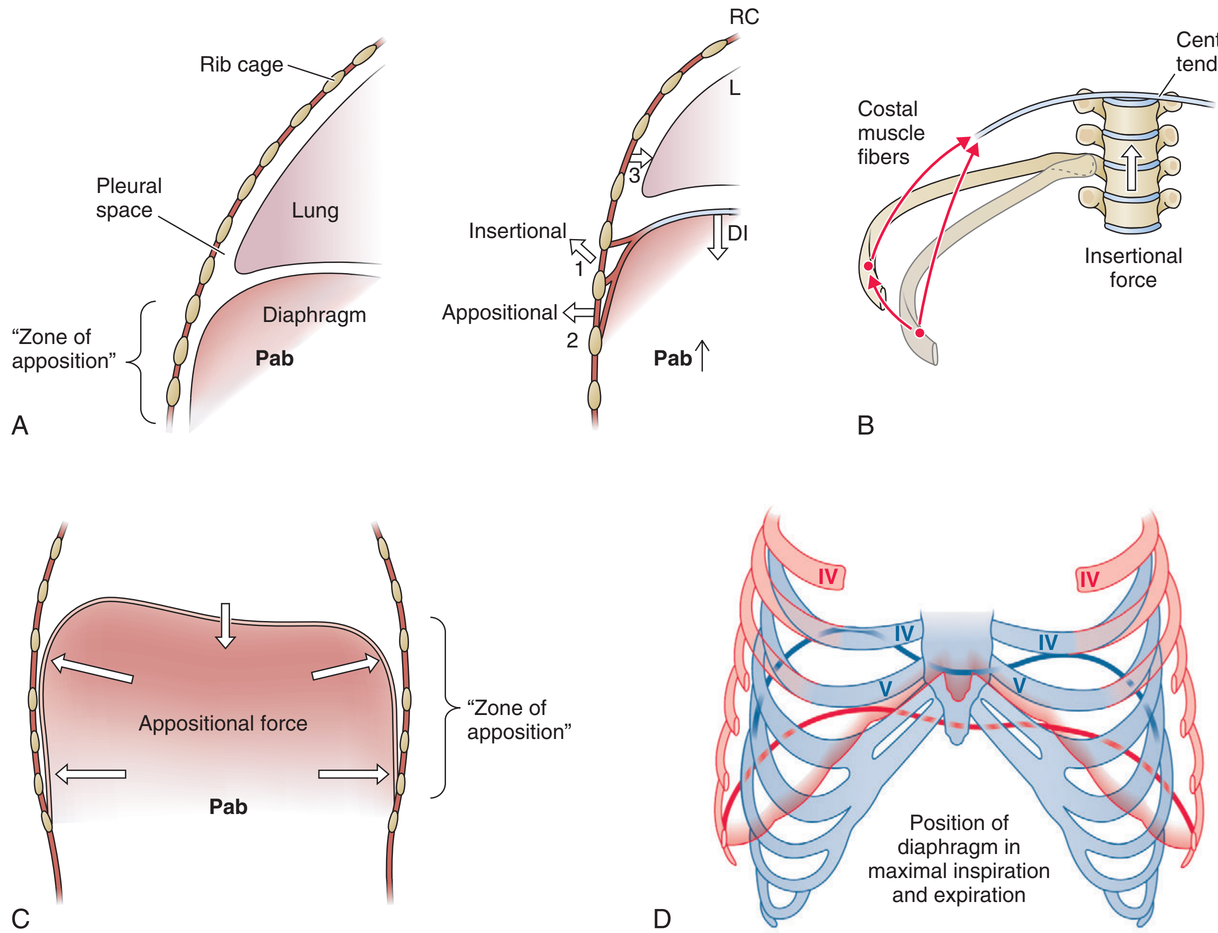

Figure 6-4 Actions of the diaphragm. **A,** Zone of apposition and summary of diaphragmatic actions. When the diaphragm contracts, a caudally oriented force is being applied on the central tendon, and the dome of the diaphragm descends (DI). Furthermore, the costal diaphragmatic fibers apply a cranially oriented force to the upper margins of the lower six ribs that has the effect of lifting and rotating them outward (insertional force, *arrow 1*). The zone of apposition makes the lower rib cage part of the abdomen, and the changes in pressure in the pleural recess between the apposed diaphragm and the rib cage are almost equal to the changes in abdominal pressure *(Pab)*. Pressure in this pleural recess rises rather than falls during inspiration because of diaphragmatic descent, and the rise in abdominal pressure is transmitted through the apposed diaphragm to expand the lower rib cage (*arrow 2*). All of these effects result in expansion of the lower rib cage. Within the upper rib cage, isolated contraction of the diaphragm causes a decrease in the anteroposterior diameter, and this expiratory action is caused primarily by the fall in pleural pressure (*arrow 3*). **B,** Insertional force; **C,** appositional force; **D,** shape of the diaphragm and the bony thorax at maximum inspiration and expiration.

anterior surface of the spinal column (**Figure 6-4**). The motor innervation of the diaphragm is from the phrenic nerves, which also provide a proprioceptive supply to the muscle. When tension develops within the diaphragmatic muscle fibers, a caudally oriented force is applied on the central tendon, and the dome of the diaphragm descends; this descent has two effects. First, it expands the thoracic cavity along its craniocaudal axis, and consequently the pleural pressure falls. Second, it produces a caudal displacement of the abdominal visceral contents and an increase in the abdominal pressure, which in turn results in an outward motion of the ventral abdominal wall and the lower rib cage (appositional force). Thus, when the diaphragm contracts, a cranially oriented force is being applied by the costal diaphragmatic fibers to the upper margins of the lower six ribs that has the effect of lifting and rotating them outward (insertional force) (see Figure 6-4). The actions mediated by the changes in pleural and abdominal pressures are more complex. Viewed as the only muscle acting on the rib cage, the diaphragm has two opposing effects when it contracts: On the upper rib cage, it causes a decrease in the anteroposterior diameter, and this expiratory action results primarily from the fall in pleural pressure (see Figure 6-4). On the lower rib cage, it causes an expansion. In fact, this is the pattern of chest wall motion observed in *tetraplegic patients* with transection injury at the fifth cervical segment of the spinal cord or below, who have complete paralysis of the inspiratory muscles except for the diaphragm. This inspiratory action on the lower rib cage is caused by the concomitant action of two different forces, the "insertional" force already described and the "appositional" force.

The Sternocleidomastoids

The sternocleidomastoids arise from the mastoid process and descend to the ventral surface of the manubrium sterni and the medial third of the clavicle. Their neural supply is from the accessory nerve. The action of the sternocleidomastoids is to displace the sternum cranially during inspiration, to expand the upper rib cage more in its anteroposterior diameter than in its transverse one, and to decrease the transverse diameter of the lower rib cage. In normal subjects breathing at rest, however, the sternocleidomastoids are inactive, being recruited only when the inspiratory muscle pump is abnormally loaded or when ventilation increases substantially. Therefore, they should be considered to be accessory muscles of inspiration.

The Scalenes

The scalenes are composed of three muscle bundles that run from the transverse processes of the lower five cervical vertebrae to the upper surface of the first two ribs. They receive their neural supply mainly from the lower five cervical segments. Their action is to increase (slightly) the anteroposterior diameter of the upper rib cage. Although initially regarded as accessory muscles of inspiration, they are invariably active during inspiration. In fact, seated normal subjects cannot breathe without contracting the scalenes even when they reduce the required inspiratory effort by reducing tidal volume. Therefore, scalenes in humans are primary muscles of inspiration, and their contraction is an important determinant of the expansion of the upper rib cage during breathing.

The Abdominal Muscles

The abdominal muscles with respiratory activity are those constituting the ventrolateral wall of the abdomen (i.e., the rectus abdominis ventrally and the external oblique, internal oblique, and transversus abdominis laterally). They are innervated by the lower six thoracic nerves and the first lumbar nerve. As they contract, they pull the abdominal wall inward, thus increasing the intraabdominal pressure. This in turn causes the diaphragm to move cranially into the thoracic cavity, increasing the pleural pressure and decreasing lung volume. Thus, their action is expiratory. Expiration usually is a passive process but can become active when minute ventilation has to be increased (e.g., during exercise) or during respiratory distress. Expiratory muscle action also is essential during cough.

PHYSIOLOGY: THE ABILITY TO BREATHE: THE LOAD-CAPACITY BALANCE

For a person to take a spontaneous breath, the inspiratory muscles must generate sufficient force to overcome the elastance of the lungs and chest wall (lung and chest wall elastic loads), as well as the airway and tissue resistance (resistive load). This effort requires an adequate output of the centers controlling the muscles, anatomic and functional nerve integrity, unimpaired neuromuscular transmission, an intact chest wall, and adequate muscle strength. The mechanisms involved can be schematically represented by considering the ability to take a breath as a balance between inspiratory load and neuromuscular competence (**Figure 6-5**). Under normal conditions, this system is polarized in favor of neuromuscular competence (i.e., there are reserves that permit considerable increases in load). For spontaneous breathing, however, the inspiratory muscles should be able to sustain the aforementioned load over time as well as adjusting the minute ventilation to afford adequate gas exchange. The ability of the respiratory muscles to sustain this load without the onset of fatigue is called endurance and is determined by the balance between energy supply and energy demand (**Figure 6-6**).

Energy supply depends on the inspiratory muscle blood flow, the blood substrate (fuel) concentration and arterial oxygen content, the muscle's ability to extract and use energy sources, and the muscle's energy stores. Under normal circumstances, energy supply is adequate to meet the demand, and a large recruitable reserve exists (see Figure 6-6). Energy demand increases proportionally with the mean pressure developed by the inspiratory muscles per breath (P_I), expressed as a fraction of maximum pressure that the respiratory muscles can voluntarily develop ($P_I/P_{I_{max}}$), the minute ventilation ($\dot{V}_E$), the inspiratory duty cycle (T_I/T_{TOT}), and the mean inspiratory flow rate

Figure 6-5 Balance between inspiratory load and neuromuscular competence. The ability to take a spontaneous breath is determined by the balance between the load imposed on the respiratory system (pressure developed by the inspiratory muscles, P_I) and the neuromuscular competence of the ventilatory pump (maximum inspiratory pressure; $P_{I_{max}}$). Normally, this balance weighs in favor of competence, permitting significant increases in load. However, if the competence is, for whatever reason, reduced below a critical point (e.g., drug overdose, myasthenia gravis), the balance may then weigh in favor of load, rendering the ventilatory pump insufficient to inflate the lungs and chest wall. *(Modified from Vassilakopoulos T, Roussos C: Neuromuscular respiratory failure. Figure 6-6 Factors determining the balance between energy supply and energy demand in maintaining neurorespiratory capacity. Respiratory muscle endurance is determined by the adequacy of energy for ventilatory needs. Normally, the supply is adequate to meet the demand, and a large reserve exists. Whenever this balance weighs in favor of demand, the respiratory muscles ultimately become fatigued, leading to inability to sustain spontaneous breathing. $P_I/P_{I_{max}}$, inspiratory pressure–maximum inspiratory pressure ratio; T_I/T_{TOT}, duty cycle (ratio of fraction of inspiration to total breathing cycle duration); $\dot{V}_E$, minute ventilation; V_T/T_I, mean inspiratory flow (tidal volume–inspiratory time ratio). *(Modified from Vassilakopoulos T, Roussos C: Neuromuscular respiratory failure. (VT/TI) and is inversely related to the efficiency of the muscles. Fatigue develops when the mean rate of energy demands exceeds the mean rate of energy supply (i.e., when the balance is polarized in favor of demands).

The product of TI/T_{TOT} and the mean transdiaphragmatic pressure expressed as a fraction of maximal transdiaphragmatic pressure (Pdi/Pdi_{max}) defines a useful "tension-time index" (TTIdi) that is related to the endurance time (i.e., the time that the diaphragm can sustain the load imposed on it). Whenever TTIdi is smaller than the critical value of 0.15, the load can be sustained indefinitely, but when TTIdi exceeds the critical zone of 0.15 to 0.18, the load can be sustained for only a limited period—in other words, the endurance time. This variable was found to be inversely related to TTIdi. The TTI concept is assumed to be applicable not only to the diaphragm but also to the respiratory muscles as a whole:

$$\mathrm{TTI} = \mathrm{PI}/\mathrm{PI}_{max} \times \mathrm{TI}/\mathrm{T}_{TOT}$$

Because endurance is determined by the balance between energy supply and demand, TTI of the inspiratory muscles has to be in accordance with the energy balance view. In fact, as Figure 6-6 demonstrates, PI/PI_{max} and TI/T_{TOT}, which constitute the TTI, are among the determinants of energy demand; an increase in either that will increase the TTI value also will increase the demand. But what determines the ratio PI/PI_{max}? The numerator, the mean inspiratory pressure developed per breath, is determined by the elastic and resistive loads imposed on the inspiratory muscles. The denominator, the maximum inspiratory pressure, is determined by the neuromuscular competence (i.e., the maximum inspiratory muscle activation that can be voluntarily achieved). It follows, then, that the value of PI/PI_{max} is determined by the balance between load and competence (see Figure 6-5). But PI/PI_{max} also is one of the determinants of energy demand (see Figure 6-6); therefore, the two balances (i.e., between load and competence and between energy supply and demand) are in essence linked, creating a single system (**Figure 6-7**). Schematically, when the central hinge of the system moves upward or is at least at the horizontal level, spontaneous ventilation can be sustained indefinitely (see Figure 6-7). The ability of a subject to breathe spontaneously depends on the fine interplay of many different factors. Normally, this interplay moves the central hinge far upward and creates a great ventilatory reserve for the healthy person. When the central hinge of the system, for whatever reason, moves downward, spontaneous ventilation cannot be sustained, and ventilatory failure ensues.

HYPERINFLATION

Hyperinflation (frequently observed in obstructive airway diseases) compromises the force-generating capacity of the diaphragm for a variety of reasons: First, the respiratory muscles, like other skeletal muscles, obey the length-tension relationship. At any given level of activation, changes in muscle fiber length alter tension development. This is because the force-tension developed by a muscle depends on the interaction between actin and myosin fibrils (i.e., the number of myosin heads attaching and thus pulling the actin fibrils closer within each sarcomere). The optimal fiber length (Lo) for which tension is maximal is the length at which all myosin heads attach and pull the actin fibrils. Below this length (as with hyperinflation, which shortens the diaphragm), actin-myosin interaction becomes suboptimal, and tension development declines. Second, as lung volume increases, the zone of apposition of the diaphragm decreases in size, and a larger fraction of the rib cage becomes exposed to pleural pressure. Hence, the diaphragm's inspiratory action on the rib cage diminishes. When lung volume approaches total lung capacity, the zone of apposition all but disappears (**Figure 6-8**), and the diaphragmatic muscle fibers become oriented horizontally internally (see Figure 6-8). The insertional force of the diaphragm is then expiratory, rather than inspiratory, in direction. This observation explains the inspiratory decrease in the transverse diameter of the lower rib cage in subjects with emphysema and severe hyperinflation (Hoover's sign). Third, the resultant flattening of the diaphragm increases its radius of curvature (Rdi) and, according to Laplace's law, Pdi = 2Tdi/Rdi, diminishes its pressure-generating capacity (Pdi) for the same tension development (Tdi).

Figure 6-7 Factors determining the two aspects of balance in the system maintaining neurorespiratory capacity: (1) load and competence and (2) energy supply and demand. The relationship between these system components is depicted schematically. The PI/PI_{max}, one of the determinants of energy demand (see Figure 6-6), is replaced by its equivalent: the balance between load and neuromuscular competence (see Figure 6-5). In fact, this correlation is the reason the two balances are linked. When the central hinge of the system moves upward or is at least at the horizontal level, a balance exists between ventilatory needs and neurorespiratory capacity, and spontaneous ventilation can be sustained. In healthy persons, the hinge moves far upward, creating a large reserve. For abbreviations, see legends to Figures 6-5 and 6-6. *(Modified from Vassilakopoulos T, Roussos C: Neuromuscular respiratory failure. RESPIRATORY MUSCLE RESPONSES TO CHANGES IN LOAD

ACUTE RESPONSES TO INCREASED LOAD

Respiratory Muscle Fatigue

Fatigue is defined as the loss of capacity to develop force and/or velocity in response to a load that is reversible by rest. Fatigue should be distinguished from weakness, in which reduced force generation is fixed and not reversed by rest, although the presence of weakness may itself predispose a muscle to fatigue. The site and mechanisms of fatigue remain controversial. Theoretically, the site of fatigue may be located at any link in the long chain of events involved in voluntary muscle contraction leading from the brain to the contractile machinery. A widely used convention is to classify fatigue as central fatigue, peripheral high-frequency fatigue, or peripheral low-frequency fatigue.

Central fatigue is present when a maximal voluntary contraction generates less force than does maximal electrical stimulation. If maximal electrical stimulation superimposed on a maximal voluntary contraction can potentiate the force generated by a muscle, a component of central fatigue exists. This procedure applied to the diaphragm consists of the *twitch occlusion test*, which may separate central from peripheral fatigue. This test examines the transdiaphragmatic pressure (Pdi) response to bilateral phrenic nerve stimulation superimposed on graded voluntary contractions of the diaphragm. Normally, the amplitude of the Pdi twitches in response to phrenic nerve stimulation decreases as the voluntary Pdi increases. During $\mathrm{Pdi_{max}}$, no superimposed twitches can be detected. When central diaphragmatic fatigue is present, superimposed twitches can be demonstrated. A number of experiments have suggested that a form of central diaphragmatic "fatigue" may develop during respiratory loading such that, at the limits of diaphragmatic endurance, a significant portion of the reduction in force production is due to failure of the central nervous system to completely activate the diaphragm. Central fatigue may be caused by a reduction in the number of motor units that can be recruited by the motor drive or by a decrease in motor unit discharge rates, or both. The observed decreased central firing rate during fatigue may in fact be a beneficial adaptive response preventing the muscle's self-destruction by excessive activation.

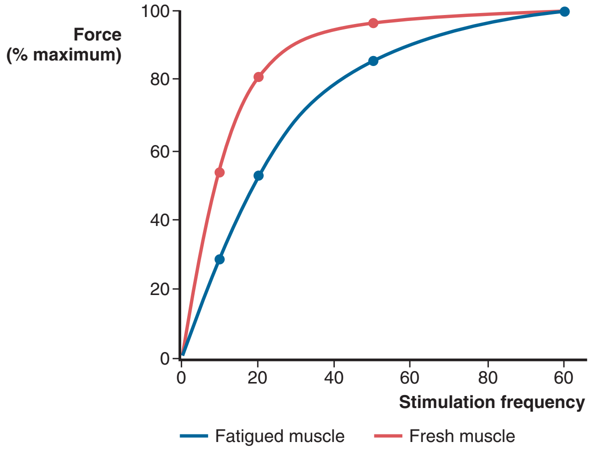

Figure 6-9 Force-frequency relationship of in vivo human respiratory muscles. The force-frequency curve for fresh muscle is shown in *red*, and that for muscle after a fatiguing task is shown in *blue*; a disproportionate force loss at low stimulation frequencies is evident. *(Modified from Moxham J, Wiles CM, Newham D, Edwards RH: Contractile function and fatigue of the respiratory muscles in man*, Ciba Found Symp *82:197–212, 1981.)*

Peripheral fatigue refers to failure at the neuromuscular junction or distal to this structure and is present when muscle force output falls in response to direct electrical stimulation. This type of fatigue may occur as a consequence of failure of impulse propagation across the neuromuscular junction, the sarcolemma or the T tubules (transmission fatigue), impaired excitation-contraction coupling, or failure of the contractile apparatus of the muscle fibers. Peripheral fatigue can be further classified into high- and low-frequency types on the basis of the shape of the muscle force-frequency curve (**Figure 6-9**). High-frequency fatigue results in depression of the forces generated by a muscle in response to high-frequency electrical stimulation (50 to 100 Hz), whereas low-frequency fatigue results in depression of force generation in response to low-frequency stimuli (1 to 20 Hz). *High-frequency fatigue* (see Figure 6-9) is attributed to transmission fatigue. Teleologically, transmission block could be beneficial in some instances by protecting the muscle against excessive depletion of its ATP stores. Normal subjects breathing against high-intensity inspiratory resistive loads develop high-frequency fatigue, which resolves very quickly after cessation of the strenuous diaphragmatic contractions.

When the loss of force is not accompanied by a parallel decline in the electrical activity, impaired excitation-contraction coupling is thought to be responsible. This type of fatigue is characterized by a selective loss of force at low frequencies of stimulation (see Figure 6-9) despite maintenance of the force generated at high frequencies of stimulation, indicating that the contractile proteins continue to generate force so long as sufficient calcium is released by the sarcoplasmic reticulum. This *low-frequency fatigue* is characteristically long-lasting, with recovery occurring over several hours. Low-frequency fatigue occurs during high-force contractions and is less likely to develop when the forces generated are smaller, even if these are maintained for longer time periods, thereby achieving the same total work. As previously stated, fatigue develops when the mean rate of energy demands exceeds the mean rate of energy supply to the muscle (see Figure 6-6), resulting in depletion of muscle energy stores, acidosis from lactate accumulation, and excessive production of oxygen-derived free radicals. The exact interplay of all of these factors is not yet identified. Low-frequency fatigue occurs in the diaphragm of experimental animals during cardiogenic or septic shock, and in the diaphragm and sternocleidomastoid of normal subjects after breathing against very high inspiratory resistance or after sustaining maximum voluntary ventilation (for 2 minutes) (**Figure 6-10**). The clinical relevance of respiratory muscle fatigue is difficult to ascertain, because performing the measurements that are required for fatigue detection is problematic in situations in which fatigue is likely to be present (such as during acute hypercapnic respiratory failure).

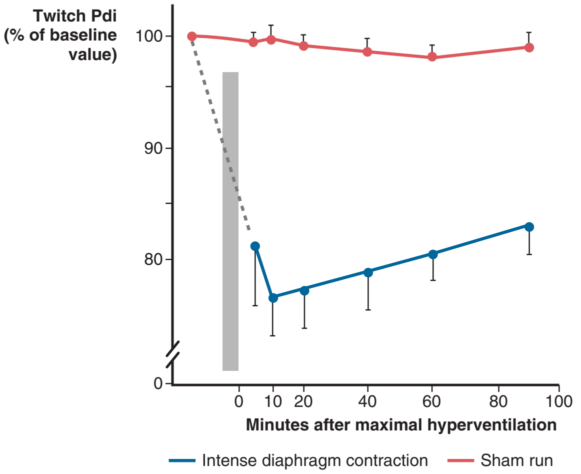

Figure 6-10 Low-frequency fatigue of the diaphragm in normal subjects. The mean twitch tension (i.e., twitch transdiaphragmatic pressure [Pdi]) is shown before and at intervals up to 90 minutes after intense diaphragmatic contraction (in this case, a 2-minute period of maximal normocapnic hyperventilation) in nine healthy adults (*blue symbols*). Data after a sham ("normal breathing") run in the same subjects are shown in *red.* A significant decline in twitch Pdi is observed that has only partially recovered at 90 minutes, which confirms the presence of low-frequency diaphragmatic fatigue. *(Data from Hamnegård CH, Wragg SD, Kyroussis D, et al: Diaphragm fatigue following maximal ventilation in man,* Eur Respir J *9:241–247, 1996.)*

INFLAMMATION AND INJURY

Strenuous diaphragmatic contractions (induced by resistive breathing, which accompanies many disease states such as chronic obstructive pulmonary disease [COPD] and asthma) initiate an inflammatory response consisting of elevation of plasma cytokines and recruitment and activation of white blood cell subpopulations. These cytokines are produced within the diaphragm secondary to the increased muscle activation. Strenuous resistive breathing results in diaphragmatic ultrastructural injury (such as sarcomere disruption, necrotic fibers, flocculent degeneration, and influx of inflammatory cells) in both animals and humans. The mechanisms involved are not definitively established but may involve intradiaphragmatic cytokine induction, adhesion molecule upregulation, calpain activation, and reactive oxygen species formation. Cytokines also are essential in orchestrating muscle recovery after injury by enhancing proteolytic removal of damaged proteins and cells (through recruitment and activation of phagocytes) and by activating satellite cells. Satellite cells are quiescent cells of embryonic origin that reside in the muscle and are transformed into myocytes when the muscle becomes injured, to replace damaged myocytes.

CHRONIC RESPONSES TO INCREASED LOAD

Plasticity and Adaptation

The respiratory muscles are plastic organs that respond with structural and functional changes or adaptations to chronic changes in the load they are facing and thus in their activity.

COPD is the paradigm of a disease characterized by chronically increased respiratory muscle load. A major adaptation of the respiratory muscles is fiber type transformation. The myosin heavy chain component of the myosin molecule constitutes the basis for the classification of muscle fibers as either type I or type II (**Figure 6-11**). Myosin heavy chain exists in various isoforms, which in increasing order of maximum shortening velocity are myosin heavy chain (MHC) I, IIa, and IIb, the last type being the fastest (see Figure 6-11). The diaphragm in healthy humans is composed of approximately 50% type I fatigue-resistant fibers, 25% type IIa, and 25% type IIb. Muscles can modify their overall MHC phenotype in two ways: (1) preferential atrophy or hypertrophy of fibers containing a specific MHC isoform and (2) actual transformation from one fiber type to another. In COPD, a transformation of type II to type I fibers occurs, resulting in a great predominance of type I fatigue-resistant fibers. This altered makeup increases the resistance of the diaphragm to fatigue development but at the same time compromises the force-generating capacity, because type I fibers can generate less force than type II fibers can.

Adaptation is not restricted to only fiber type transformation. In an animal model of COPD (in emphysematous hamsters), the number and the length of sarcomeres decrease, resulting in a leftward shift of the length-tension curve, so that the muscle adapts to the shorter operating length induced by hyperinflation. These alterations may help restore the mechanical advantage of the diaphragm in chronically hyperinflated states. In humans, this adaptation seems to occur by sarcomere length shortening.

Respiratory Muscle Response to Inactivity: Unloading

Respiratory muscles adapt not only when they function against increased load but also when they become inactive, as happens

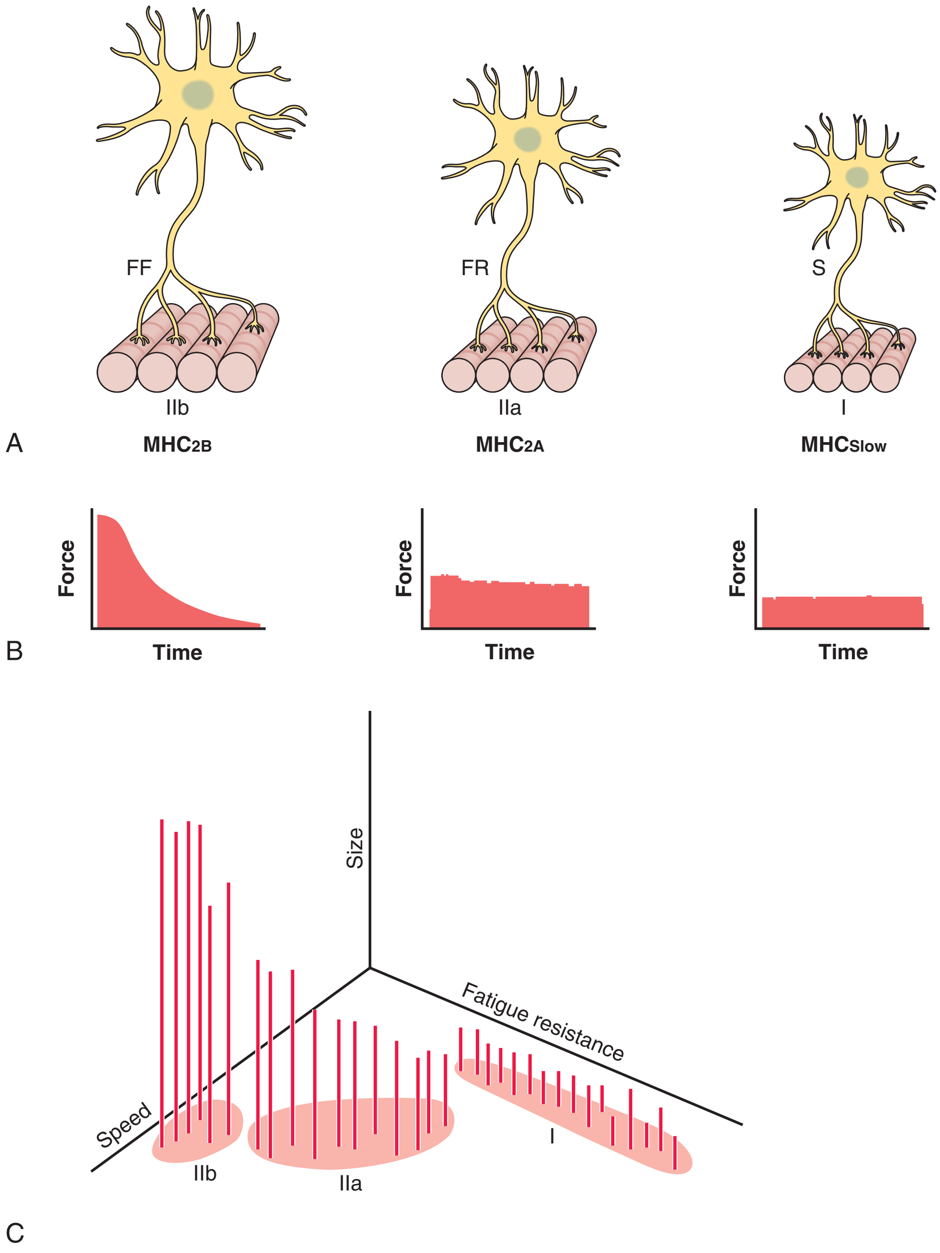

Figure 6-11 Properties of skeletal muscle fiber types. Different fiber types in the diaphragm muscle are distinguished by size, myosin heavy chain content, contractile characteristics (force and speed of contraction), and fatigue resistance (type S, slow; type FR, fast-twitch, fatigue-resistant; and type FF motor units, fast-twitch, fatigable—types I, IIa, and IIb, respectively), as well as myosin heavy chain (MHC) isoform expression (MHCSlow, MHC2A, and MHC2B). **A,** Size; **B,** force; **C,** size-speed of contraction-fatigue resistance. *(Modified from Mantilla CB, Sieck GS: Mechanisms underlying motor unit plasticity in the respiratory system,* J Appl Physiol *94:1230-1241, 2003; and Jones DA: Skeletal muscle physiology. In Roussos C, editor:* The thorax, *ed 2, New York, 1995, Marcel Dekker, pp 3-32.)*

during denervation or when a mechanical ventilator takes over their role as force generator to create the driving pressure permitting airflow into the lungs. Inactivity and unloading of the diaphragm associated with mechanical ventilation are harmful, resulting in decreased diaphragmatic force-generating capacity, diaphragmatic atrophy, and diaphragmatic injury. This combination of effects has been designated *ventilator-induced diaphragmatic dysfunction* (VIDD). The mechanisms are not fully explained, but muscle atrophy, oxidative stress, structural injury, and muscle fiber remodeling contribute to a variable extent in the development of VIDD.

TESTING RESPIRATORY MUSCLE FUNCTION

Muscles have two functions: to develop force and to shorten. In the respiratory system, *force* usually is estimated as pressure and *shortening* as lung volume change.

VITAL CAPACITY

Vital capacity (VC) is easily measured with spirometry; decreases in VC point to respiratory muscle weakness. The VC averages approximately 50 mL/kg in normal adults. VC changes are not specific, however, and decreases may result from both inspiratory and expiratory muscle weakness and may be associated with restrictive lung and chest wall diseases. A marked fall (of greater than 30%) in VC in the supine compared with that in the erect posture (which in the normal person is 5% to 10%) is associated with severe bilateral diaphragmatic weakness.

MAXIMAL STATIC MOUTH PRESSURES

Measurement of the maximum static inspiratory (PI_{max}) or expiratory (PE_{max}) pressure that a subject can generate at the mouth is a simple way to estimate inspiratory and expiratory

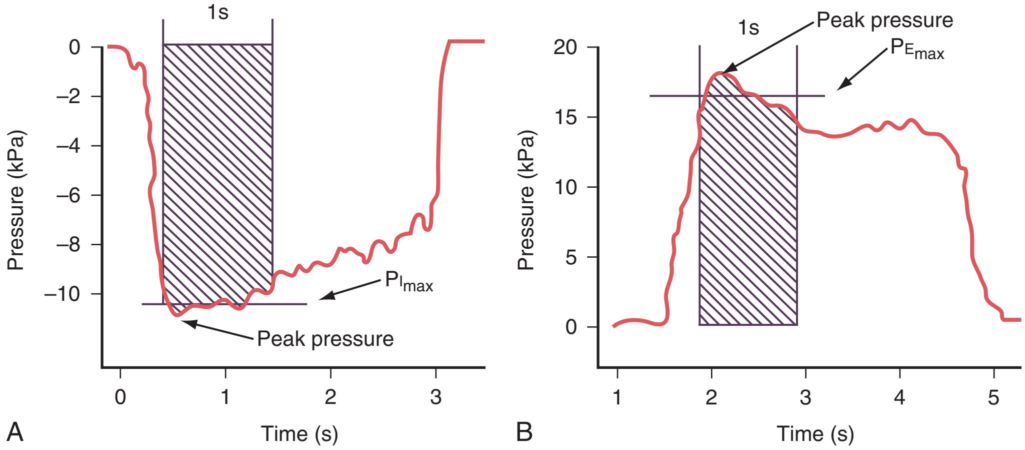

Figure 6-12 Maximum inspiratory-expiratory pressures. **A,** Pressure tracing from a subject performing a maximal inspiratory maneuver (PI_{max}). A peak pressure is seen, and the 1-second average is determined by calculating the *shaded area.* **B,** Typical pressure tracing from a subject performing a maximal expiratory maneuver (PE_{max}). *(Modified from American Thoracic Society/European Respiratory Society: ATS/ERS statement on respiratory muscle testing,* Am J Respir Crit Care Med *166:518–624, 2002.)*

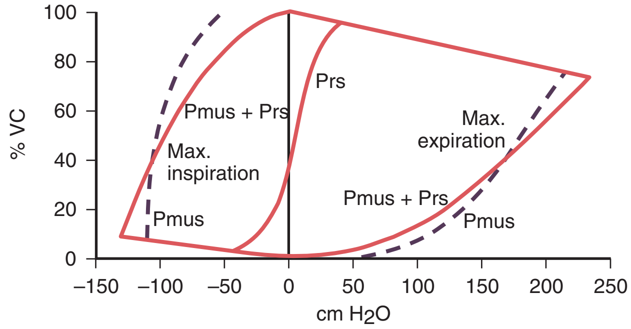

Figure 6-13 Relationship of muscle and respiratory pressures at different lung volumes. *Vertical axis* represents lung volume as a percentage of vital capacity (% VC). *Horizontal axis* represents alveolar pressure in cm H_2O. The *broken lines* indicate the pressure contributed by the muscles. *Pmus*, pressure developed by the respiratory muscles; *Prs*, pressure of the respiratory system. *(Modified from Agostoni E, Mead J: Statics of the respiratory system. muscle strength. These pressures are measured at the side port of a mouthpiece that is occluded at the distal end. A small leak is incorporated to prevent glottic closure and buccal muscle use during inspiratory or expiratory maneuvers. The pressure must be maintained for at least 1.5 seconds, so that the maximum pressure sustained for 1 second can be recorded (Figure 6-12). The pressure measured during these maneuvers (Pmo) reflects the pressure developed by the respiratory muscles (Pmus), plus the passive elastic recoil pressure of the respiratory system including the lung and chest wall (Prs) (Figure 6-13). At FRC, Prs is 0, so Pmo represents Pmus. However, at residual volume (RV), where PI_{max} usually is measured, Prs may be as much as 30 cm H_2O and thus makes a significant contribution to PI_{max} of up to 30% (or more if Pmus is decreased). Similarly, PE_{max} is measured at total lung capacity (TLC), where Prs can be up to 40 cm H_2O. Clinical measures and normal values of PI_{max} and PE_{max} do not conventionally subtract the elastic recoil of the respiratory system. Normal values are available for adults, children, and elderly persons. The tests are easy to perform and well tolerated, yet they are associated with significant between- and within-subject variability, as well as learning effect. Nevertheless, a PI_{max} of −80 cm H_2O usually excludes clinically important inspiratory muscle weakness.

TRANSDIAPHRAGMATIC PRESSURE

When inspiratory muscle weakness is confirmed, the next diagnostic step is to unravel whether the underlying problem is diaphragmatic weakness, because the diaphragm is the most important inspiratory muscle. This determination is accomplished by the measurement of maximum transdiaphragmatic pressure (Pdi_{max}). Pdi_{max} is the difference between gastric pressure (reflecting abdominal pressure) and esophageal pressure (reflecting intrapleural pressure) on a maximal inspiratory effort after the insertion of appropriate balloon catheters in the stomach and the esophagus, respectively.

SNIFF PRESSURES

A *sniff* is a short, sharp voluntary inspiratory maneuver performed through one or both unoccluded nostrils. It achieves rapid, fully coordinated recruitment of the diaphragm and other inspiratory muscles. The nose acts as a Starling resistor, so nasal flow is low and largely independent of the driving pressure that is the esophageal pressure. Pdi measured during a sniff (sniff Pdi) reflects diaphragm strength, and Pes reflects the integrated pressure of the inspiratory muscles on the lungs (sniff Pes) (Figure 6-14). Pressures measured in the mouth, nasopharynx, or one nostril give a clinically useful approximation of esophageal pressure during sniffs without the need to insert esophageal balloons, especially in the absence of significant obstructive airway disease.

The nasal sniff pressure is the easiest measurement for the subject. Pressure is measured by wedging a catheter in one nostril by use of foam, rubber bungs, or dental impression molding (Figure 6-15). The subject sniffs through the contralateral unobstructed nostril. A wide range of normal values has been documented, reflecting the variability in normal muscle strength from person to person. In clinical practice, Pdi,sn_{max} values greater than 100 cm H_2O in males and 80 cm H_2O in females are unlikely to be associated with clinically significant diaphragm weakness. Values of maximal sniff esophageal or nasal pressure greater than 70 cm H_2O (in males) or 60 cm

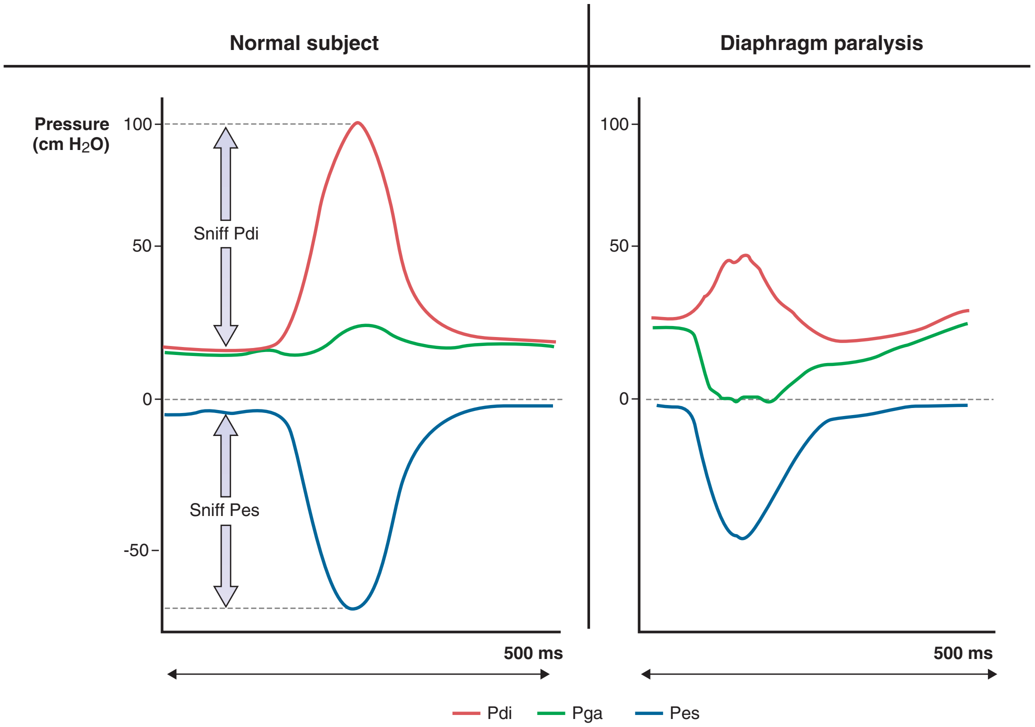

Figure 6-14 Examples of the sniff maneuver. *Left panel* shows a recording from a healthy subject. Note that the esophageal (pleural) pressure change is subatmospheric, whereas the intraabdominal pressure becomes more positive. Measurement conventions for the sniff esophageal (sniff Pes) and sniff transdiaphragmatic (sniff Pdi) pressures are illustrated. The *right panel* shows a recording from a patient with bilateral diaphragmatic paralysis. Note that there is now a negative pressure change in the abdominal compartment, because the diaphragm fails to prevent pressure transmission from the thorax.

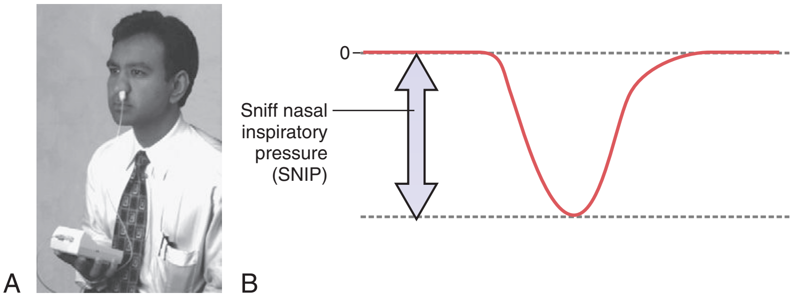

Figure 6-15 The sniff maneuver. A nasal bung and an adapted pressure meter are used for this test. **A,** Measurement setup. The meter returns a numerical value that represents the amplitude of the pressure swing between atmospheric (0) pressure and the nadir. **B,** The tracing produced. The meter returns a numerical value that is the amplitude of the pressure swing between atmospheric (0) pressure and the nadir.

H_2O (in females) also are unlikely to be associated with significant inspiratory muscle weakness.

ELECTROPHYSIOLOGIC TESTING

Electrophysiologic testing helps in determining whether weakness is due to muscle, nerve, or neuromuscular transmission impairment. This determination requires the measurement of Pdi in response to bilateral supramaximal phrenic nerve electrical or magnetic stimulation, with concurrent recording of the elicited electromyogram (EMG) at the diaphragm—the compound muscle action potential (CMAP)—with either surface or esophageal electrodes (Figure 6-16).

If the phrenic nerve is stimulated, the diaphragm contracts. Each contraction is called a twitch. If the stimulus is intense enough, all phrenic fibers are activated synchronously, giving reproducible results. The intensity of the twitch increases with the frequency of stimulation. If multiple impulses stimulate the phrenic nerve, the contractions summate to cause a tetanic contraction. Thus, if both phrenic nerves are stimulated with various frequencies (1, 10, 20, 50, and 100 Hz) at the same lung volume with closed airway (to prevent entry of air with consequent changes in lung volume and initial length of the diaphragm), the isometric *force-frequency curve* of the diaphragm is obtained (see Figure 6-9). Stimulation of the phrenic nerve with high frequencies is technically difficult to achieve (because of displacement of the stimulating electrode by local contraction of the scalene muscles and movement of the arm and shoulder due to activation of the brachial plexus). Therefore, the transdiaphragmatic pressure developed in response to single supramaximal phrenic nerve stimulation at 1 Hz, called the *twitch Pdi,* is commonly measured. Although technically demanding, this approach has the great advantage of being independent of patient effort or motivation. The twitch Pdi also allows for the measurement of *phrenic nerve conduction time,* or *phrenic latency* (i.e., the time between the onset of the stimulus and the onset of CMAP [M wave] on the diaphragmatic EMG tracing) (see Figure 6-16, *B*). A prolonged conduction time suggests nerve involvement.

CONTROVERSIES AND PITFALLS

- The actual mechanisms of respiratory rhythmogenesis have not been definitively established. When the pre-Bötzinger complex was discovered, it was hypothesized to be the sole generator of respiratory rhythm. Subsequent work suggested the presence of a second respiratory rhythm generator, located rostral to the pre-Bötzinger complex in the region of the retrotrapezoid nucleus–parafacial respiratory group (RTN/pFRG) and functioning primarily as a conditional oscillator for generating expiratory motor output; this model is the core of the "two-oscillator" hypothesis. The existence of a second respiratory oscillator is still controversial, and whether it persists into adulthood also is still debated (although with waning intensity).
- Still to be determined within the framework of respiratory rhythm generation is whether single pacemaker neurons in the pre-Bötzinger complex generate the respiratory rhythm or whether the pre-Bötzinger complex network functions as a self-organized group pacemaker, wherein individual pacemaker neurons can be embedded but are not essential for emergent network rhythms that depend on connectivity and synaptically activated burst-generating currents. So-called emergent systems are widespread in biology. They consist of autonomous agents that interact according to simple rules and produce meaningful population-level behaviors. When these behaviors are rhythmic, the underlying network always incorporates two essential features: positive feedback, which serves to coordinate individual elements and promote the formation of a collective temporal pattern, and negative feedback, which can temporarily halt or reverse the assembly process fueled by positive feedback. These processes, by their nature, alternate. The rhythms are called *emergent* because individual agents interact in accordance with simple rules, but none possesses a blueprint for the collective behavior that results.
- The clinical relevance of respiratory muscle fatigue is controversial. Physicians usually institute noninvasive or invasive mechanical ventilation in patients presenting with conditions in which the load the respiratory muscles are facing is fatiguing, because clinical signs of severe respiratory distress (such as tachypnea, accessory muscle use, and diaphoresis) develop before respiratory muscle fatigue is established. Furthermore, the objective diagnosis of respiratory muscle fatigue is impractical in the clinical arena (such as the emergency department), because the required electrophysiologic testing is time-consuming and technically demanding, which makes it hard to implement in acutely dyspneic patients with respiratory distress.
- With most volitional tests of respiratory muscle function, a significant learning effect is characteristic. Thus, repeat testing is required before the diagnosis of respiratory muscle weakness is established, especially in elderly persons or in patients for whom cooperation may be difficult.

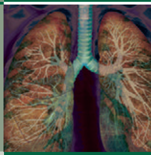
Section 2
DIAGNOSTIC TECHNIQUES



Chapter 7
Imaging Techniques

Simon P.G. Padley • David M. Hansell

Today, clinicians have two main imaging techniques at their disposal for the investigation of patients with chest disease—plain radiography, which produces a projectional image, and computed tomography (CT), which provides a cross-sectional view. Other techniques, such as magnetic resonance imaging (MRI), radionuclide scanning, and ultrasonography, can provide valuable additional information but are rarely performed without previous chest radiography or CT. Because imaging is an integral part of the practice of respiratory medicine, an understanding of the strengths and weaknesses of these various techniques is vital. The advent of high-resolution and spiral (helical) CT techniques has lent further precision to the clinical investigation of suspected chest disease, but the use of such sophisticated tests should not be indiscriminate; accurate interpretation of the chest radiograph remains the mainstay of thoracic imaging.

PLAIN CHEST RADIOGRAPHY

TECHNICAL CONSIDERATIONS

The views of the chest most frequently performed are the erect posteroanterior and lateral projections, taken with the patient's breath held at total lung capacity. On a frontal (posteroanterior) chest radiograph, just under half of the lung is free from overlying structures, such as the ribs or diaphragm. Many technical factors determine how well the lungs are demonstrated. The characteristics of current digital imaging systems make it possible to adjust the final image and optimize exposure of the least and most dense parts of the chest in a single are image.

Because the coefficients of x-ray absorption for bone and for soft tissue approach one another at high kilovoltage, the skeletal structures do not obscure the lungs on a higher-kilovoltage radiograph to the same degree as on low-kilovoltage radiographs. The high-kilovoltage radiograph thus demonstrates much more of the lung. Improved penetration of the mediastinum also allows some of the central airways to be seen. Although high-kilovoltage radiographs are preferable for routine examinations of the lungs and mediastinum, low-kilovoltage radiographs provide good detail of unobscured lung because of the improved contrast between lung vessels and surrounding lung. Furthermore, dense lesions—for example, calcified pleural plaques—are particularly well demonstrated on low-kilovoltage films.

The past decade has seen a major change in plain film radiography with the development of digital imaging systems, which are now ubiquitous in modern radiology departments. Digital chest radiography, yielding images either stored on a phosphor plate and then digitally scanned or captured directly onto a detector plate, has been combined with computer-based picture archiving and communications systems (PACSs) for distribution of images around the hospital or over wider networks. The much wider latitude of digital systems also allows the image to be "postprocessed" to provide optimum visualization of the relevant structures

The frontal (posteroanterior) (**Figure 7-1**) and lateral (**Figure 7-2**) projections are sufficient for most purposes in chest radiography. Other radiographic views are less frequently required, but they should not be overlooked because they may solve a particular problem quickly and cheaply. The lateral *decubitus* view is not, as its name implies, a lateral view. It is a frontal view taken with use of a horizontal beam and the patient in a side-lying position. Its main purpose is to demonstrate the movement of fluid in the pleural space (**Figure 7-3**). An adaptation of this view is the "lateral shoot-through" sometimes used in bed-bound patients: A lateral radiograph of the supine patient is taken to show an anterior pneumothorax behind the sternum (not always visible on a frontal chest radiograph) (**Figure 7-4**). If a pleural effusion is not loculated, it gravitates, to some extent, to the dependent part of the pleural cavity. Thus, in a decubitus patient, the fluid will layer between the chest wall and the lung edge. This view also may be useful for demonstrating a small pneumothorax, because the visceral pleural edge of the lung falls away from the chest walls in the nondependent hemithorax.

For the *lordotic* view, now rarely performed, the x-ray beam is angled 15 degrees cranially, either by positioning the patient upright and directing the beam up or by leaving the beam horizontal and leaning the patient backward. On this view, the lung apices are demonstrated free from the superimposed clavicle and first rib. It may be useful to differentiate pulmonary shadows from incidental calcification of the costochondral junctions (**Figure 7-5**).

PORTABLE CHEST RADIOGRAPHY

Portable or mobile chest radiography has the obvious advantage that the examination can be carried out without moving the patient from the ward. However, the portable radiograph has disadvantages. Use of the shorter-focus film distance results in undesirable magnification, and most portable machines are unable to deliver the power required for high-kilovoltage techniques. Furthermore, the maximum current is limited so that longer exposure times are needed, which potentially increases blurring of the image. Portable lateral radiographs are even less likely to be successful because of the extremely long exposure times required to obtain adequate penetration.

Patient positioning for portable radiography is difficult, and the resultant radiographs often are suboptimal. Even with use of the so-called erect position, in which the patient sits up, the chest is rarely as vertical as it is in a standing patient. Because many patients are unable to move to the radiography department for a formal radiograph, any method of improving the quality of a portable chest radiograph, such as digital radiography, represents a significant advance.

DIGITAL CHEST RADIOGRAPHY

The most widely employed systems use conventional radiographic equipment but use a reusable photostimulatable plate instead of conventional film. The reusable phosphor plate is housed in a cassette and stores some of the energy of the incident x ray as a latent image. On scanning the plate with a laser beam, the stored energy is emitted as light that is detected by a photomultiplier and converted into a digital signal. The digital information is then manipulated, displayed, and stored in whatever format is desired. The phosphor plate can be reused once the latent image has been erased by exposure to light. Most currently available computed radiography systems produce a digital radiograph with a resolution of more than 10 line pairs per millimeter. The fundamental requirement to segment the image into a finite number of pixels has resulted in much work to determine the relationship between pixel size, which affects spatial resolution, and the detectability of focal abnormalities. Although it might seem desirable to aim for an image composed of pixels of the smallest possible size, an inverse relationship occurs between pixel size and the cost and speed of data handling. Thus, pixel size is ultimately a compromise between image quality and ease of data processing and storage.

An unequivocal advantage of digital computed radiography over conventional film radiography is the linear

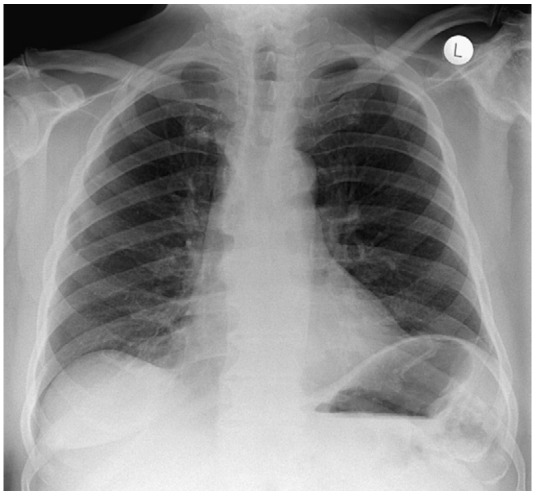


Figure 7-1 A standard digital posteroanterior radiograph demonstrating the wide latitude that can be routinely achieved. This image provides good detail of both lung and mediastinal anatomy.

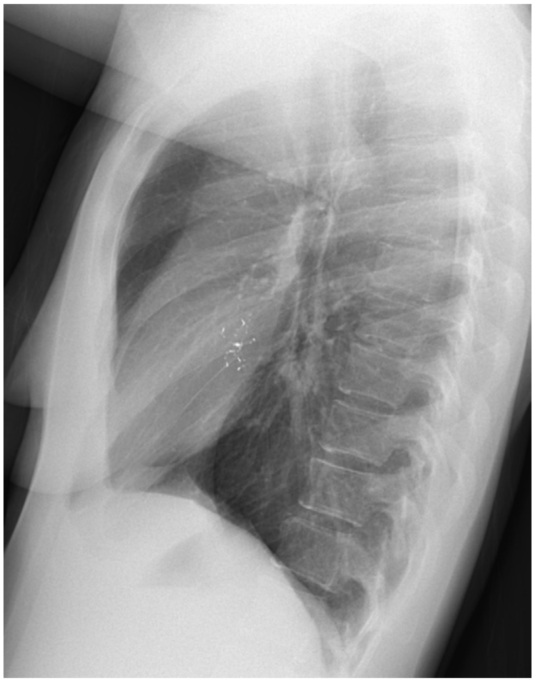

Figure 7-2 Standard lateral chest radiograph. The dorsal spine vertebral bodies are of progressively lower density toward the diaphragm. The metallic density over the cardiac silhouette is an atrial septal defect closure device.

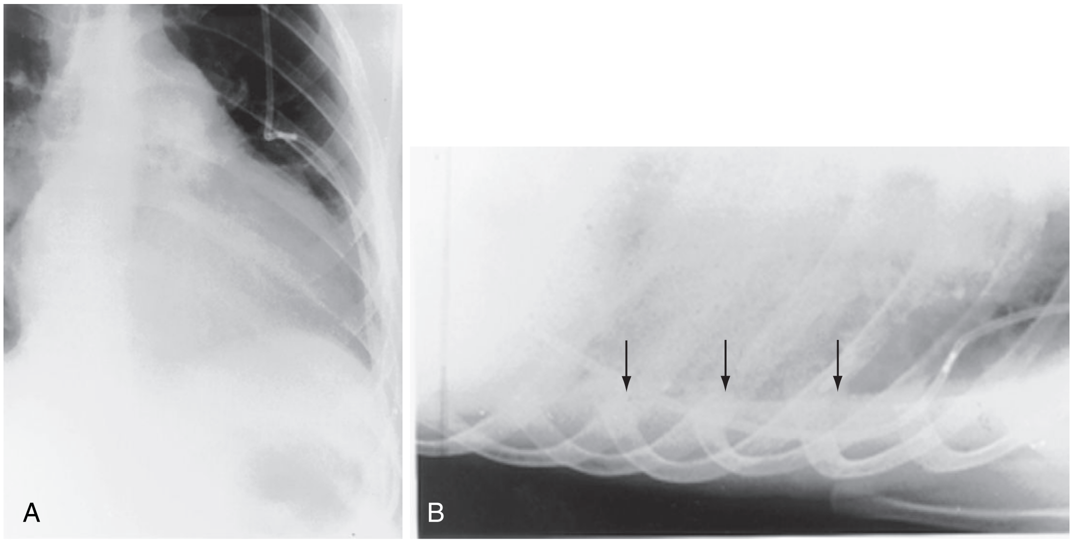

Figure 7-3 Demonstration of small effusions. **A,** Posteroanterior chest radiograph obtained in a patient with a ventriculoperitoneal shunt. More soft tissue than usual is present between the gastric air bubble and the base of the lung because of a subpulmonic effusion. **B,** Decubitus view shows redistribution of fluid to the dependent part of the chest (*arrows*).

photoluminescence-dose response, which is much greater than that of conventional film. This extremely wide latitude coupled with the facility for image processing produces diagnostic images over a wide range of exposures.

Observer performance studies have shown that computed radiography is just as useful as conventional film radiography for virtually any relevant application. However, postprocessing of the digital image has to be used to match the digital radiograph to the specific task. Enhancement of the image for one purpose often degrades it for another but is easily achieved in most PACS reporting systems.

COMPUTED TOMOGRAPHY

The same basic principles that allow film radiography apply with CT—namely, the absorption of x rays by tissues that contain constituents of different atomic number. By use of multiple projections and computed calculations of radiographic density, slight differences in x-ray absorption are displayed as a cross-sectional image. The components of a CT scanner include an x-ray tube that rotates around the patient and an array of x-ray detectors opposite the tube, together contained within the gantry. The patient lies on the examination couch, which moves the patient through the aperture of the CT gantry. The data acquired are then processed by the CT computer, resulting in the final images as displayed on the CT monitor.

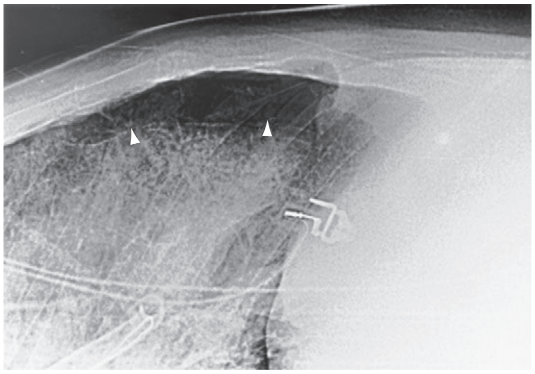

Figure 7-4 Lateral shoot-through digital radiograph of the chest obtained in a patient in the intensive care unit. The anterior pneumothorax (*arrowheads* indicate the visceral pleural edge) was not obvious on the anteroposterior portable radiograph.

An impressive and rapid improvement in CT hardware capability has occurred over the past decade. Most particularly, the advent of multiple-channel CT scanners has resulted in the ability to acquire simultaneous helical datasets. An accompanying increase in gantry rotation speed coupled with the reduction in the size of the individual detectors has resulted in the ability to acquire extremely detailed images in very short scan times. On the current "top specification" scanners from the major manufacturers, up to 320 channels are available, each with a detector size of as small as 0.5 mm. The entire thorax can now be scanned at submillimeter resolution in 1 to 2 seconds. Thus, spiral (also known as volume or helical) scanning entails continuous scanning and table movement into the CT gantry (**Figure 7-6**). The information is reconstructed into axial sections, perpendicular to the long axis of the patient, identical to conventional CT sections.

Temporal resolution has been further improved, because data reconstruction algorithms now allow CT images to be generated after a partial rotation of the gantry. Thus, temporal resolution of as little as 65 msec is now possible, enabling modern multichannel CT scanners to acquire cardiac gated images that effectively freeze cardiac motion. This capability in turn can be applied to allow detailed analysis of coronary artery and cardiac anatomy.

The analysis of what is frequently hundreds of individual images that are produced as the result of a single CT examination is undertaken on dedicated CT or PACS workstations. Postprocessing of these thin sections also allows the production

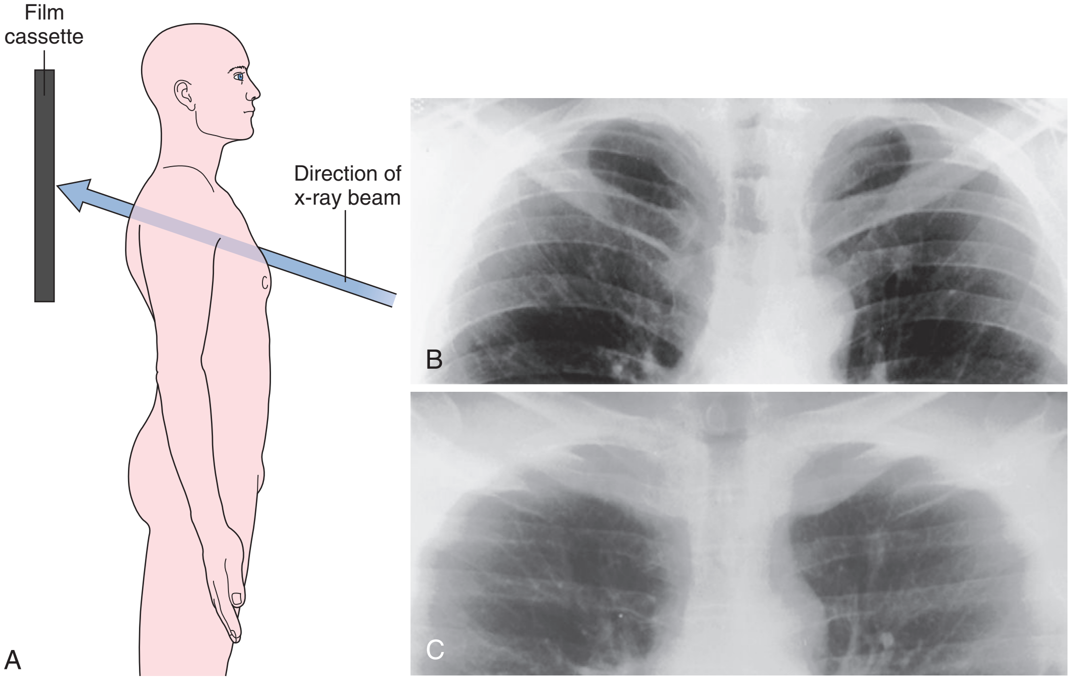

Figure 7-5 The value of lordotic views. **A,** Method of obtaining a lordotic view of the lung apices: The x-ray beam is angled upward. **B,** Selected area from a standard posteroanterior view of the upper lung zones in a patient who presented with hemoptysis, with a suggestion of a small opacity projected over the anterior end of the left first rib. **C,** A lordotic view confirms that the small opacity is intrapulmonary (rather than calcified costochondral cartilage).

of multiplanar reformats (MPRs), maximum and minimum intensity projections (MIPs and MinIPs), and angiographic images. Skeletal structures can be automatically removed, or surface-rendered images that mimic appearances familiar to the bronchoscopist can be produced with a few mouse clicks. These images are visually pleasing and allow an exquisite appreciation of anatomy. They also have a role in the planning of interventional procedures, including transbronchial needle biopsy and endoluminal stent insertion (Figure 7-7).

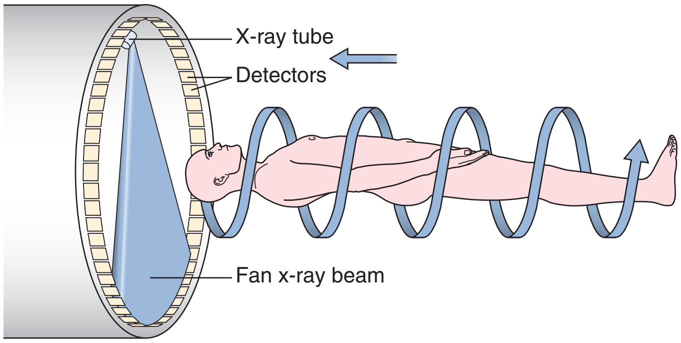

Figure 7-6 The principle of spiral (helical) computed tomography. The patient moves into the scanner with the x-ray tube continuously rotating and the detectors acquiring information. The rapidity of data acquisition allows a complete examination of the thorax to be performed in a single breath-hold.

TECHNICAL CONSIDERATIONS

The CT image is composed of a matrix of picture elements (*pixels*). A fixed number of pixels make up the matrix, so the size of each pixel varies according to the diameter of the circle to be scanned. A typical matrix in a modern CT system would be 512 by 512 pixels. The smaller the image field of view, the smaller the area represented by a pixel and the higher the spatial resolution of the image. In practical terms, the field of view size is adjusted to the size of the area of interest, usually the chest diameter.

Often, marked differences can be seen in the "look" of the images obtained on the various models of CT scanners. Such differences are largely the result of specific features of the software reconstruction algorithms used to smooth the image, to a greater or lesser extent, by averaging the density of neighboring pixels. The lung is a high-contrast environment, so less smoothing is needed than in other parts of the body. Higher-spatial-resolution algorithms (which make image "noise"—a granular appearance—more conspicuous) generally are more desirable for lung work.

SECTION THICKNESS

Although a CT section is viewed as a two-dimensional image, it has a third dimension of depth. The depth, or section thickness, is determined by a combination of factors, depending on

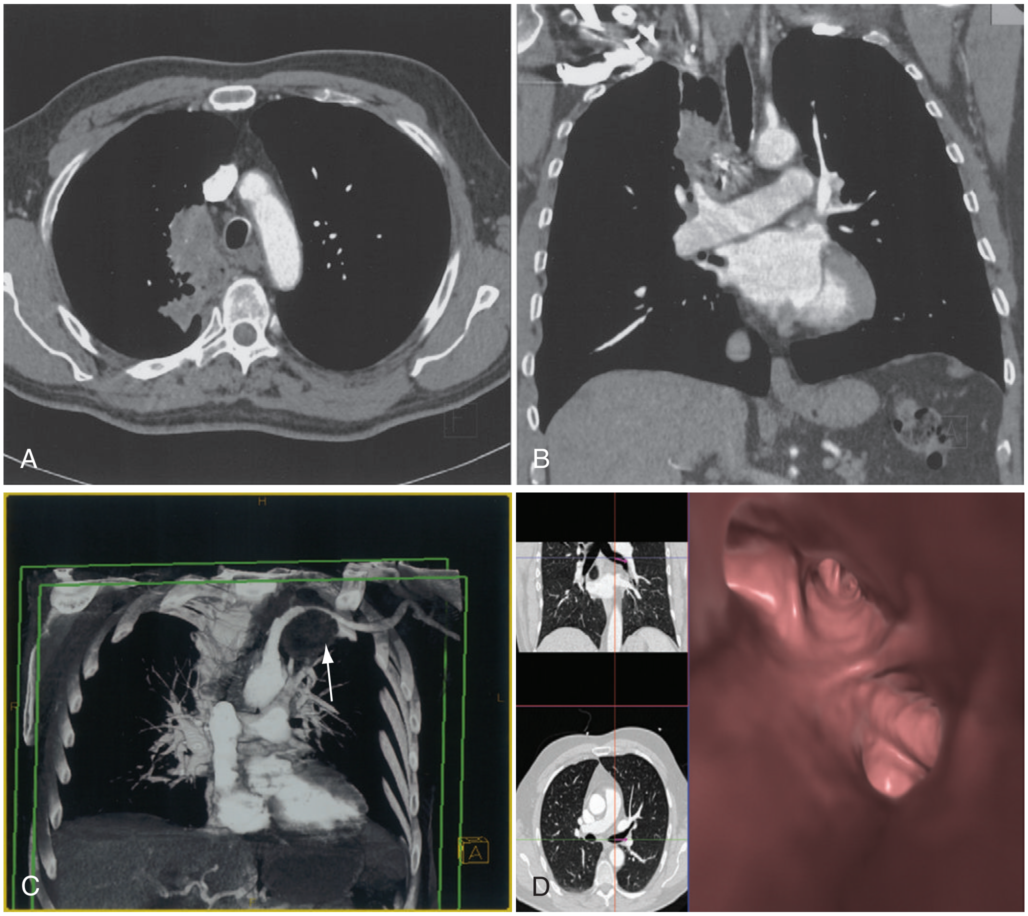

Figure 7-7 Dataset from a multidetector computed tomography study. **A,** This axial image demonstrates a bronchogenic carcinoma in a right paratracheal position. **B,** A reformatted image derived from the same data demonstrates the same abnormality in the coronal plane without loss of resolution. **C,** A coronal volume-rendered image obtained in a different patient demonstrates a left superior sulcus tumor encasing the left subclavian artery (*arrow*). **D,** Virtual bronchoscopy image from a normal subject.

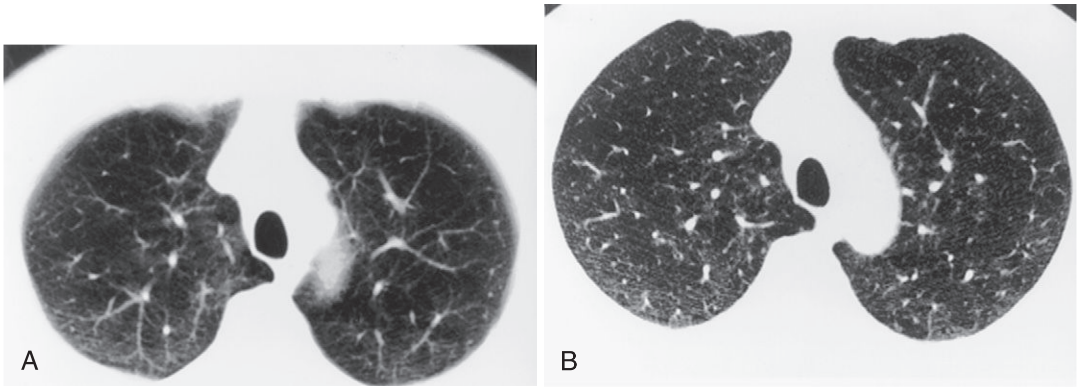

Figure 7-8 The partial volume effect on computed tomography (CT) scan appearance. **A,** This 10-mm CT section shows a poorly defined opacity, adjacent to the left superior mediastinum, apparently within the lung. **B,** The 1.5-mm section through the same region reveals that the appearance in **A** results from a partial volume effect—that is, the aortic arch is partially included in the 10-mm-thick sections.

the exact parameters utilized, including focal spot size, thickness of the individual detector elements, and width of the x-ray beam collimation. Because a section has a predetermined thickness, each pixel has a volume and this three-dimensional element is referred to as a *voxel*. The computer calculates the average radiographic density of tissue within each voxel, and the final CT image consists of a representation of the numerous voxels (not individually visible without magnification) in the section. The single attenuation value of a voxel represents the average of the attenuation values of all of the various structures within the voxel. The thicker the section, the greater the chance that different structures will be included within the voxel and the greater the signal averaging that occurs. This is known as the *partial volume effect*; the easiest way to reduce this effect is to use thinner sections (Figure 7-8).

When the entire chest is examined, contiguous thin sections are reconstructed for analysis. If the study is undertaken on a multichannel system, the dataset may be reconstructed at thinner intervals predetermined by the thickness of the detector rows, and these thinner sections may be used for reporting or multiplanar reconstructions. Thinner sections also are used to study fine detail and complex areas of anatomy, such as the aortopulmonary window and subcarinal regions. Another specific example for which narrow sections may be useful is to display differential densities (which would otherwise be lost because of the partial volume effect) of the small foci of fat or calcium that are sometimes seen within a hamartoma.

If exposure factors are otherwise kept the same, the total patient radiation dose varies very little between different multichannel systems. Of note, however, a striking difference in the radiation dose to the patient is associated with use of contiguous sections versus interspaced fine sections. Thus, the effective dose to the patient with interspaced fine sections (e.g., 1 or 2 mm) every 10 mm, such as used for high-resolution CT of the lung parenchyma, is 5 to 10 times less than that imposed by single-channel or multichannel spiral CT of the entire chest volume. The disadvantage of interspaced sections is the inability to view the data in any plane, but for the purposes of assessment of the lung interstitium, this added refinement usually is not of sufficient added diagnostic value to warrant the increased radiation burden. This consideration is especially important in the relatively younger patient.

WINDOW SETTINGS

The average density of each voxel is measured in Hounsfield units (H); these units have been arbitrarily chosen so that zero is water density and −1000 is air density. The span of Hounsfield units reflecting density in the thorax is wider than in any other part of the body, ranging from that for aerated lung (approximately −800 H) to that for ribs (+700 H). Two variables are used that allow the operator to select the range of densities to be viewed—window width and window center (or level).

The *window width* determines the number of Hounsfield units to be displayed. Any densities greater than the upper limit of the window width are displayed as white, and any below the limit of the window are displayed as black. Between these two limits, the densities are displayed in shades of gray. The median density of the window chosen is the *window center* or level; this center can be moved higher or lower as desired, thus moving the window up or down through the range. The narrower the window width, the greater the contrast discrimination within the window. No single window setting can depict the wide range of densities encountered in the chest on a single image. For this reason, at least two sets of images are required to demonstrate the lung parenchyma and soft tissues of the mediastinum, respectively (Figure 7-9). Standard window widths and centers for thoracic CT vary between departments, but generally for the soft tissues of the mediastinum, a window width of 400 to 600 H and a center of +30 H is appropriate. For the lungs, a wide window of 1500 H and a center of approximately −500 H are usually satisfactory. For bones, the widest possible window setting at a center of +30 H is best.

Window settings have a profound influence on the size and conspicuity of normal and abnormal structures. Nonetheless, it is impossible to prescribe precise window settings because of the element of observer preference and also differences between machines. The most accurate representation of an object seems to be achieved if the value of the window level is halfway between the density of the structure to be measured and the density of the surrounding tissue. For example, the diameter of a pulmonary nodule, measured on soft tissue settings appropriate for the mediastinum, will be grossly underestimated. When inappropriate window settings are used, imaging of smaller structures (e.g., peripheral pulmonary vessels) will be affected proportionately much more than that of larger structures.

INTRAVENOUS CONTRAST ENHANCEMENT

Intravenous contrast enhancement is needed only in specific instances, because of the high contrast on CT between vessels and surrounding air in the lung and between vessels and surrounding fat within the mediastinum. One such instance is to

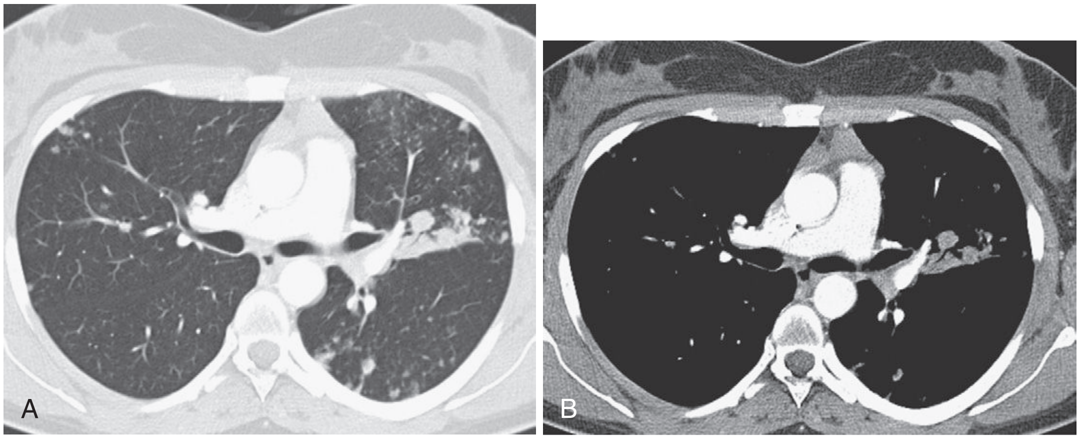

Figure 7-9 The effect of window settings on computed tomography scan appearance. A 5-mm-thick computed tomography section is displayed on different window settings. **A,** On lung windows (center, 500 H; width, 1500 H), nodules in the lungs and pulmonary vessels are clearly visible. **B,** On soft tissue windows (center, 35 H; width, 400 H), the contrast-enhanced vessels in the mediastinum and the soft tissue structures are delineated, but the lung detail is lost.

aid the distinction between hilar vessels and a soft tissue mass. The exact timing of the injection of contrast material depends most on the time the CT scanner takes to scan the thorax. With multichannel CT scanners, the circulation time specific for the patient becomes an important factor.

Contrast medium rapidly diffuses out of the vascular space into the extravascular space, so that opacification of the vasculature after a bolus injection with a "power injector" quickly declines, and structures such as lymph nodes steadily increase in density over time. Such dynamics result in a point at which a solid structure may have exactly the same density as an adjacent vessel. The timing and duration of the contrast medium infusion must therefore be taken into account in interpreting images obtained in a contrast-enhanced CT study. Rapid scanning protocols with automated injectors tend to improve contrast enhancement of vascular structures at the expense of enhancement of solid lesions because of the rapidity of scanning. With spiral CT, it is possible to achieve good opacification of all of the thoracic vascular structures by using small volumes of contrast material. Optimal contrast enhancement is a prerequisite for the diagnosis of pulmonary embolism or aortic and great vessel abnormalities. To achieve optimal contrast enhancement, many CT systems now use an automated triggering system. Thus, in examining the pulmonary arteries, a low-dose repeating scan will monitor the density in the pulmonary outflow tract once every second. When a predetermined density threshold is reached as a result of the arrival of intravenous contrast, the preplanned examination is triggered. The couch rapidly moves the patient from the monitoring position to the start position, a prerecorded breath-hold instruction is given to the patient over a loudspeaker, and the data acquisition commences. The acquisition is timed to correspond with appropriate enhancement of anatomic structures if contrast has been administered.

For examining inflammatory lesions, such as the reaction around an empyema, it may be necessary to delay scanning by 30 seconds, to allow contrast to diffuse into the extravascular space. For examining the liver and adrenals in evaluation of a patient with suspected lung cancer, the optimal phase of contrast enhancement to maximize the conspicuity of hepatic metastases is during the portal venous phase of contrast enhancement, and this occurs 60 to 80 seconds after contrast injection.

HIGH-RESOLUTION COMPUTED TOMOGRAPHY

TECHNICAL CONSIDERATIONS

Over the past two decades, the development of high-resolution computed tomography (HRCT) has had great impact on the approach to the imaging of diffuse interstitial lung disease and bronchiectasis. Images of the lung produced by HRCT correlate closely with the macroscopic appearance of pathologic specimens, so in the context of diffuse lung disease, HRCT represents a substantial improvement over chest radiography. Three factors associated with significantly improved spatial resolution of CT—hence the designation "high-resolution"—are narrow beam collimation, use of a high-spatial-frequency reconstruction algorithm, and a small field of view.

Narrow collimation of the x-ray beam reduces volume averaging within the section and so increases spatial resolution compared with standard 10-mm collimation. For routine HRCT scanning, 1.50-mm beam collimation generally is regarded as optimal. Narrow collimation has a marked effect on the appearance of the lungs, notably the vessels and bronchi—the branching vascular pattern seen particularly in the midzones on standard 10-mm sections has a more nodular appearance with narrow sections, because shorter segments of the obliquely running vessels are included in the section. In addition, parenchymal details become more clearly visualized (**Figure 7-10**).

In HRCT lung imaging, a high-spatial-frequency algorithm is used to take advantage of the inherently high-contrast environment of the lung. The high-spatial-frequency algorithm (also known as the edge-enhancing, sharp, or formerly "bone" algorithm) reduces image smoothing and makes structures visibly sharper but at the same time makes image noise more obvious (see Figure 7-10).

Several artifacts are consistently identified on HRCT images, but they do not usually degrade the diagnostic content of the images. Nevertheless, it is useful to be able to recognize the more common ones. Probably the most frequently encountered is a streaking appearance, which arises from patient motion. Cardiac motion sometimes causes movement of the adjacent lung with consequent degradation of image quality. Some CT scanners are able to eliminate this artifact by triggering the acquisition of the slice from the electrocardiogram (ECG) tracing so that the data are collected during diastole, when

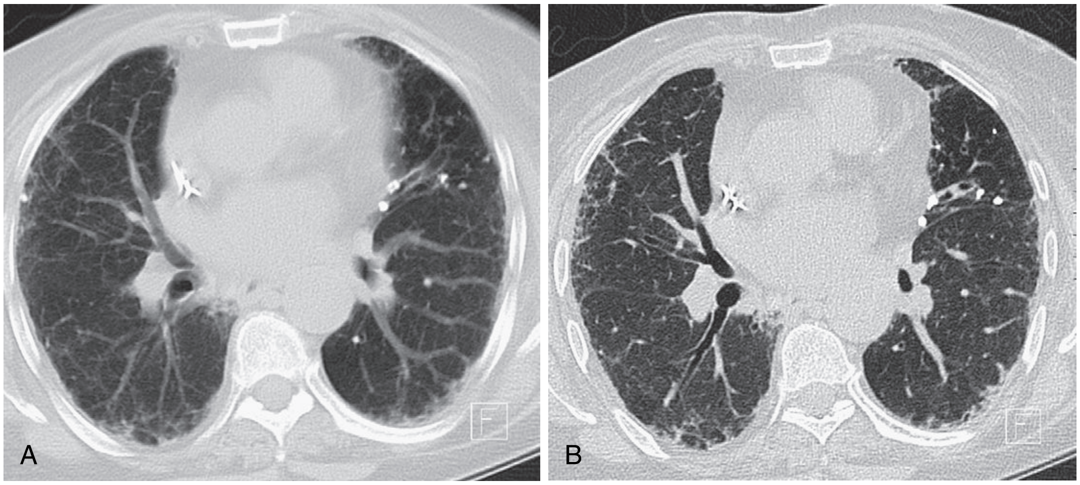

Figure 7-10 The effect of computed tomography (CT) section thickness and edge enhancement on image appearance. **A,** A 10-mm-thick section reconstructed with edge enhancement from a multidetector CT (MDCT) dataset. **B,** A 1.5-mm-thick section with high edge enhancement from the same dataset, typical of a high-resolution CT (HRCT) lung image from a volume acquisition.

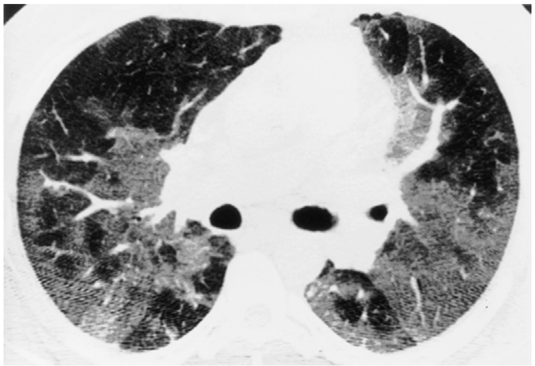

Figure 7-11 High-resolution computed tomography image demonstrating artifact caused by aliasing and quantum mottleing. Detail is obscured in the posterior parts of the lungs. The patchy parenchymal opacification results from desquamative interstitial pneumonitis.

cardiac motion is minimized. To optimize this technique, the scanner must have a short rotation time and also be capable of formatting a CT image from data from a partial rotation. This reduces the data acquisition time window to as little as 360 msec.

The size of the patient has a direct effect on the quality of the lung image—the larger the patient, the more conspicuous the noise, which is seen as granular streaks because of increased x-ray absorption by the patient. This artifact is particularly evident in the posterior lung adjacent to the vertebral column. The phenomenon of aliasing results in a fine, streaklike pattern radiating from sharp, high-contrast interfaces. The severity of the aliasing artifact is related to the geometry of the CT scanner, and, unlike quantum mottle, aliasing is independent of the radiation dose. These artifacts are exaggerated by the nonsmoothing, high spatial-resolution reconstruction algorithm but do not mimic normal anatomic structures and are rarely severe enough to obscure important detail in the lung parenchyma (Figure 7-11).

The degree to which HRCT samples the lung depends primarily on the spacing between the thin sections. An HRCT examination also may vary in terms of the number of sections, the position of the patient, the phase in which respiration is suspended, the window settings at which the images are displayed, and the manipulation of the image by postprocessing. No single protocol can be recommended to cover every eventuality. However, the simplest protocol entails 1.5-mm collimation sections at 20-mm intervals from apex to lung bases. Any given scanning protocol may need to be modified—a patient referred with unexplained hemoptysis ideally is scanned with contiguous standard sections through the major airways (to show a small endobronchial abnormality) and interspaced narrow sections through the remainder of the lungs (to identify bronchiectasis).

When early interstitial disease is suspected, for example, in asbestos-exposed persons in whom the chest radiograph is normal in appearance, HRCT scans often are performed with the patient in the prone position, to prevent any confusion with the increased opacification seen in the dependent posterior basal segments in many normal subjects scanned in the usual supine position. The increased density seen in the posterior dependent lung with supine positioning disappears in normal persons when the scan is repeated at the same level with prone positioning. No advantage is gained by scanning a patient in the prone position if no obvious diffuse lung disease is found on a contemporary chest radiograph.

A limited number of scans taken at end expiration can reveal evidence of air trapping caused by small airway disease, which may not be detectable on routine inspiratory scans. Areas of air trapping range from a single secondary pulmonary lobule to a cluster of lobules that give a patchwork appearance of low attenuation areas adjacent to higher attenuation, normal lung parenchyma (Figure 7-12).

Alterations of the window settings of HRCT images sometimes make detection of parenchymal abnormalities impossible when there is a subtle increase or decrease in attenuation of the lung parenchyma. Uniformity of window settings from patient to patient aids consistent interpretation of the lung images. In general, a window level of −500 to −800 HU and a width of between 900 and 1500 HU are usually satisfactory. Modification of the window settings for particular tasks is often desirable; for example, in looking for pleuroparenchymal abnormalities in asbestos-exposed patients, a wider window of up to 2000 HU may be useful. Conversely, a narrower window of approximately 600 HU may emphasize the subtle density differences that characterize emphysema and small airway disease.

The relatively high radiation dose to the patient inherent in all CT scanning needs to be appreciated. The radiation burden

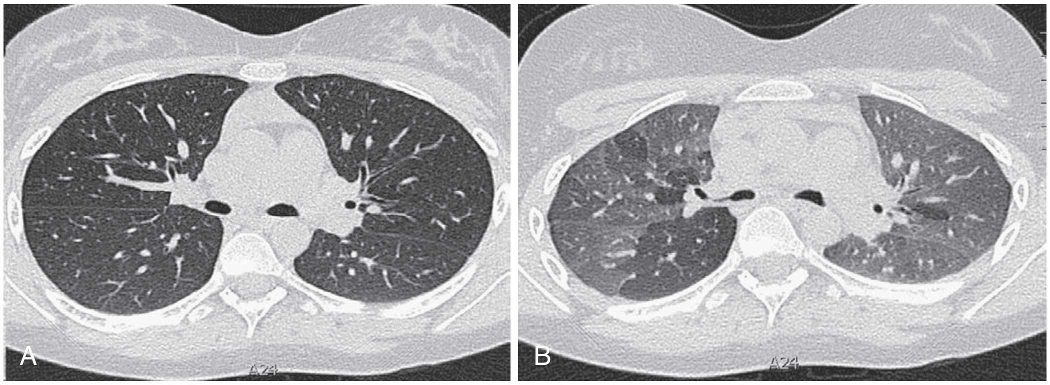

Figure 7-12 **A,** High-resolution computed tomography (CT) scan through the lower lung lobes of a patient with severe asthma. The inspiratory image through the upper zones is normal. **B,** A high-resolution CT image at end expiration emphasizes the regional air trapping due to small airways obstruction.

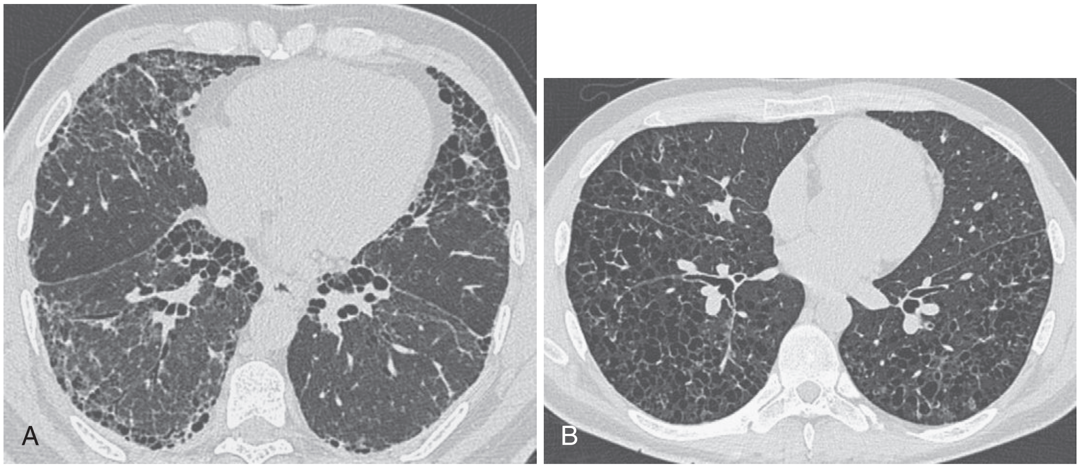

Figure 7-13 High-resolution computed tomography patterns in diffuse interstitial lung disease. **A,** Subpleural reticular pattern typical of established fibrosing alveolitis. **B,** Multiple irregularly shaped cystic spaces within the lungs in a young patient with preserved lung volumes. Images through the lung bases were more normal. This high-resolution computed tomography pattern and distribution combination is virtually pathognomonic for Langerhans cell histiocytosis.

to the patient is considerably less with HRCT than with conventional CT scanning. It has been estimated that the mean radiation dose delivered to the skin with HRCT by use of 1.5-mm sections at 20-mm intervals is 6% that of conventional 10-mm contiguous scanning protocols. A further method of reducing the radiation burden to the patient is to decrease the milliamperage; it is possible to reduce the milliamperage by up to 10-fold and still obtain comparably diagnostic images. Although continuous refinement in CT technology is reducing the radiation burden to patients, CT still delivers a relatively high radiation dose to patients, so this imaging modality must not be used indiscriminately.

CLINICAL APPLICATIONS OF HIGH-RESOLUTION COMPUTED TOMOGRAPHY

Increasingly, HRCT is used to confirm or refute the impression of an abnormality seen on a chest radiograph. It may also be used to achieve a histospecific diagnosis in some patients who have obvious, but nonspecific, radiographic abnormalities.

It probably is impossible to determine the frequency with which HRCT will show significant parenchymal abnormalities when the chest radiograph appears normal. Studies of individual diseases show that HRCT demonstrates abnormalities despite normal chest radiographs in 29% of patients with systemic sclerosis and in up to 30% of those with asbestosis. For hypersensitivity pneumonitis, the proportion may be even higher. As indicated by the average sensitivity results of several studies, HRCT seems to have a sensitivity of approximately 94%, compared with 80% for chest radiography; this increased sensitivity does not seem to be achieved at the expense of decreased specificity.

In patients with clinical and lung function evidence of diffuse lung disease, HRCT is now central in the diagnostic workup, with clinical performance greatly exceeding that of plain chest radiography and may obviate the need for lung biopsy. In the original study that compared the diagnostic accuracy of chest radiography and CT in the prediction of specific histologic diagnosis in patients with diffuse lung disease, Mathieson and associates showed that three observers could make a confident diagnosis in 23% of cases on the basis of chest radiographs and in 49% of cases with use of CT; the correct diagnosis was made in 77% and 93% of these readings, respectively (Figure 7-13).

A number of subsequent early HRCT studies acted as the forerunners of a large body of work that has established HRCT as a cornerstone in the assessment of patients suspected of having diffuse lung disease but for whom the clinical features and appearance on the chest radiograph do not allow a confident diagnosis to be made. A number of diffuse lung diseases

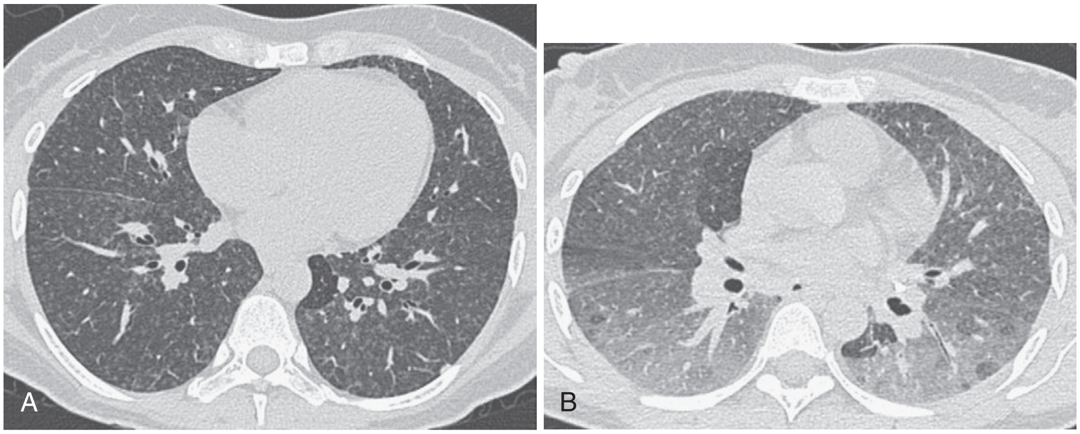

Figure 7-14 High-resolution computed tomography scans of the chest in a patient with subacute hypersensitivity pneumonitis. **A,** Widespread nodular and ground glass patterns. **B,** The areas of decreased attenuation evident posteriorly are made more obvious on this scan obtained at end expiration.

can have a "diagnostic" appearance on HRCT when findings are interpreted by experienced chest radiologists; such diseases include fibrosing alveolitis, sarcoidosis, Langerhans cell histiocytosis, lymphangioleiomyomatosis, pneumoconiosis, and hypersensitivity pneumonitis (Figure 7-14). An intriguing observation is that the ability of HRCT to allow observers to provide correct histospecific diagnoses seems to be maintained in advanced end-stage disease.

However, HRCT is sometimes used indiscriminately for patients in whom the high certainty of diagnosis from clinical and radiographic findings does not justify the extra cost and radiation burden. No evidence shows that an HRCT examination adds anything of diagnostic value for a patient who has progressive shortness of breath, finger clubbing, crackles at the lung bases, and the typical radiographic pattern and lung function profile of fibrosing alveolitis. Nevertheless, the ability of HRCT to characterize disease, and often to deliver a definite and correct diagnosis in patients with nonspecific radiographic shadowing, frequently is helpful.

Much interest has been shown in defining the role of HRCT in staging disease activity, particularly for fibrosing alveolitis, in which cellular histology indicates disease activity and is used to predict both responses to treatment and prognosis. As shown by more recent evidence, a predominance of ground glass opacification in fibrosing alveolitis predicts a good response to treatment and increased actuarial survival compared with patients with a more reticular pattern, which denotes established fibrosis. Similar observations about the potential reversibility of disease can be made with use of HRCT in patients who have sarcoidosis, in whom a ground glass or a nodular pattern predominates. In other conditions, the identification of ground glass opacification on HRCT, although nonspecific, almost invariably indicates a potentially reversible disease—for example, extrinsic allergic alveolitis, diffuse pulmonary hemorrhage, and *Pneumocystis jiroveci* pneumonia (Box 7-1). An important exception is bronchoalveolar cell carcinoma, in which areas of ground glass opacification that merge into areas of frank consolidation or a more nodular pattern may be seen. Another caveat applies with the situation in which fine, intralobular fibrosis is seen on HRCT as widespread ground glass opacification; in this rare occurrence, evidence of traction bronchiectasis usually is present within the areas of ground-glass opacification.

The ability of CT to discriminate among various patterns of disease has clarified the basis for the sometimes complex mixed obstructive and restrictive functional deficits found in some diffuse lung diseases. A good example is hypersensitivity pneumonitis, in which both interstitial and small airway disease coexist; patterns caused by these different pathologic processes can be readily appreciated on HRCT. The extent of the various HRCT patterns correlates with the expected functional indices of restriction and obstruction, respectively. Other conditions in which CT is able to tease out the morphologic abnormalities responsible for complex functional deficits include fibrosing alveolitis with coexisting emphysema and sarcoidosis associated with a combination of interstitial fibrosis and small airway obstruction by peribronchiolar granulomata.

In patients for whom lung biopsy is deemed necessary, HRCT may be invaluable to indicate which type of biopsy procedure is likely to be successful in obtaining diagnostic material. The broad distinction between peripheral disease versus central and bronchocentric disease is easily made on HRCT. Thus, disease with a subpleural distribution, such as fibrosing alveolitis, is most unlikely to be sampled by transbronchial biopsy, whereas diseases with a bronchocentric distribution on HRCT, such as sarcoidosis and lymphangitis carcinomatosa, are consistently accessible to transbronchial biopsy. In patients for whom an open or thoracoscopic lung biopsy is contemplated, HRCT assists in determining the optimal biopsy site. Pathologic examination of a lung biopsy specimen can still justifiably be regarded as the final arbiter of the presence or absence of subtle interstitial lung disease. Because HRCT images provide a kind of "in vivo big picture," many lung pathologists now combine the imaging and pathologic information before assigning a final diagnosis, and in many centers, the benefits of a team approach to the diagnosis of diffuse lung disease are recognized. The indications for HRCT

Box 7-1 Causes of Ground Glass Opacification

Pneumocystis jiroveci or cytomegalovirus pneumonia
Acute respiratory distress syndrome–acute interstitial pneumonia
Hypersensitivity pneumonitis—subacute
Desquamative interstitial pneumonitis
Pulmonary edema
Idiopathic pulmonary hemorrhage
Bronchioloalveolar cell carcinoma
Alveolar proteinosis
Lymphocytic interstitial pneumonia
Respiratory bronchiolitis–interstitial lung disease

Box 7-2 Indications for High-Resolution Computed Tomography of the Lungs

- To narrow the differential diagnosis or to make a histospecific diagnosis in patients with obvious but nonspecific radiographic abnormalities
- To detect diffuse lung disease in patients with normal or equivocal radiographic findings
- To elucidate unexpected pulmonary function test results
- To investigate the underlying problem in patients presenting with hemoptysis
- To evaluate disease reversibility, particularly in patients who have fibrosing alveolitis
- To guide the type and site of lung biopsy

that have been developed over the past 20 years are summarized in Box 7-2.

MAGNETIC RESONANCE IMAGING

Plain radiography, CT, ultrasound imaging, contrast angiography, and isotope scanning constitute the mainstays of thoracic disease imaging. Although magnetic resonance imaging (MRI) has developed a role complementary to these techniques, it generally is considered a problem-solving tool rather than a technique of first choice.

MRI entails placing the subject in a very strong magnetic field (typically 0.2 to 1.5 tesla) and then irradiating the area under examination with pulses of radiowaves. Anatomic MRI depends on the presence of water within tissue to produce the signal required for interpretation. Protons within this water exist within different local atomic environments and, consequently, have different properties. These differences, measured as magnetic resonance, can be exploited by sequence manipulation to generate differences in contrast between tissues in the final image. Thus, the frequency of the radiofrequency pulse transmitted into the patient is carefully selected so that it causes hydrogen protons within water to be disturbed from the orientation that they have assumed as a result of being placed inside the powerful magnetic field within the bore of the magnet. After the transient disturbance caused by the radiofrequency pulse, these protons, which are acting akin to small bar magnets, relax back into their original resting position. As they do this, they release energy as a further pulse of radio waves, which are detected by the receiver coils located in the wall of the bore of the magnetic coil or, more commonly, in a variety of receiver coils placed more directly around the area under investigation. These coils frequently are known by the body part they have been designed to examine—thus, a knee, head, neck, or body coil is placed appropriately at the start of the examination. In the case of thoracic imaging, the body coil usually consists of a pair of coil mats placed in front of and behind the patient.

Historically, the main strengths of MRI are the high intrinsic soft tissue contrast generated, the lack of artifact from bone, the absence of exposure to ionizing radiation, and the ability to produce images in any chosen plane. The major weaknesses of MRI in the thorax have, until recently, been its susceptibility to image degradation secondary to respiratory and cardiac motion, as well as the relatively long times required to perform an examination. In general, the quality of MR images is related to the field strength of the scanner and the peak power and speed of the amplifiers that generate the interrogating radiofrequency pulses.

For thoracic imaging, ECG-triggering facilities, whereby the acquisition of imaging data can be coordinated with the cardiac cycle to reduce flow artifact, are essential. Various methods of compensation for respiratory motion have been developed. Some approaches use external devices such as respiratory bellows, which detect movement of the chest wall, with data collection occurring when motion is at its least. Other methods are essentially software developments that compensate for respiratory disruption of magnetic spins. Most of these techniques have been superseded on modern scanners by the ability to acquire images of the thorax with use of breath-hold techniques.

MEDIASTINAL AND CHEST WALL IMAGING

The most common indications for the use of MRI in respiratory disease are for investigation of neoplastic disease, most commonly bronchogenic carcinoma. In addition to the primary disease, secondary complications such as cerebral secondaries, spinal metastases, and retroperitoneal fibrosis all lend themselves to evaluation by MRI. MRI also permits assessment for invasion of mediastinal structures such as the major airways, heart and great vessels, chest wall, and diaphragm and allows differentiation among different forms of soft tissue, fluid, hemorrhage, local hematoma formation, and aneurysms (Figures 7-15 and 7-16). With modern multichannel CT techniques, MRI now holds relatively little advantage over CT in assessing chest wall invasion, except with superior sulcus tumors. However, MRI does provide superb anatomic detail without subjecting the patient to radiation exposure—an important consideration in the pediatric age group, in which a number of follow-up studies may be required (Figure 7-17). The disadvantage of MRI in the very young child is the necessity for general anesthesia in many cases.

LUNG PARENCHYMAL IMAGING

Use of magnetic resonance techniques for imaging the lungs has been limited by a number of significant technical challenges. First, the lungs are constantly moving because of respiratory and cardiac motion. Second, they have a low water content relative to other biologic tissues, so they have a low proton density and return relatively little signal. Third, because of the multiple interfaces between air and soft tissue, innumerable small disturbances arise in the magnetic field. This loss of homogeneity at air-tissue interfaces results in a phenomenon known as magnetic susceptibility artifact, further reducing signal and increasing noise. Thus, on standard sequences, normal lung exhibits little signal and often is obliterated by artifact. Attempts to tackle this problem are showing increasing promise—for example, in the area of suppurative lung disease in younger patients.

VENTILATION STUDIES

Another area of intense interest has been the use of polarized gases (helium 3 and xenon 129) to show pulmonary ventilation. With this technique, a process of heating and irradiating with polarized light produces polarized gases. The gases (which have a short half-life) are inhaled and imaged using optimized sequences. The use of dual-frequency probes allows gas and proton images to be acquired and registered, enabling function and anatomy to be correlated.

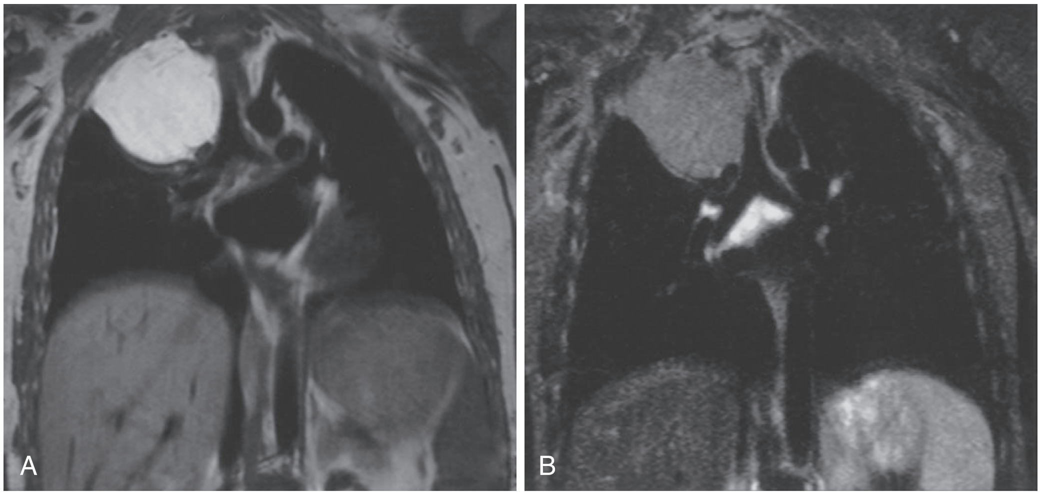

Figure 7-15 Magnetic resonance imaging of a right upper zone lung mass in an 11-year-old boy. **A,** A coronal T1-weighted sequence demonstrates a high-signal-intensity apical mass. **B,** With the addition of fat saturation, reducing the signal returned from fat, the signal intensity in the mass falls significantly. This imaging feature confirms the fatty nature of the mass, which was a large pleural lipoma.

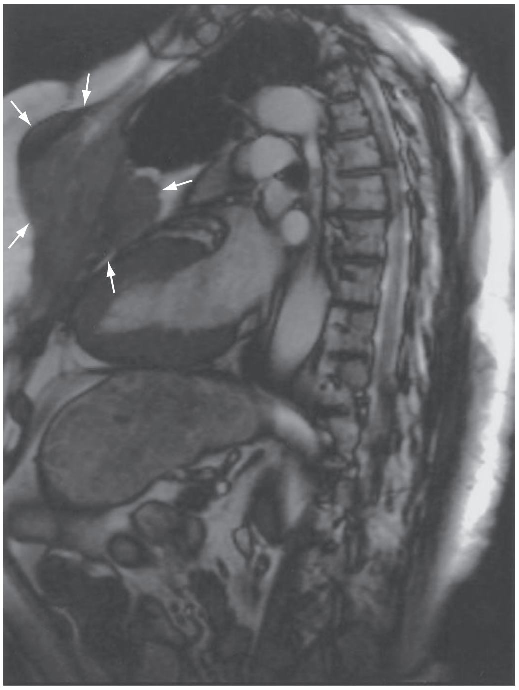

Figure 7-16 Chest wall invasion by tumor demonstrated with magnetic resonance imaging. Oblique sagittal T2-weighted image through the long axis of the left ventricle demonstrates an adjacent chest wall mass (*arrows*) extending through the interior chest wall into the overlying breast tissue. This was due to recurrent breast carcinoma.

MAGNETIC RESONANCE ANGIOGRAPHY

Magnetic resonance also can be used to demonstrate vascular anatomy by differential visualization of flowing blood and stationary tissue; this may be achieved with or without intravenous MRI contrast agents. Generally, the use of contrast increases the signal returned from blood, increases the signal-to-noise ratio, and allows acquisition times to be shorter. This modality, known as magnetic resonance angiography (MRA), can be used to look at venous or arterial flow, together or separately (see Figure 7-17).

The contrast agents used in MRI generally and MRA in particular are based almost exclusively on gadolinium chelates. Most such agents are sequestered in the extracellular spaces; they cause shortening of the T1 relaxation time and thus increase the signal from the enhanced tissue on T1-weighted sequences. The distribution of these agents is very similar to that of the iodinated contrast agents used routinely in CT.

PULMONARY EMBOLI AND INFARCTION

At present, MRI is not routinely used in patients with suspected pulmonary embolism and infarction, but it has been the subject of much research: In a number of published series, breath-hold pulmonary MRA has been found to show fifth-order pulmonary vessels and to permit diagnosis of emboli to the segmental level. Presence of smaller pulmonary emboli can be inferred by lack of segmental and subsegmental perfusion. Three-dimensional MRA datasets can be acquired and displayed on workstations as moving projections to demonstrate areas of deficient perfusion.

VASCULAR MALFORMATIONS AND CONGENITAL ANOMALIES

Increasing evidence suggests that MRI can clearly define a number of vascular and developmental anomalies of the lungs by combining anatomic and flow studies. Such anomalies include the scimitar syndrome, hypogenetic lung syndrome, pulmonary artery agenesis, bronchopulmonary sequestration, and vascular malformations (see Figure 7-17).

CARDIOVASCULAR IMAGING

MRI is now a key technique for imaging the heart and great vessels and is widely used for the assessment of cardiac anatomy and function. Rapid and accurate assessment of wall motion, determination of ejection fraction, and stress testing for reversible ischemia, hibernating myocardium, and valvular disease are now routine. The ultimate challenge—namely, accurate imaging of the coronary arteries—is under intense investigation, although this application has not yet reached routine practice. Nevertheless, MRI is now able to provide comprehensive noninvasive cardiac assessment that is likely to challenge more established techniques such as nuclear medicine and echocardiography.

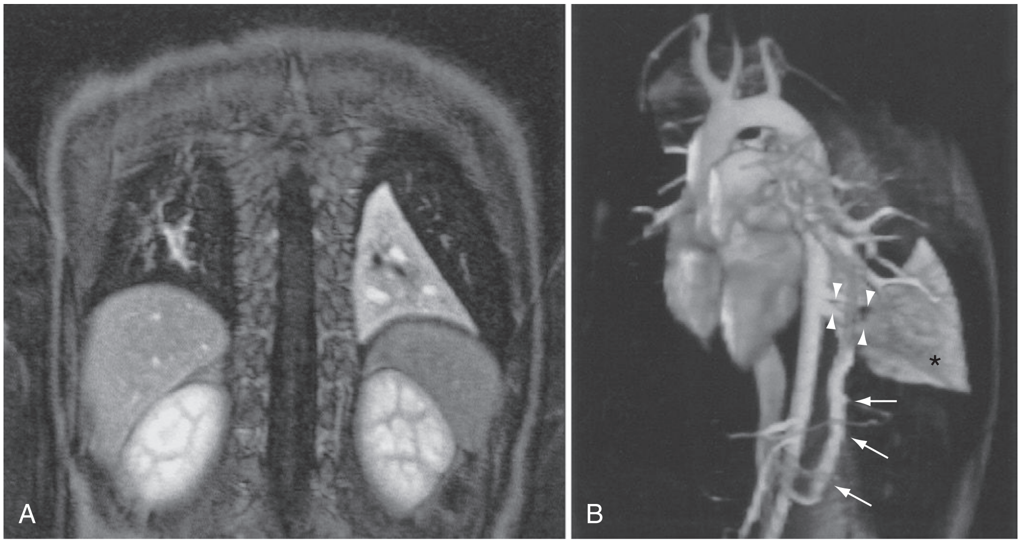

Figure 7-17 Extralobar pulmonary sequestration. **A,** A coronal contrast-enhanced breath-hold image demonstrates the avidly enhancing pulmonary sequestration at the left lung base. Note the clear plane between the triangular sequestrated segment and the diaphragm and underlying spleen. **B,** Volume-rendered angiographic image demonstrating the same triangular sequestrated segment *(asterisk)* with two supplying branches from the aorta *(arrowheads)* and complex venous drainage. The largest vein drains subdiaphragmatically *(arrows)* into the left renal vein.

PULMONARY ANGIOGRAPHY

Pulmonary angiography is used to investigate pulmonary circulation when other, less invasive, methods have failed to provide the requisite information. The most frequent indication is for suspected pulmonary embolism, often after ventilation-perfusion scanning. In the acute assessment of pulmonary embolism, the angiogram is undertaken within 24 hours of clinical presentation. However, a delay of 48 to 72 hours should not preclude the use of pulmonary angiography, although the diagnostic yield progressively declines because of fragmentation of thrombi over time, especially if anticoagulation has been instituted.

Pulmonary angiography is now rarely used. Apart from the relative expense and invasive nature of angiography, it is perceived to have a high complication rate (although this is not supported by the published evidence), so it has been largely replaced by CT.

The technique of pulmonary angiography involves fluoroscopically directed insertion of a guidewire followed by a modified pigtail catheter into the right and then the left main pulmonary arteries in turn, with injection of a nonionic contrast administered at an appropriate flow rate. At least two views per side are required, with additional oblique or magnification views as necessary. Catheter access usually is through the femoral vein, with use of the internal jugular and subclavian veins as possible alternatives. Most departments undertake angiography with digital subtraction vascular equipment (Figure 7-18). Problems with misregistration artifact, inherent in digital subtraction systems and caused by respiratory or cardiac cycle phase differences between the mask image and the contrast image, usually can be overcome. Crossing the tricuspid valve may induce an arrhythmia that usually is transient. Therefore, electrocardiogram (ECG) monitoring is mandatory, and the use of prophylactic antiarrhythmic agents or temporary pacing-wire insertion is common practice in some centers. Right-sided heart catheter pressure measurements and gas analysis also may be undertaken.

When a pulmonary embolus is present, it most frequently is situated in the posterior segments of the lower lobe. Thrombi beyond the segmental vessel level are detected less reliably than more central thrombi. However, the significance of thrombi confined to subsegmental vessels is unclear. The typical angiographic findings with pulmonary embolism are those of vascular cutoff or, when vascular occlusion is not complete, an intraluminal filling defect with contrast passing around and beyond the clot. Indirect signs of embolism include areas of

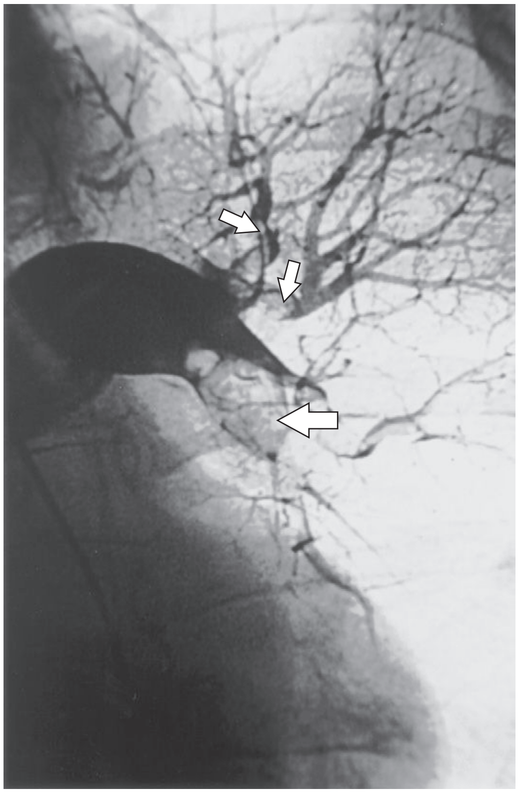

Figure 7-18 Digital subtraction pulmonary angiogram. A large thrombus causes a filling defect within the contrast in the artery of the left lower lobe *(large arrow)*. Smaller thrombi are present within the proximal branches to the upper lobe *(small arrows)*.

relatively delayed or reduced perfusion, late filling of the venous circulation, and vessel tortuosity. When the angiogram is performed to investigate suspected chronic thromboembolic disease, vascular changes to look for include local stenosis or thin webs, luminal ectasia, and irregularities of the normal tapering pattern.

BRONCHIAL ARTERY EMBOLIZATION

Bronchial artery embolization usually is performed to treat massive hemoptysis in patients who are unsuitable candidates for surgical management. The most common causes of bronchial artery hypertrophy and consequent hemorrhage are suppurative lung diseases (particularly bronchiectasis) and fibrocavitary disease that involves mycetomas. Less common causes of hemorrhage from the bronchial circulation include bronchial carcinoma, chronic pulmonary abscess, and congenital cyanotic heart disease. No absolute contraindications to bronchial artery embolization are known, although the patient should be hemodynamically stable and able to cooperate.

The most common anatomic arrangement on bronchial arteriography is that of one main right bronchial artery arising from a common intercostobronchial trunk, which comes off the thoracic aorta at approximately the level of T5, and two left bronchial arteries arising more inferiorly. However, bronchial arteries may arise from the thyrocervical trunk, the internal mammary artery, the costocervical trunk, the subclavian artery, a lower intercostal artery, or the inferior phrenic artery or even the abdominal aorta. The right intercostal bronchial trunk takes off from the aorta at an acute upward angle, whereas the left bronchial arteries leave the aorta at more-or-less right angles, and special catheters have been designed to facilitate selective catheterization. Superselective catheterization of the bronchial circulation allows precise delivery of embolic material, thereby preventing spillover into the aorta or inadvertent embolization of the spinal artery.

Fiberoptic bronchoscopy often is advocated before bronchial artery embolization to establish the site of hemorrhage. However, a large-volume hemoptysis almost invariably results in vigorous coughing, thereby spreading blood throughout the bronchial tree, which makes localization impossible. CT angiography also is a useful preliminary investigation, delineating bronchial artery anatomy, guiding intervention, and sometimes localizing the lobe or segment from which the bleeding originates. Few criteria exist to determine which angiographically demonstrated bronchial arteries should be embolized. Guidelines are particularly relevant when several bronchial arteries have been identified and the site of hemorrhage is not obvious from previous thoracic imaging. Embolization is directed at the vessels considered most likely to be the source of hemorrhage (Figure 7-19). Bronchial arteries of diameter greater than 3 mm may be considered to be pathologically enlarged. In patients with diffuse, suppurative lung disease, most commonly cystic fibrosis, attempts are made to embolize all significantly enlarged bronchial arteries bilaterally. If no abnormal bronchial arteries are identified, a systematic search is made for aberrant bronchial arteries. When a patient continues to experience hemoptysis after embolization, all suspicious systemic arteries should be examined for a source of bleeding, and it may be necessary to angiographically investigate the pulmonary circulation for a source of bleeding.

A variety of embolic materials have been used for the embolization of bronchial arteries, ranging from spheres of polyvinyl alcohol in a variety of sizes to small pieces of surgical gel (Gelfoam). Although coils lodged proximally in the bronchial artery have been used, they can prevent subsequent catheterization.

After bronchial artery embolization, many patients experience transient fever and chest pain. Some patients cough up a small amount of blood, which possibly arises from limited infarction of the bronchial mucosa. Serious complications after bronchial artery embolization are rare, the most serious being transverse myelitis, probably caused by contrast toxicity rather than inadvertent embolization. Inadvertent spillover of embolization material into the thoracic aorta may cause distant ischemia in the legs or abdominal organs.

The aim of bronchial artery embolization is the immediate control of life-threatening hemoptysis, which is achieved in more than 75% of patients. Failures usually result from nonidentification of significant bronchial arteries and an inability to maintain the catheter position to allow subsequent embolization. Up to 20% of patients rebleed within 6 months of an initially successful bronchial artery embolization. The reasons cited for recurrent hemorrhage are recanalization of previously embolized vessels, incomplete initial embolization, and hypertrophy of small bronchial arteries not initially embolized.

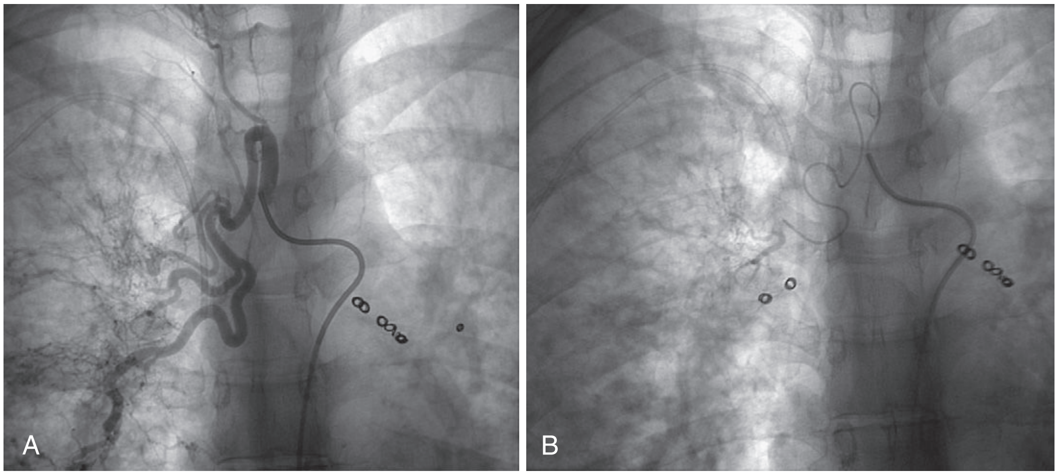

Figure 7-19 Bronchial arteriogram obtained in a patient who presented with hemoptysis. **A,** Marked hypertrophy of the bronchial artery to the right upper zone is evident. These changes were caused by cystic fibrosis. Previous embolization coils are seen over the right upper lobe. **B,** After embolization with a combination of small coils and particles, no further flow into these branches occurs.

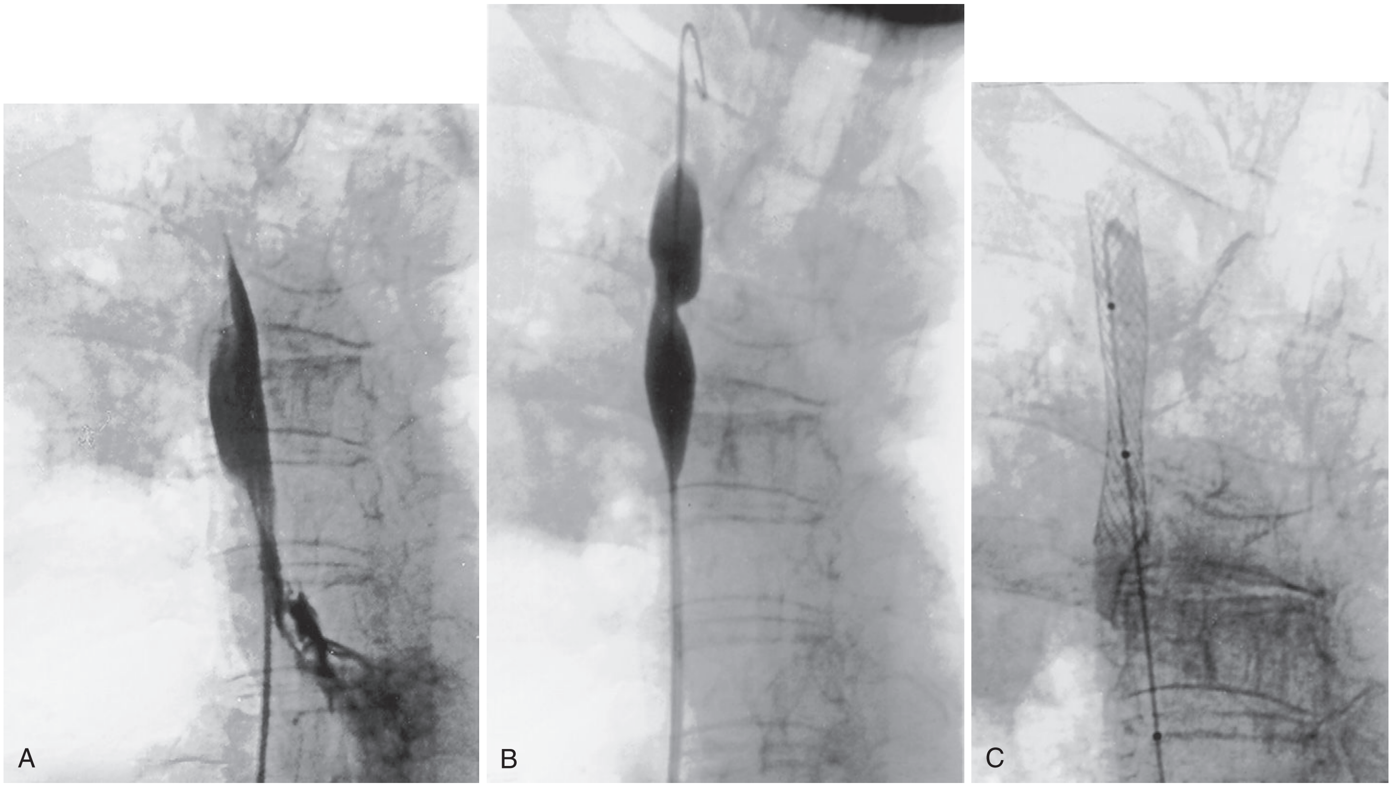

Figure 7-20 Stenting of superior vena cava obstruction. In this patient, the obstruction was caused by mediastinal malignancy. **A,** Superior venacavagram showing a tight stricture in the midportion of the superior vena cava. **B,** Balloon dilation of the stricture. **C,** Placement of a mesh-wire stent in the now-patent superior vena cava.

However, bronchial artery embolization usually can be satisfactorily repeated in patients who rebleed.

SUPERIOR VENA CAVA STENTING

Superior vena cava obstruction (SVCO) is characterized by facial and upper limb swelling, headache, and shortness of breath and usually is caused by advanced mediastinal malignancy. Conventional palliative treatment relies on radiotherapy, chemotherapy, and sometimes surgery. Radiotherapy usually produces an initial improvement, although subsequent recurrence of symptoms is frequent. Balloon angioplasty for treatment of both benign and malignant causes of SVCO has been reported, but not surprisingly, symptoms are liable to recur soon after angioplasty alone.

The percutaneous placement of metallic stents for the treatment of SVCO has several attractions. With increasing experience, reliable and successful palliation of SVCO has been reported with use of various stent designs. A superior venacavagram is necessary to identify the length of the stenosis and its site in relation to the confluence of the brachiocephalic veins and the right atrium. Identification of intraluminal thrombus or tumor may require thrombolysis before stent insertion, or the use of a covered stent. After balloon dilatation of the superior vena cava stricture, the stent is positioned across the stricture, and a postplacement venacavagram is performed to confirm free flow of blood into the right atrium (Figure 7-20). Subsequent to angioplasty and stent placement, relief of SVCO symptoms usually is rapid and dramatic. Recurrence of symptoms may be caused by venous thrombosis or tumor progression. Although rupture of the superior vena cava at the time of angioplasty is a risk, this complication seems to be extremely rare, possibly because of the tamponade provided by surrounding tumor or postirradiation fibrosis.

The role of intravascular stents in the management of nonmalignant SVCO has not yet been defined. Patients who have SVCO caused by benign fibrosing mediastinitis have been treated successfully, although occlusion of the stent secondary to the progression of the mediastinal fibrosis or with endothelial proliferation may occur.

NORMAL RADIOGRAPHIC ANATOMY

MEDIASTINUM AND HILAR STRUCTURES

The mediastinum is delineated by the lungs on either side, the thoracic inlet above, the diaphragm below, and the vertebral column posteriorly. In the context of radiographic anatomy, the various structures that make up the mediastinum are superimposed on each other, so they cannot be separately identified on a two-dimensional chest radiograph; for this reason, the normal anatomy of the individual components of the mediastinum is considered in more detail in the later section on CT of the mediastinum. Nevertheless, because a chest radiograph usually is the first imaging investigation, it is necessary to appreciate the normal appearances of the mediastinum and the considerable possible variations resulting from the patient's body habitus and age.

The mediastinum is conventionally divided into superior, anterior, middle, and posterior compartments (Figure 7-21). The practical benefit of use of these arbitrary divisions is that specific mediastinal pathologies show a definite predilection for individual compartments (e.g., a superior mediastinal mass most frequently is caused by intrathoracic extension of the

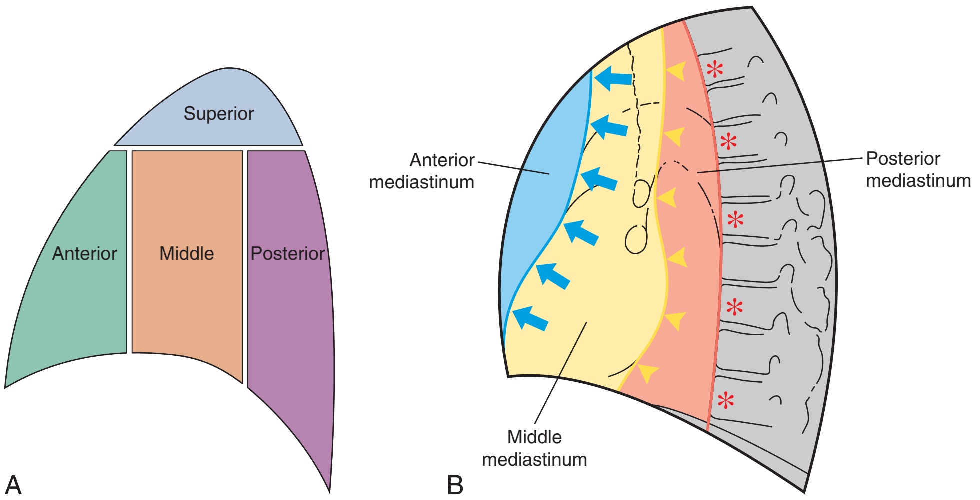

Figure 7-21 The mediastinal compartmental divisions. **A,** Arbitrary division of the mediastinum into superior, anterior, middle, and posterior compartments. **B,** An alternative scheme omits the superior mediastinal compartment. The area posterior to the sternum and anterior to the heart and great vessels *(blue arrows)* defines the anterior mediastinum in both cases. Likewise, a line placed along the posterior aspect of the trachea and heart *(yellow arrowheads)* distinguishes the middle from the posterior mediastinum, which is bounded posteriorly by the vertebra *(red asterisks)*.

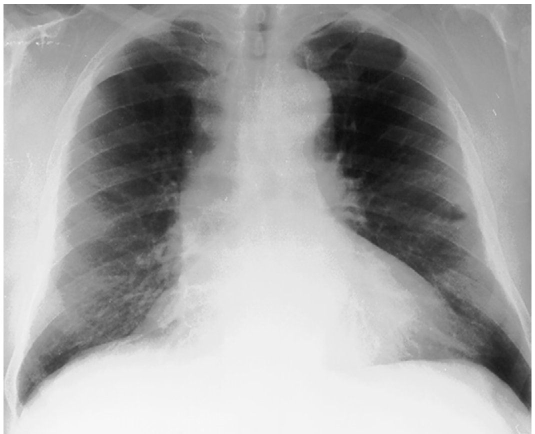

Figure 7-22 Widening of the superior mediastinum in this image is caused by abundance of mediastinal fat. In addition, bilateral cardiophrenic fat pads are present.

thyroid gland; a middle mediastinal mass usually results from enlarged lymph nodes). However, localization of a mass within one of these compartments does not normally allow a specific diagnosis to be made, and neither do the arbitrary boundaries preclude disease from involving more than one compartment.

Only the outline of the mediastinum and the air-containing trachea and bronchi (and sometimes esophagus) is clearly seen on a normal posteroanterior chest radiograph. On a chest radiograph, the right brachiocephalic vein and superior vena cava form the right superior mediastinal border. This border usually is vertical and straight (in contrast with the situation in which right paratracheal lymphadenopathy is present, when the right superior mediastinal border tends to be undulate), and it becomes less distinct as it reaches the thoracic inlet. The right side of the superior mediastinum can appear to be considerably widened in patients who have an abundance of mediastinal fat (Figure 7-22); such persons often have prominent cardiophrenic fat pads. The mediastinal border to the left of the trachea above the aortic arch is the result of summation of the left carotid and left subclavian arteries, together with the left brachiocephalic and jugular veins. The left cardiac border consists of the left atrial appendage, which merges inferiorly with the left ventricle. The silhouette of the heart should always be sharply outlined. Any blurring of the border results from loss of immediately adjacent aerated lung, usually by collapse or consolidation.

The density of the heart shadow to the left and right of the vertebral column should be identical—any difference indicates pathology (e.g., an area of consolidation or a mass in a lower lobe). On a well-penetrated film, a density with a convex lateral border frequently is seen through the right heart border—this apparent mass is caused by the confluence of the right pulmonary veins as they enter the left atrium and is of no clinical significance.

The trachea and main bronchi should be visible through the upper and middle mediastinum. The trachea is rarely straight and often is to the right of the midline at its midpoint. In older persons, the trachea may be markedly displaced by a dilated aortic arch below. In approximately 60% of normal subjects, the right wall of the trachea (the right paratracheal stripe) can be identified as a line of uniform thickness (less than 4 mm in width); when visible, it excludes the presence of any adjacent space-occupying lesion, most usually lymphadenopathy. The angle between the left and right main bronchi, which forms the carina, usually is somewhat less than 80 degrees. Splaying of the carina is a relatively crude sign of subcarinal disease, in the form of either a massive subcarinal lymphadenopathy or a markedly enlarged left atrium. A more sensitive sign of subcarinal disease is obscuration of the upper part of the azygoesophageal line, which usually is visible in its entirety on a chest radiograph with good penetration (Figure 7-23). The origins of the lobar bronchi, when they are projected over the mediastinal shadow, usually can be identified, but segmental bronchi within the lungs generally are not seen on plain radiography.

The normal hilar shadows on a chest radiograph represent the summation of the pulmonary arteries and veins, with little contribution from the overlying bronchial walls or lymph nodes of normal size. The hila are of approximately the same size, and the left hilum normally lies between 0.5 and 1.5 cm above the level of the right hilum. The size and shape of the hila show remarkable variation in normal persons, making subtle abnormalities difficult to identify.

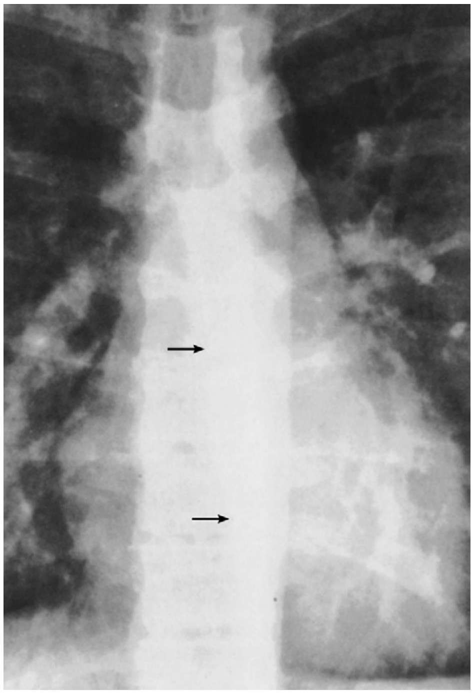

Figure 7-23 Chest radiograph made using the advanced multiple beam equalization radiography (AMBER) system. The normal azygoesophageal line is demonstrated (*arrows*).

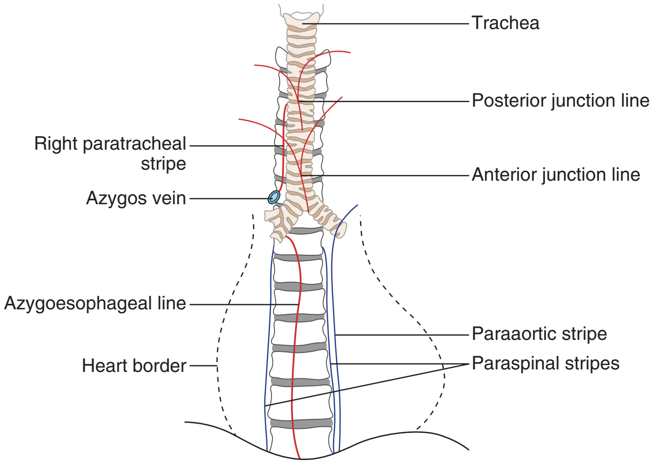

Figure 7-24 Diagram showing some of the mediastinal lines and stripes frequently seen on a frontal chest radiograph.

PULMONARY FISSURES, VESSELS, AND BRONCHI

The two lungs are separated by the four layers of pleura behind and in front of the mediastinum. The resultant posterior and anterior junction lines often are visible on frontal chest radiographs as nearly vertical stripes, the posterior junction line lying higher than the anterior (Figure 7-24). Because these junction lines are not invariably seen (their visibility is largely dependent on whether the pleural reflections are tangential to the x-ray beam), their presence or absence is not usually of significance.

The lobes of lung are surrounded by visceral pleura—the major (or oblique) fissure separates the upper and lower lobes of the left lung. The major (or oblique) fissure and the minor (horizontal or transverse) fissure separate the upper, middle, and lower lobes of the right lung. In the absence of abnormality, the minor fissure is visible in more than half of posteroanterior chest radiographs. In normal persons, the minor fissure is slightly bowed upward and runs horizontally; any deviation from this configuration usually is caused by loss of volume of a lobe. The major fissures are not visible on a frontal radiograph and are inconsistently identifiable on lateral radiographs. Inability to detect a fissure usually reflects that the fissure is not exactly in the line of the x-ray beam. Occasionally, however, fissures may be incompletely developed—a point familiar to thoracic surgeons, who sometimes encounter difficulty in performing a lobectomy because of incomplete cleavage between lobes. Accessory fissures are occasionally seen; for example, in the left lung a minor fissure can be present, which separates the lingula from the remainder of the upper lobe.

All of the branching structures seen within normal lungs on a chest radiograph represent pulmonary arteries or veins. The pulmonary veins may sometimes be differentiated from the pulmonary arteries—the superior pulmonary veins have a distinctly vertical course. Often, however, it is impossible to differentiate arteries from veins in the lung periphery. On a chest radiograph taken in the erect position, a gradual increase in the diameter of the vessels is seen, at equidistant points from the hilum, traveling from lung apex to base; this gravity-dependent effect disappears if the patient is supine or in cardiac failure.

The lobes of the lung are divided into segments, each of which is supplied by its own segmental pulmonary artery and accompanying bronchus. The walls of the segmental bronchi are rarely seen on the chest radiograph, except when lying parallel with the x-ray beam, in which case they are seen end on as ring shadows measuring up to 8 mm in diameter. The most frequently identified segmental airways are the anterior segmental bronchi of the upper lobes.

DIAPHRAGM AND THORACIC CAGE

The interface between aerated lung and the hemidiaphragms is sharp, and the highest point of each dome normally is medial to the midclavicular line. The right dome of the diaphragm is higher than the left by up to 2 cm in the erect position, unless the left dome is elevated by air in the stomach. Laterally, the hemidiaphragm forms an acute angle with the chest wall. Filling in or blunting of these costophrenic angles usually represents pleural disease, either pleural thickening or an effusion. In elderly persons, localized humps on the dome of the diaphragm, particularly posteriorly (and therefore most obvious on a lateral radiograph), are common and represent minor weaknesses or defects of the diaphragm. Interposition of the colon in front of the right lobe of the liver is a frequently seen normal variant (so-called Chilaiditi syndrome).

Apparent pleural thickening along the lateral chest wall in the middle zones is a frequent observation in obese patients; it is caused by subpleural fat bulging inward. Deformities of the thoracic cage may cause distortion of the normal mediastinum and so simulate disease. One of the most common deformities is pectus excavatum, which, by compressing the heart between the depressed sternum and vertebral column, causes displacement of the apparently enlarged heart to the left and blurring of the right heart border (Figure 7-25). A similar appearance may arise with an unusually straight thoracic spine, referred to as *straight back syndrome*.

ANATOMY OF THE LATERAL CHEST RADIOGRAPH

Consistent viewing of lateral chest radiographs in the same orientation, whether a right or a left lateral projection, improves

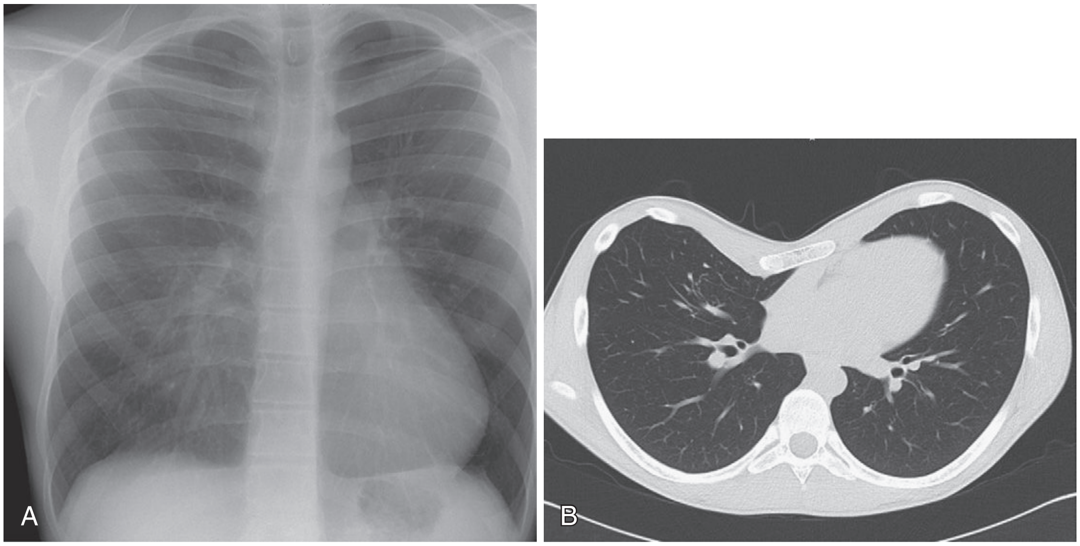

Figure 7-25 **A,** Chest radiograph, posteroanterior view, obtained in a patient with marked pectus excavatum. The blurring of the right heart border and the apparent increase in heart size are a direct consequence of a depressed sternum. Note the 7 configuration of the ribs. **B,** Computed tomography scan shows the sternal depression.

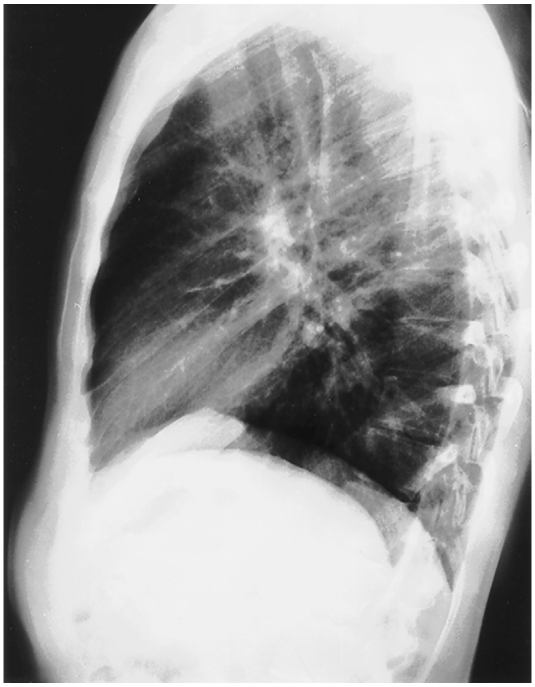

Figure 7-26 The lateral chest radiograph in a normal subject.

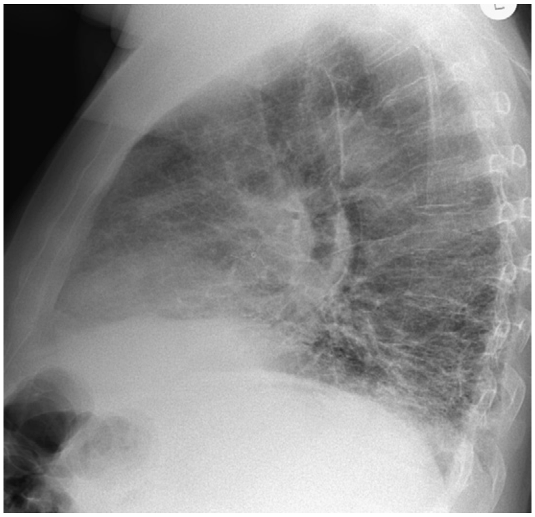

Figure 7-27 Loss of the normal increase in transradiancy toward the lower part of the dorsal spine in a patient with interstitial lung disease.

the ability to detect deviations from normal. In the lateral view, the trachea is angled slightly posteriorly as it runs toward the carina, and its posterior wall is always visible as a fine stripe (Figure 7-26). The posterior walls of the right main bronchus and the right intermediate bronchus are outlined by air and also are seen as a continuous stripe on the lateral radiograph. The overlying scapulae are invariably seen running almost vertically in the upper part of the lateral radiograph (and may be misinterpreted as intrathoracic structures). Further confusing shadows are formed by the soft tissues of the outstretched arms, which project over the upper mediastinum. The carina is not visible as such on the lateral radiograph, and the two transradiancies projected over the lower trachea represent the right main bronchus (superiorly) and the left main bronchus (inferiorly).

Overlying structures on a lateral radiograph obscure most of the lung. In normal persons, the unobscured lung in the retrosternal and retrocardiac regions should be of the same transradiancy. Furthermore, as the eye travels down the spine, a gradual increase in transradiancy should be apparent. The loss of this phenomenon suggests the presence of disease in the posterior-basal segments of the lower lobes (e.g., fibrosing alveolitis) (Figure 7-27).

The two major fissures are seen as diagonal lines, of a hair's breadth, that run from the upper dorsal spine to the anterior surface of the diaphragm. Care must be taken not to confuse the obliquely running rib edges with fissures. The minor fissure extends horizontally from the middle right major fissure. It is often not possible to differentiate the right from the left major fissures with confidence. Similarly, although the two hemidiaphragms may be identified individually (especially if the gastric bubble is visible under the left dome of the diaphragm), differentiation between the right and the left hemidiaphragm is often impossible. A useful sign is the relative heights of the two

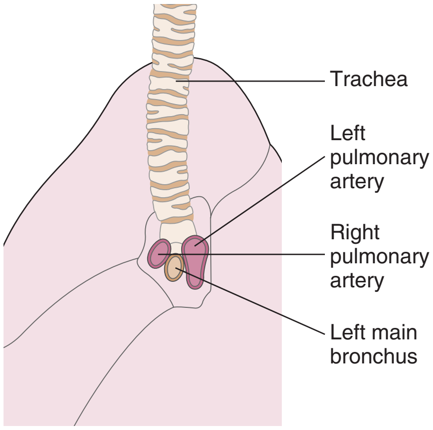

Figure 7-28 Diagram showing the proximal pulmonary arteries seen on a lateral chest radiograph.

Table 7-1 Causes of Consolidation

Common	Rare
Infection	Allergic lung diseases
Infarction	Connective tissue diseases
Cardiogenic pulmonary edema	Drug reactions
Noncardiogenic pulmonary edema	Hemorrhage
Acute respiratory distress syndrome	Lymphoma
Neurogenic edema	Radiation injury
Drug-induced edema	Amyloid
Miscellaneous	Eosinophilic lung disease
Sarcoid	
Alveolar proteinosis	

domes—the dome farther from the film normally appears higher because of magnification.

The summation of both hilar on the lateral radiograph generates a complex shadow. However, one general point is useful in the interpretation of this difficult area—the right pulmonary artery lies anterior to the trachea and right main bronchus, whereas the left pulmonary artery arches over the left main bronchus so that a large part of it lies posterior to the major bronchi (Figure 7-28). A bandlike opacity often is seen along the lower third of the anterior chest wall behind the sternum. It represents a normal density and occurs because less aerated lung is in contact with the chest wall, because the space is occupied by the heart; it should not be confused with pleural disease.

POINTS IN THE INTERPRETATION OF A CHEST RADIOGRAPH

Even when an obvious radiographic abnormality is present, use of a systematic method of reviewing the chest radiograph is essential. With increasing experience, appreciation of deviation from normal appearances becomes rapid, which leads quickly to a directed search for related abnormalities. Before interpretation of a chest radiograph, it is vital to establish whether any previous radiographs are available for comparison—the sequence and pattern of change often are as important as the identification of a radiographic abnormality. Information gained from preceding radiographs, particularly the lack of serial change, often prevents needless further investigation.

A check that the radiograph is of satisfactory quality includes an estimation of the adequacy of radiographic exposure, depth of inspiration, and position of the patient. The intervertebral disk spaces of the entire dorsal spine should be visible on a correctly exposed chest radiograph, and the midpoint of the right hemidiaphragm lies at the level of the anterior end of the sixth rib if the (normal) subject has taken in a satisfactory breath. The medial ends of the clavicles should be equidistant from the spinous processes of the cervical vertebral bodies.

The order in which the various parts of a chest radiograph are examined is unimportant. A suggested sequence is to start with a check of the position of the trachea, the mediastinal contour (which should be sharply outlined in its entirety), and then the position, outline, and density of the hilar shadows. The certain identification of a hilar abnormality often requires comparison with a previous radiograph; any suspicion of a hilar abnormality necessitates the retrieval of any previous chest radiographs. At least as important as an abnormal contour for detecting a mass at the hilum is a discrepancy in density between the two sides—both hilar shadows, at equivalent points, should be of equal density, and a mass at the hilum (or an intrapulmonary mass projected over the hilum) is evident as an increased density of the affected hilum. For a questionably abnormal hilum, the lateral radiograph sometimes is helpful in clarifying the situation, provided that the normal anatomy is kept in mind (i.e., most of the right pulmonary artery lies anterior to the trachea and the bulk of the left pulmonary artery lies behind the trachea). Thus, a suspected right hilar mass on a frontal radiograph that appears to be behind the trachea on a lateral view is unlikely to represent a prominent right pulmonary artery and is therefore most likely to be an abnormal mass (the converse rule applies to a suspicious left hilum).

The lungs may then be examined in terms of their size, the relative transradiancy of each zone, and the position of the horizontal fissure. Pulmonary vessels are seen as far out as the outer third of the lung, and the number of vessels should be roughly symmetric on the two sides. Next, the position and clarity of the hemidiaphragms should be noted, followed by an assessment of the ribs and soft tissues of the chest wall. Before a chest radiograph can be regarded as normal, close inspection of areas that are poorly demonstrated, or that contain structures sometimes misinterpreted, is indicated. Such areas include the central mediastinum (where even a large mass may be invisible on the posteroanterior view), the lungs behind the diaphragm and heart, the lung apices (often obscured by the overlying clavicles and ribs), and the lung and pleura just inside the chest wall.

RADIOGRAPHIC SIGNS

Consolidation

Consolidation, also referred to as air space shadowing, is caused by opacification of the air-containing spaces of the lung. The causes of consolidation are numerous (Table 7-1) and include almost any pathologic process that results in the filling of the normal alveolar spaces and small airways. The responsible material is almost invariably of fluid density, and usually the volume of the displacing fluid equals the volume of air displaced. This normally results in no net change in size of the lobar anatomy. Typically, it is not possible to tell from the radiologic appearances what has caused the air space filling, especially in the absence of a clinical history. The possible exception to this generalization is with air space shadowing resulting from cardiogenic alveolar edema, when associated signs of congestive cardiac failure are found. In analyzing an area of pulmonary opacification, the presence of a number of radiologic characteristics allows the confident characterization of air space shadowing.

Typically, the shadowing is ill-defined, except when it directly abuts a pleural surface (including the interlobar fissures), in which case it is sharply demarcated (Figure 7-29). Although consolidation respects lobar boundaries, there are no such barriers to spread into adjacent lung segments, which are frequently contiguously involved. Thus, an area of consolidation within a single lobe often enlarges in an irregular manner, and a discrete, well-defined opacity (so-called round pneumonia) is the exception and not the rule (Figure 7-30).

The vascular markings within an area of consolidation usually become obscured, because the contrast between the air-containing lung and the soft tissue density vascular markings is lost. By contrast, the bronchi, which usually are too thin-walled to be differentiated from the surrounding lung parenchyma, become apparent in negative contrast to the air space opacification, to produce the true hallmark of consolidation, the air bronchogram (Figure 7-31). A relatively uncommon but very suggestive radiologic sign of consolidation is the acinar shadow, in which an individual secondary pulmonary lobule becomes opacified but remains surrounded by normally aerated lung. The resultant soft tissue density nodule usually is on the periphery of a more confluent area of consolidation and normally measures 0.5 to 1 cm in diameter. These acinar opacities most commonly are seen in association with mycobacterial and varicella-zoster pneumonias but can occur with any other cause of consolidation (Figure 7-32). Occasionally, an acinus is left normally aerated but surrounded by opacified air spaces; this radiologic sign has been termed the *air alveologram*. When consolidation is not fully developed and has caused only partial filling of the air spaces, the resultant radiographic appearance is ground glass opacification (Figure 7-33). Again, a wide range of possible causes has been documented, and in addition to causes of consolidation, this pattern may result from interstitial lung infiltration.

When an area of consolidation undergoes necrosis, because of either infection or infarction, liquefaction may result, and if

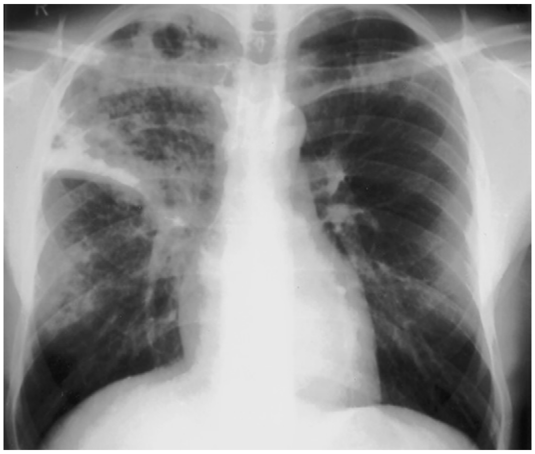

Figure 7-29 Patchy consolidation caused by tuberculosis. Where this area of involvement abuts the horizontal fissure, the inferior surface of the consolidation is sharply defined.

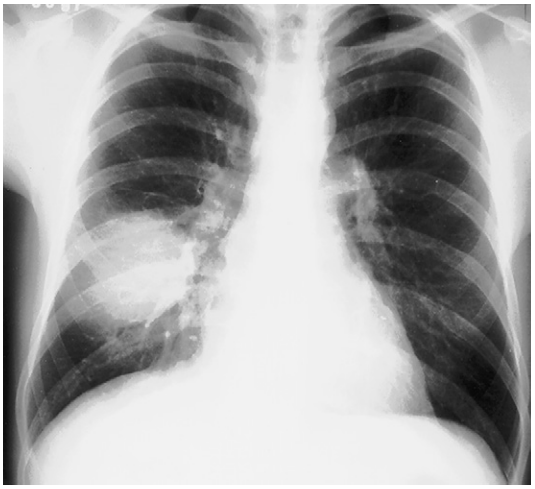

Figure 7-30 Well-defined, rounded opacity in the right middle lung zone, which fades out peripherally. This "round pneumonia" was caused by pneumococcal infection.

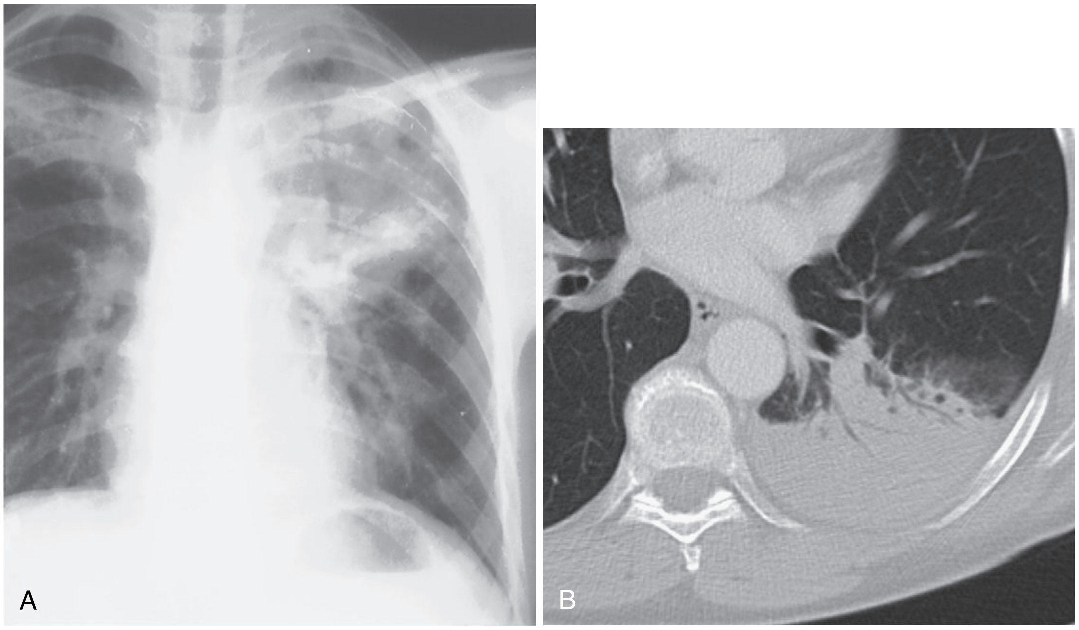

Figure 7-31 Air bronchogram in consolidation. **A,** Plain radiograph of the left upper zone in a patient with tuberculosis shows an air bronchogram. **B,** Computed tomography scan through the left lower lobe in a different patient demonstrates an area of segmental pneumonia.

either a gas-forming organism or communication with the bronchial tree is present, an air-fluid level may develop in addition to cavity formation (Figure 7-34). Consolidation frequently produces a silhouette sign, as described by Felson and Felson. Although this radiographic sign may be seen in association with a wide number of intrapulmonary pathologic processes, it is the relatively transitory nature of many forms of consolidation that best demonstrates the features of this finding. The original description stated that when an intrathoracic lesion touched a border of the heart, aorta, or diaphragm, it obliterated that border on the radiograph. Furthermore, a small area of consolidation may obliterate a normal air–soft tissue interface as effectively as a large area. This contingency is demonstrated well by the obliteration of the right heart border by subtle middle lobe consolidation that might otherwise be overlooked.

Understanding the significance of the silhouette sign allows the observer to localize an area of consolidation or other pulmonary opacity. Only if an area of consolidation lies in direct contact with a normal structure is the silhouette of that structure lost. If an area of consolidation and a normal structure–lung interface merely lie along the same x-ray path, they are superimposed on the radiograph but do not demonstrate the silhouette sign. Thus, lingular consolidation is likely to obscure the heart border, but left lower lobe consolidation usually does not (Figures 7-35 through 7-37). Several potential causes for a falsely positive silhouette sign are recognized. Some relatively common anatomic variants that result in a reduced anteroposterior diameter of the thorax, such as pectus excavatum or straight back syndrome, cause loss of the right heart border as the depressed sternum distorts the normal anatomy (see Figure 7-25). Occasionally, a scoliosis, usually concave to the left and often of relatively trivial clinical significance, causes the right heart border to be projected over the spine. It is only when the heart border is projected over the right lung that the silhouette sign can be elicited. Underexposed radiographs may appear to demonstrate the silhouette sign, so it is imperative that the technical quality of the radiograph be taken into account.

Collapse

Partial or complete volume loss in a lung or lobe is referred to as *collapse* or *atelectasis*. The two terms are essentially interchangeable, and both imply a diminished volume of air in the lung with associated reduction of lung volume. Any of several different mechanisms may be responsible for lung or lobar collapse.

Relaxation or Passive Collapse

The lung retracts toward its hilum when air or an abnormal amount of fluid accumulates in the pleural space.

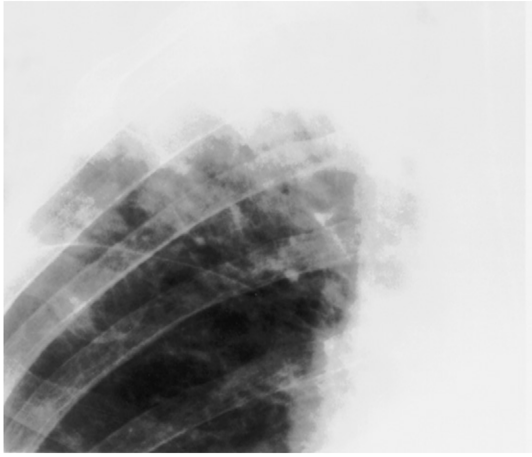

Figure 7-32 Acinar opacities seen at the periphery of confluent right upper lobe consolidation in a patient with tuberculosis. Note the elevation of the horizontal fissure.

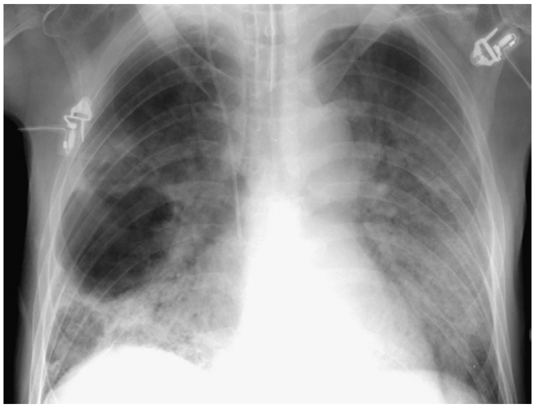

Figure 7-34 Large right lower lobe cavity in a patient with widespread pneumonic consolidation. In this radiograph obtained with the patient supine, an air-fluid level is not evident.

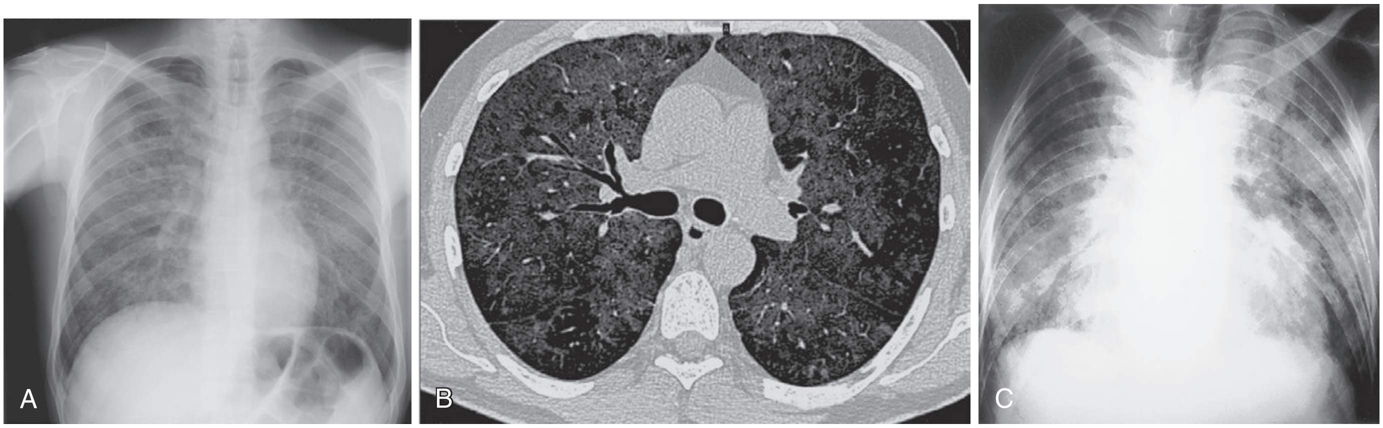

Figure 7-33 Ground glass opacification in the middle and lower zones associated with *Pneumocystis jiroveci* pneumonia. **A,** Chest radiograph shows perihilar poorly defined, increased (ground glass) density. The patient was a young man who was seropositive for human immunodeficiency virus (HIV) infection. **B,** High-resolution computed tomography image from the same patient demonstrates variable lung attenuation with markedly black airways highlighted by the ground glass patchy infiltrate. **C,** Diffuse and severe ground glass and air space infiltrate is seen on a chest radiograph obtained in a different patient with *P. jiroveci* pneumonia. *(**A,** Courtesy Dr. M. Taylor.)*

Cicatrization Collapse

The normal expansion of the lung, to contact the parietal pleura, depends on a balance between outward forces in the chest wall and opposite elastic forces in the lung. If the lung is abnormally stiff, this balance is disturbed, lung compliance is decreased, and the volume of the affected lung is reduced. Perhaps the best example of this phenomenon is volume loss associated with pulmonary fibrosis.

Adhesive Collapse

In the normal lung, the forces that govern surface tension become more pronounced as the surface area of the air space is reduced. Hence, the collapse of smaller airways and alveoli tends to occur at lower lung volumes—a tendency that is offset by surfactant, which reduces the surface tension of the fluid that lines the alveoli. This reduction usually is sufficient to overcome the tendency to collapse in the normal lung. However,

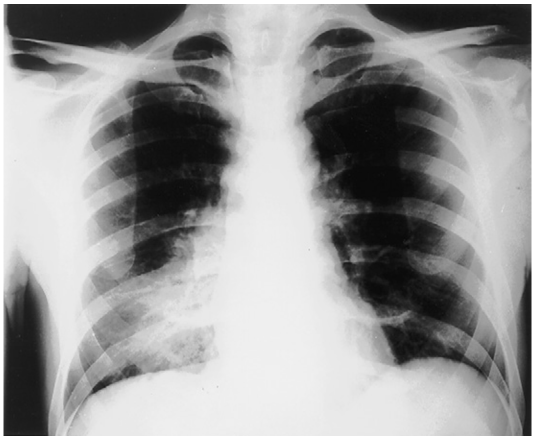

Figure 7-37 Right lower lobe consolidation. The right heart border is clearly defined. Because the consolidation is not complete, the hemidiaphragm has not been effaced.

if the mechanism is disturbed, as in respiratory distress syndrome, collapse of the alveoli occurs, and typically the larger airways remain patent.

Reabsorption Collapse

In acute bronchial obstruction, gases in the alveoli are steadily taken up by the blood in the pulmonary capillaries and are not replenished, leading to alveolar collapse. The degree of collapse may be counteracted by collateral air drift if the obstruction is distal to the main bronchus and also by infection and accumulation of secretions. If the obstruction becomes chronic, subsequent reabsorption of intraalveolar secretions and exudate may result in complete collapse—the usual mechanism of collapse seen in carcinoma of the bronchus. When the cause of collapse is a proximal obstructing mass, the S sign of Golden may be apparent. This sign refers to the S shape made by the relevant fissure as the distal part of a lobe collapses, but the proximal part of a lobe maintains its bulk because of the presence of a tumor.

Radiographic Signs of Lobar Collapse

The radiographic appearance in pulmonary collapse depends on a number of factors, including the mechanism of collapse, the extent of collapse, the presence or absence of consolidation in the affected lung, and the preexisting state of the pleura. This last factor includes the presence of underlying pleural tethering or thickening and the presence of pleural fluid. Preexisting lung disease, such as fibrosis and pleural adhesions, may alter the expected displacement of anatomic landmarks in lung collapse. An air bronchogram is rare in reabsorption collapse but is usual in passive and adhesive collapse and may be seen in cicatrization collapse if fibrosis is particularly dense.

Signs of collapse may be direct or indirect. *Indirect* signs are the result of compensatory changes that occur as a consequence of the volume loss. The *direct* signs of collapse include displacement of interlobar fissures, loss of aeration, and vascular and bronchial signs. Indirect signs include elevation of the hemidiaphragm, mediastinal displacement, hilar displacement, compensatory hyperinflation, and crowding of the ribs. There tends to be a reciprocal relationship between the individual compensatory signs of collapse, so with mediastinal shift to the side of collapse, significant diaphragmatic elevation is unlikely. For example, in lower lobe collapse, if hemidiaphragmatic elevation is marked, hilar depression is less marked.

Displacement of Interlobar Fissures Displacement of interlobar fissures is the most reliable sign, and the degree of displacement depends on the extent of collapse.

Loss of Aeration The increased density of a collapsed area of lung may not become apparent until collapse is almost complete. However, if the collapsed lung is adjacent to the mediastinum or diaphragm, the presence of the silhouette sign may indicate loss of aeration.

Vascular and Bronchial Signs If a lobe is partially collapsed, crowding of its vessels may be visible; also, if an air bronchogram is seen, the bronchi may appear to be crowded together.

Elevation of the Hemidiaphragm Elevation of the hemidiaphragm may be seen in lower lobe collapse but is uncommon in collapse of the other lobes.

Mediastinal Displacement In upper lobe collapse, the trachea often is displaced toward the affected side; in lower lobe collapse, the heart may be displaced to the same site.

Hilar Displacement The hilum may be elevated in upper lobe collapse and depressed in lower lobe collapse.

Compensatory Hyperinflation The remaining normal lung may become hyperinflated and thus may appear more transradiant, with the vessels more widely spaced than in the corresponding area of the contralateral lung. With considerable collapse of a lung, compensatory hyperinflation of the contralateral lung may occur, with herniation of lung across the midline.

Crowding of the Ribs On the side of the collapse, common radiographic features include narrowing of the intercostal spaces with crowding together of the ribs, which reflects the diminished overall volume of the affected hemithorax.

Complete Lung Collapse

With complete collapse of an entire lung (in the absence of an accompanying pneumothorax, large pleural effusion, or extensive consolidation), complete opacification of that hemithorax is seen, with displacement of the mediastinum to the affected side and elevation of the hemidiaphragm. Compensatory hyperinflation of the contralateral lung occurs, often with herniation across the midline. Herniation most often is in the retrosternal space, anterior to the ascending aorta, but may occur posterior to the heart (Figure 7-38).

Individual Lobar Collapse

The descriptions that follow apply to collapse of individual lobes, uncomplicated by preexisting pulmonary or pleural disease. The alterations in the positions of the fissures, mediastinal structures, and diaphragms are shown in Figures 7-39 to 7-43.

Right Upper Lobe Collapse As the right upper lobe collapses (see Figure 7-39), the horizontal fissure rotates around the hilum and the lateral end moves upward and medially toward the superior mediastinum. The anterior end moves upward, toward the apex. The upper half of the oblique fissure moves anteriorly. The two fissures become concave superiorly. In severe collapse, the lobe may be flattened against the superior mediastinum and may obscure the upper pole of the hilum. The hilum is elevated, and its lower pole may be prominent. Deviation of the trachea to the right is usual, and compensatory hyperinflation of the right middle and lower lobes may be apparent.

Middle Lobe Collapse In right middle lobe collapse (see Figure 7-40), the horizontal fissure and lower half of the oblique fissure move toward each other, a feature best seen on the lateral projection. Because the horizontal fissure tends to be more mobile, it usually shows greater displacement. On the frontal (anteroposterior) radiograph, changes associated with middle lobe collapse may be subtle, because the horizontal fissure may not be visible, and increased opacity does not become apparent until collapse is almost complete. Critical analysis of the radiograph sometimes reveals obscuration of the right heart border as the only clue. The lordotic anteroposterior projection is rarely required but may be used to bring the displaced fissure into the line of the x-ray beam and occasionally may elegantly demonstrate middle lobe collapse. Because the volume of this lobe is relatively small, indirect signs of volume loss are rarely obvious.

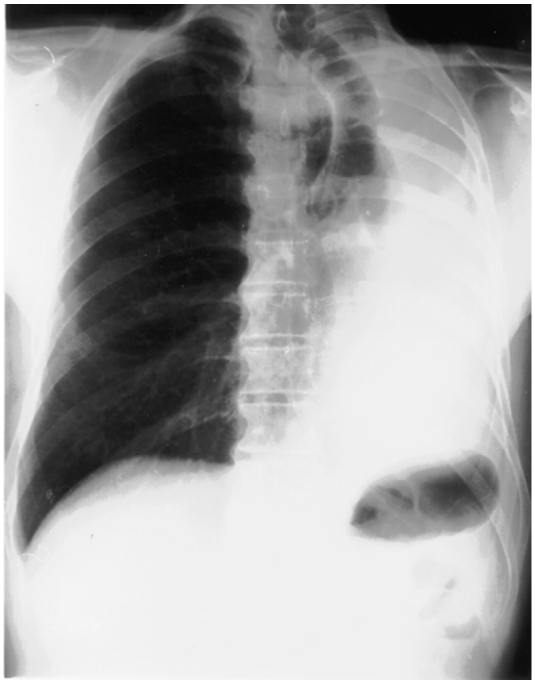

Figure 7-38 Collapse of the left lung. A proximal obstructing tumor is evident within the left main bronchus, with complete collapse of the left lung and a mediastinal shift to the left.

Left Lower Lobe Collapse In left lower lobe collapse (see Figure 7-41), the normal oblique fissures extend from the level of the fourth thoracic vertebra posteriorly to the diaphragm, close to the sternum anteriorly. The position of these fissures on the lateral projection is the best index of lower lobe volumes. When a lower lobe collapses, the oblique fissure moves posteriorly but maintains its normal slope. In addition to posterior movement, the collapsing lower lobe causes medial displacement of the oblique fissure, which may become visible in places on the frontal projection.

Right Lower Lobe Collapse Right lower lobe collapse (see Figure 7-42) causes partial depression of the horizontal fissure, which may be apparent on the frontal projection. Increased opacity of a collapsed lower lobe is usually visible on the frontal projection also. A completely collapsed lower lobe may be so small that it flattens and merges with the mediastinum to produce a thin, wedge-shaped shadow. In left lower lobe collapse, the heart may obscure this opacity, and a penetrated view may be required to demonstrate it. Mediastinal structures and parts of the diaphragm adjacent to the nonaerated lobe are obscured. When significant lower lobe collapse occurs, especially when the collapsed lobe is so small as to be invisible as a separate opacity, confirmatory evidence usually is apparent from close inspection of the relevant hilum. This area typically is depressed and rotated medially, with loss of the normal hilar vascular structures, which is made all the more obvious if a previous film is available for comparison. In addition, indirect signs of collapse, such as upper lobe hyperinflation, are present. Diaphragmatic elevation is unusual.

Lingula Collapse The lingula often is involved in collapse of the left upper lobe, but occasionally it may collapse individually, in which case the radiographic features are similar to those of middle lobe collapse. With absence of a horizontal fissure on the left, however, anterior displacement of the lower half of the oblique fissure and increased opacity anterior to it become important signs. On the frontal projection, the left heart border becomes obscured.

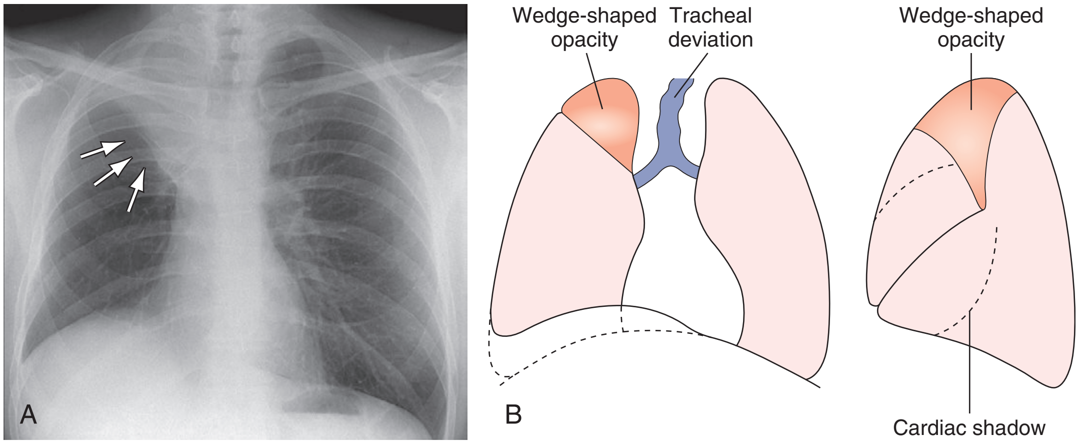

Figure 7-39 Right upper lobe collapse caused by a right hilum tumor. **A,** On the chest radiograph, the horizontal fissure takes on an S configuration, known as the S sign of Golden (*arrows*). **B,** Line diagram of pathoanatomic changes: *left*, frontal view; *right*, lateral view.

C

Figure 7-43 Left upper lobe collapse with shift of the mediastinum to the left and loss of definition of the mediastinal structures. **A,** In this patient, a large tumor *(arrow)* is causing left upper lobe and lingula collapse. The opacification fades out more inferiorly. **B,** Line diagram of pathoanatomic changes: *left*, frontal view; *right*, lateral view. **C,** In another patient, very tight left upper lobe collapse was due to a small tumor. The appearances are different, but volume loss is marked in both instances.

Left Upper Lobe Collapse The pattern of upper lobe collapse is different in the two lungs. Left upper lobe collapse (see Figure 7-43) is apparent on the lateral projection as anterior displacement of the entire oblique fissure, which becomes oriented almost parallel to the anterior chest wall. With increasing collapse, the upper lobe retracts posteriorly and loses contact with the anterior chest wall. With complete collapse, the left upper lobe may lose contact with the chest wall and diaphragm and retract medially against the mediastinum. On a lateral film, therefore, left upper lobe collapse is seen as an elongated opacity that extends from the apex and reaches, or almost reaches, the diaphragm; it is anterior to the hilum and is bounded by the displaced oblique fissure posteriorly and by the hyperinflated lower lobe.

A collapsed left upper lobe does not produce a sharp outline on the frontal view. An ill-defined, hazy opacity is present in the upper, middle, and sometimes lower zones, the opacity being densest near the hilum. Pulmonary vessels in the hyperinflated lower lobe usually are visible through the haze. The aortic knuckle typically is obscured, unless the upper lobe has collapsed anterior to it, in which case hyperexpansion of the lower lobe apical segment may occur, separating the collapsed upper lobe from the mediastinal silhouette and aortic knuckle. This separation produces an unusual-looking but characteristic medial crescent of lucency termed the Luftsichel sign. If the lingula is involved, the left heart border is obscured. The hilum often is elevated, and the trachea is deviated to the left.

Combined Lobar Collapses

Right Lower and Middle Lobe Collapse Because the right lower and middle lobes take their origin from the bronchus intermedius, an extensive lesion involving those sites may cause combined collapse. The radiographic appearance is similar to that in right lower lobe collapse (**Figure 7-44**), except that the horizontal fissure is not apparent, and the opacification reaches the lateral chest wall on the frontal view and similarly extends to the anterior chest wall on the lateral view.

Right Upper and Middle Lobe Collapse Combined collapse of the right upper and middle lobes is unusual because of the distance between the origins of their bronchi; it generally can be taken to imply the presence of more than one lesion. This combination produces appearances almost identical to those of left upper lobe collapse (**Figure 7-45**). On occasion, isolated right upper lobe collapse also produces appearances that are identical to those with left upper lobe collapse.

Rounded Atelectasis Rounded atelectasis is an unusual form of pulmonary collapse that may be misdiagnosed as a pulmonary tumor. The plain film will show an opacity that may

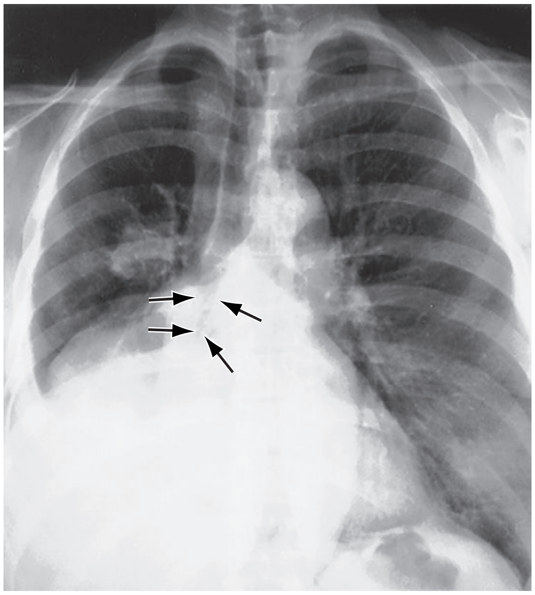

Figure 7-44 Right middle and lower lobe collapse caused by an obstructing lesion in the bronchus intermedius. A bronchial cutoff sign is visible (*arrows*). A separate pulmonary mass is present in the right upper lobe.

be several centimeters in diameter, frequently with ill-defined edges. Rounded atelectasis is always pleura-based and associated with pleural thickening. Vascular shadows may radiate from part of the opacity, said to resemble a comet's tail (Figure 7-46). The appearance is caused by peripheral lung tissue folding in on itself. Rounded atelectasis usually is related to previous asbestos exposure but also may be secondary to any exudative pleural effusion. It is not of any other pathologic significance, although when present often raises the question of a malignancy. The CT appearance usually is sufficiently diagnostic to allow differentiation from other pulmonary masses.

Unilateral Increased Transradiancy

The most common causes of increased unilateral transradiancy are technical factors, such as patient rotation, poor beam centering, or an offset grid. Usually, hypertransradiancy caused by technical factors can be identified by comparison of the soft tissues around the shoulder girdle and particularly over the axillae. Nevertheless, a number of pathologic causes of unilateral increased transradiancy are recognized.

Chest Wall A hemithorax may appear of increased transradiancy (blacker) if the x rays are less attenuated because of a reduction in the amount of overlying soft tissue. The most common cause for this appearance is a mastectomy. Rarely, the same phenomenon may be seen in patients who have congenital unilateral absence of pectoral muscles in Poland syndrome (Figure 7-47). This defect may be accompanied by associated skeletal abnormalities in the ipsilateral ribs but may be recognized by loss of the normal axillary skin fold.

Reduced Vascularity Interruption or significant reduction in the blood supply to one lung, either congenital or acquired, has increased transradiancy (Figure 7-48).

Lung Hyperexpansion If a lung is overexpanded because of either air trapping secondary to the presence of a foreign body or asymmetric emphysema, that hemithorax may demonstrate increased transradiancy. When the entire lung is affected, the hemithorax usually is relatively larger than the opposite side. However, the same phenomenon may occur with compensatory emphysema due to collapse or removal of an ipsilateral lobe. In this instance, the transradiant hemithorax may be of normal volume, and the presence of the increased transradiancy should prompt a search for other evidence of collapse or previous surgery.

A relatively increased transradiancy of one hemithorax with no obvious cause suggests the possibility of a generalized increase in radiopacity of the opposite side (for example, the posterior layering of a pleural effusion in a supine patient) (Figure 7-49).

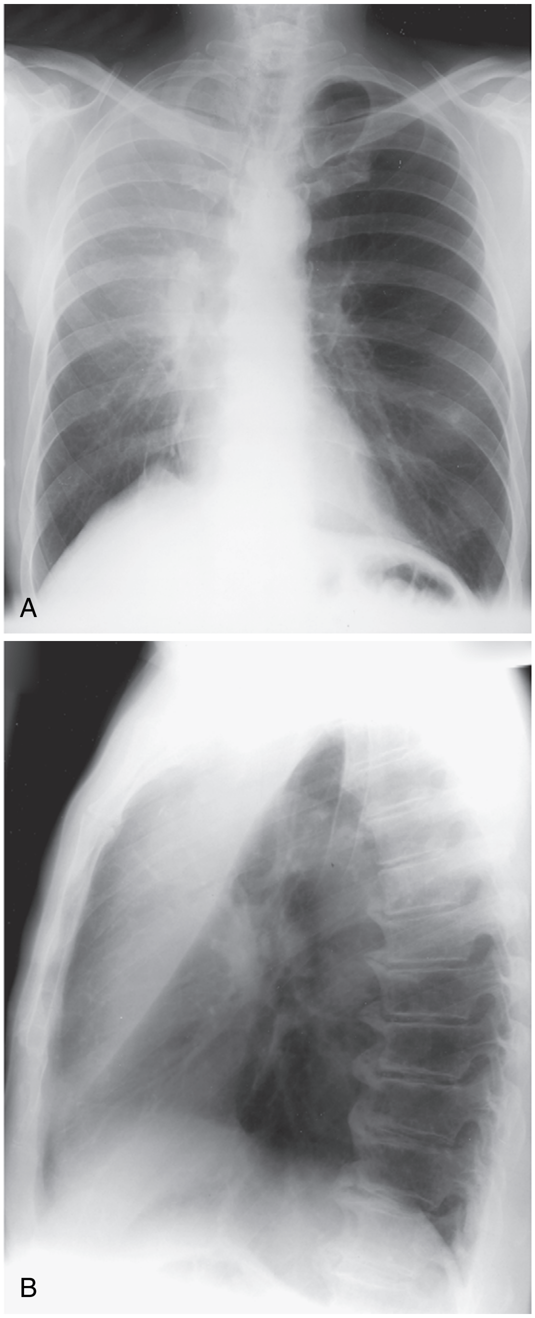

Figure 7-45 Occasionally, the combination of right middle and upper lobe collapse mimics left upper lobe and lingular collapse on the chest radiograph. Both posteroanterior (**A**) and lateral (**B**) views demonstrate changes similar to those seen on the opposite side. The major fissure shifts anteriorly and extends from the lung apex to the anterior costophrenic recess.

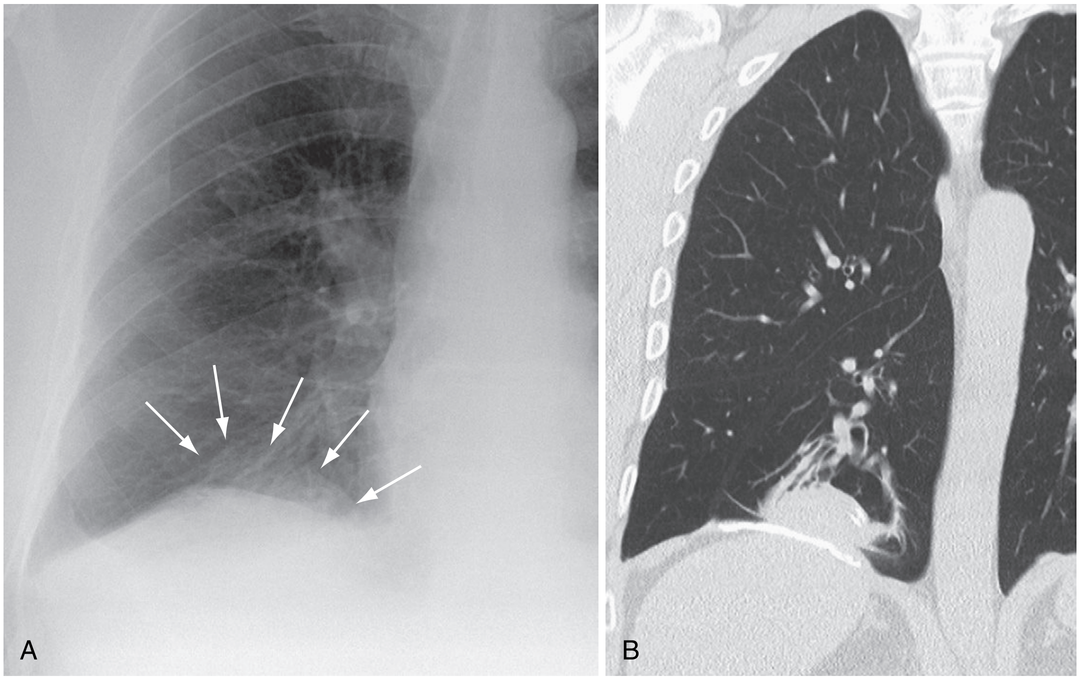

Figure 7-46 Rounded atelectasis. **A,** A poorly defined opacity is visible on the frontal radiograph (*arrows*). **B,** Coronal reformatted image from computed tomography scan reveals the characteristic pleurally based mass with radiating bronchovascular strands.

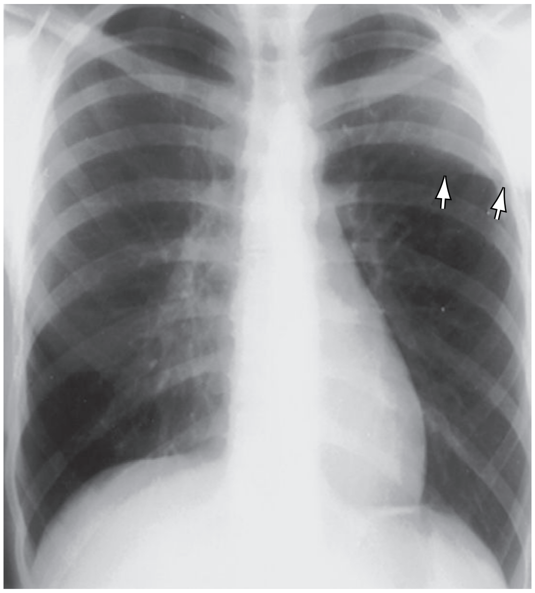

Figure 7-47 Congenital absence of the left pectoralis major muscle in Poland syndrome. In this patient, the muscle deficit was an incidental finding on a chest radiograph. Note the alteration in the left axillary skin fold compared with the right (*arrows*).

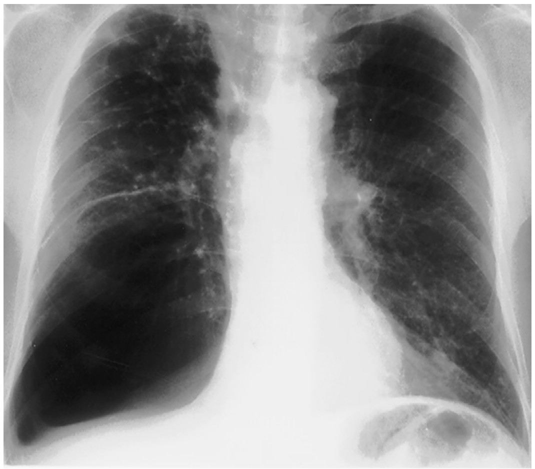

Figure 7-48 Increased transradiancy in the right lower lung zone. A large emphysematous bulla occupies the lower half of the right lung, and the apical changes are in keeping with previous tuberculosis.

The Pulmonary Mass

The finding of a solitary pulmonary nodule on the chest radiograph requires careful analysis, because the diagnostic possibilities are numerous. Once a pulmonary mass has been identified, the observer must decide first, if the lesion is genuine and second, whether the lesion is truly intrapulmonary. The possibility of a cutaneous lesion should not be overlooked, especially if only a part of the nodule is well defined. If doubt remains, repeat radiographs are obtained, with a lateral view and, if relevant, use of nipple markers. What appears at first glance to represent a solitary pulmonary mass may, on closer inspection, actually represent the most obvious of a number of pulmonary nodules. The radiology of multiple pulmonary nodules is discussed later.

When a pulmonary mass is clearly defined around its entire circumference and is projected over the lung on frontal and lateral projections, the mass is truly intrapulmonary (Figure 7-50). If a surface is in contact with another soft tissue structure, however, the possibility of an extrapulmonary mass projecting into the lung must be considered. Analysis of the breadth of the base of the lesion, the angle made with the adjacent structure, and the presence of bone destruction often allows the observer to differentiate an extrapulmonary mass that extends into the adjacent lung from an intrapulmonary mass that has grown to contact the mediastinum, diaphragm, or chest wall.

The analysis of a solitary pulmonary mass relies on a number of radiologic and clinical factors. The latter include patient age, geographic and ethnic origins, smoking history, and medical history. The likelihood that a pulmonary nodule represents a malignancy in a young nonsmoker who comes from an area in which histoplasmosis is endemic clearly is different from that for an elderly patient with a lifetime history of smoking.

Radiographic features of a pulmonary nodule that should be analyzed include size, density, margins, vascular markings, and growth rate.

Size

Generally, the likelihood of malignancy is greater with increasing size, although the opposite argument is not reliable.

Density

Most pulmonary masses are of soft tissue density. However, careful inspection must be made for the presence of calcification, because certain patterns of calcification are typical of benign lesions that may be safely observed rather than resected (Figure 7-51). A completely or centrally calcified nodule is diagnostic of a tuberculoma or histoplasmoma. Often, CT is required to confirm this pattern of calcification. Likewise, concentric rings of calcification are typical of healed histoplasmosis infection. Popcorn calcification, within the matrix of a pulmonary nodule, is highly suggestive of a hamartoma (Figure 7-52). Other forms of calcification do not reliably indicate whether a nodule is benign or malignant, and dystrophic calcification within a pulmonary malignancy is relatively common.

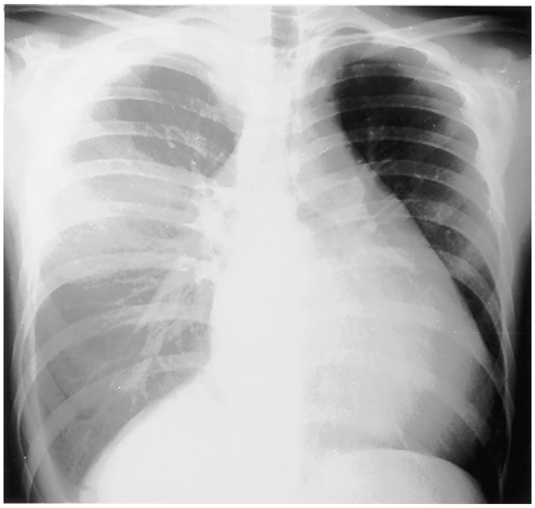

Figure 7-49 Supine radiographic view of a large right pleural effusion. The generalized increase in radiopacity of the right side is caused by posterior layering of a pleural effusion.

Margins

Perfectly smooth, round lesions are likely to be benign. This is not a completely reliable rule, however, because some primary lung malignancies and secondary deposits, particularly from soft tissue sarcomas, may be perfectly spherical. By contrast, lobulated or spiculated masses are much more likely to represent malignancy.

Vascular Markings

A rare, benign, but important cause of a pulmonary nodule is an arteriovenous malformation. The diagnosis may be suggested on the plain radiograph if a prominent feeding artery or draining vein is identified.

Growth Rate

Review of previous radiographs, when available, may establish whether a lesion is static or increasing in size. It is usual practice to express the growth of a pulmonary tumor in terms of the time taken for it to double in volume, which equates to an increase in diameter of 25%, assuming that the tumor is roughly spherical, as is usually the case. Tumors with a doubling time of less than 30 days or more than 2 years are very unlikely to result from malignancy. Often, however, no previous films are available, so the use of growth rate as a diagnostic aid is limited. Modern CT allows small pulmonary lesions to be followed over increasing intervals to confirm lack of growth. This is facilitated by the use of automated software that allows volumetric information to be derived from the CT dataset (Figure 7-53).

ENHANCEMENT CHARACTERISTICS

By the same token, it has been shown that failure of enhancement of a small lung mass after administration of a bolus of intravenous radiographic contrast also is a strong indicator of a benign histologic type and may strengthen the case for an observational approach to a small (1 to 3 cm) lung nodule in the low-risk patient.

When a solitary lung mass is evident on the chest radiograph, and no features suggest whether it is of benign etiology or a

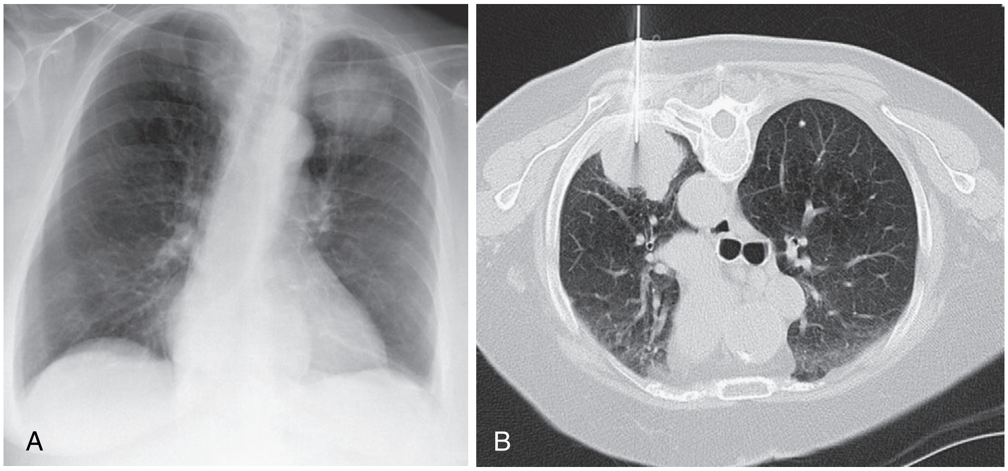

Figure 7-50 A rounded pulmonary mass. **A,** Posteroanterior chest radiograph obtained in a patient with a well-defined left upper lobe pulmonary mass. The entire circumference is visualized on the film, which shows minimal contact of the lesion with adjacent structures. **B,** Image obtained at computed tomography–guided needle biopsy demonstrates that the mass is largely surrounded by aerated lung.

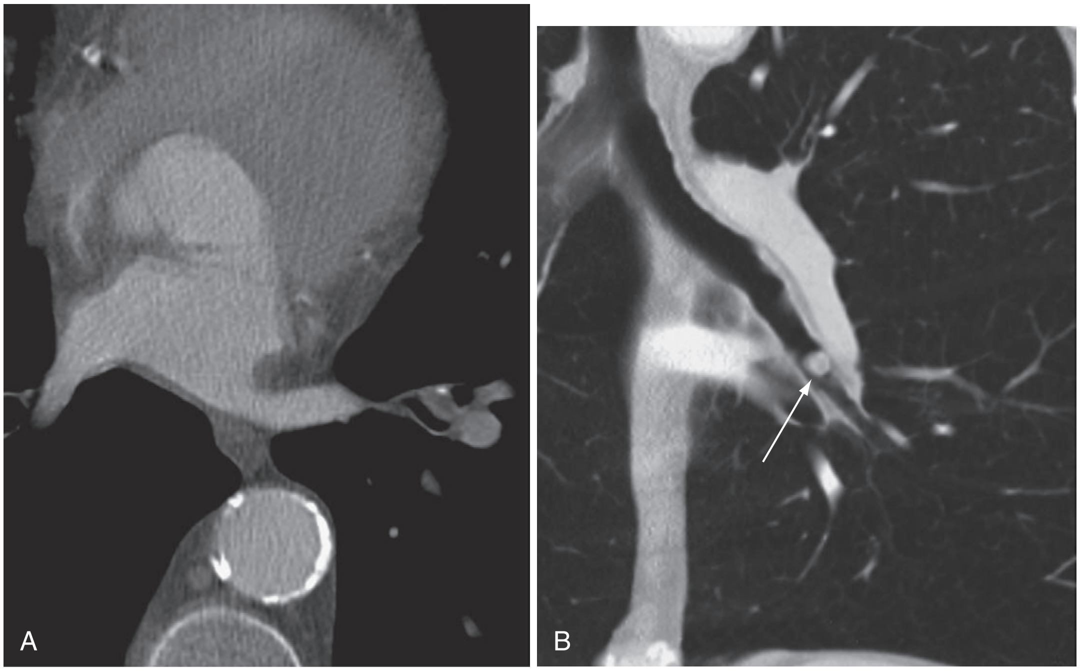

Figure 7-51 Fat and calcium density in a small endobronchial mass seen on computed tomography. A small lesion in the left lower lobe bronchus is evident on both axial (**A**) and coronal (**B**) reformatted images. This density (*arrow* in **B**) confirms that the lesion is a hamartoma.

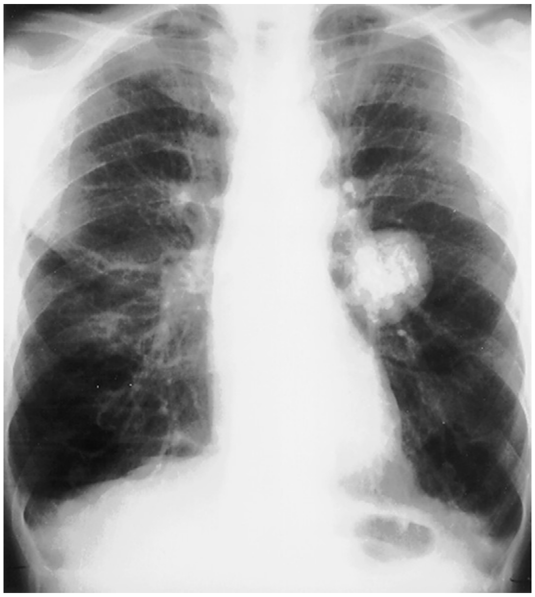

Figure 7-52 Pulmonary mass calcification. Posteroanterior chest radiograph shows a mass that projects over the left hilum. This is smoothly marginated and contains central popcorn calcification; it is unusually large but otherwise is a typical pulmonary hamartoma.

malignant lesion, it should be assumed to be a primary lung carcinoma until proven otherwise. In the assessment of a potential lung primary tumor, certain guidelines may be helpful.

Approximately half of primary lung carcinomas arise centrally in a proximal or segmental bronchus and as a result manifest as a hilar mass.

Because carcinoma of the bronchus arises in the bronchial mucosa, the tumor is likely to grow into the bronchial lumen and around the bronchus. As the bronchial lumen narrows, the distal lung may become consolidated and lose volume. Depending on the site of the tumor, a malignant solitary lung mass may be associated with lobar or segmental collapse (**Figure 7-54**) or even collapse of an entire lung (see Figure 7-38).

Peripheral tumors usually appear as solitary nodules or masses, but no features on plain films reliably differentiate a benign from a malignant pulmonary nodule. As described previously, malignant tumors often are larger, poorly defined, spiculated, or lobulated. Satellite opacities around a mass are more commonly seen with benign lesions, notably granulomatous diseases (see Figure 7-32). At least 5% of bronchial carcinomas cavitate as a consequence of central necrosis or abscess formation; the resultant cavity typically is thick-walled with an irregular inner margin (Figure 7-55). Peripheral tumors may invade the ribs or spine directly. Bone destruction must be specifically looked for and, when present, almost invariably indicates malignancy (Figure 7-56).

MULTIPLE PULMONARY NODULES

The differential diagnosis of multiple pulmonary nodules is wide in scope (Box 7-3), but analysis of the chest radiograph and a review of the clinical status of the patient will rapidly narrow the number of possibilities. Many of the radiographic features used in the analysis of the solitary pulmonary nodule can be used to advantage in the assessment of multiple lesions.

Radiographically, multiple nodules are described in terms of size, number, distribution, density, definition, cavitation, speed of growth (if serial films are available), and accompanying pleural, mediastinal, or skeletal abnormalities. Further important clinical clues may come from the clinical status of the patient. Specifically, evidence of infection, systemic illness, and previous malignancy is sought (Figures 7-57 to 7-60). Miliary nodules are a particular form of nodular shadowing. The term *miliary* derives from the resemblance in size and shape of the nodules to millet seeds, being round, well defined, and 2 to 3 mm in diameter. Although the description usually is associated with tuberculosis, this pattern of nodular infiltrate also may be due to histoplasmosis, organic and inorganic dust diseases, sarcoid, or metastases.

DIFFUSE SHADOWING

Many diseases cause diffuse lung shadowing on chest radiography. Careful analysis is required to correctly determine the nature of the abnormality and narrow the differential diagnosis. Appearances on the chest radiograph can be misleading, and the pattern of disease demonstrated at histopathologic examination or HRCT may differ considerably from the pattern of abnormality suggested by the chest radiograph. The summation of multiple small linear opacities on the chest radiograph may produce the appearance of multiple small nodules. Likewise, the superimposition of multiple small nodules may produce a granular or ground glass pattern. A variety of descriptive terms

are used in the analysis of a chest radiograph in this context, and frequently appearances are classified as being either interstitial or air space. A number of processes are capable of producing both patterns, however, so such classification may lead to erroneous narrowing of the differential diagnosis at an early stage of analysis. Thus, it is preferable to analyze the pattern in purely descriptive terms, such as reticular or nodular shadowing, to avoid this pitfall.

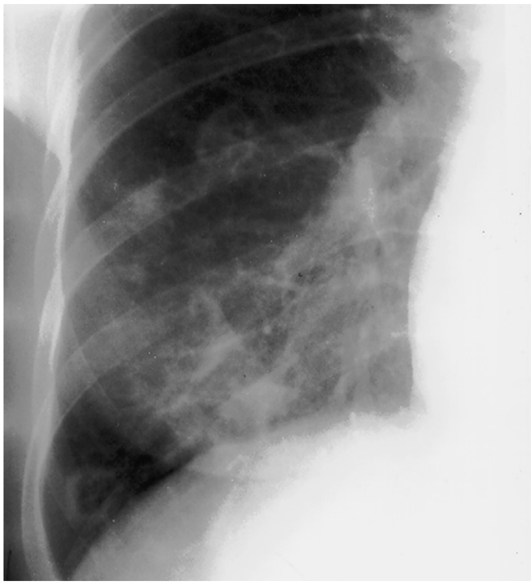

Figure 7-58 Magnified view of the right lower zone. The multiple pulmonary nodules are cavitating in this case of multiple staphylococcal abscesses in an intravenous drug abuser.

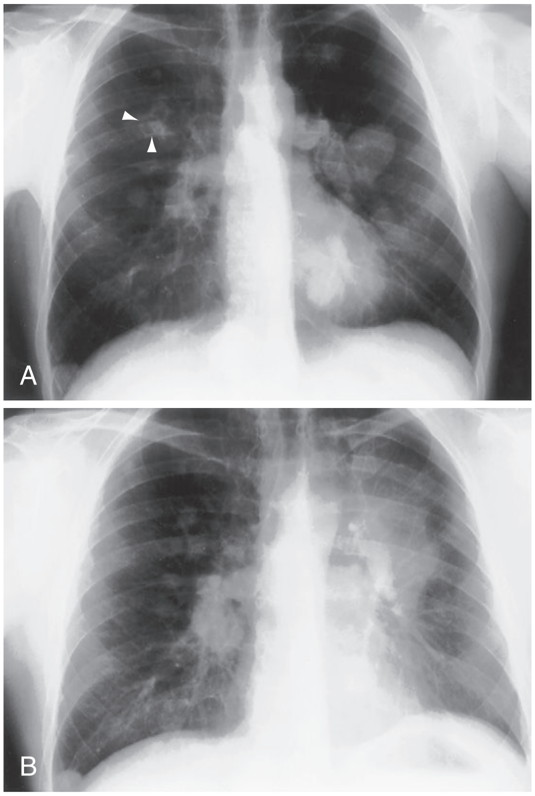

Figure 7-59 Multiple pulmonary nodules. **A,** On the initial chest radiograph, multiple pulmonary nodules are smoothly defined and of variable size; some are cavitating (*arrowheads*). **B,** Subsequent radiograph obtained within a few days of the initial film. The left perihilar nodules are no longer visible because they lie within the now collapsed left upper lobe. The patient proved to have multiple metastases from soft tissue sarcoma.

Reticular Shadowing

Reticular or linear shadowing (Figure 7-61) is made up of multiple, short, irregular linear densities, usually randomly oriented and often overlapping to produce a netlike pattern. When profuse, they may summate to form ring shadows or

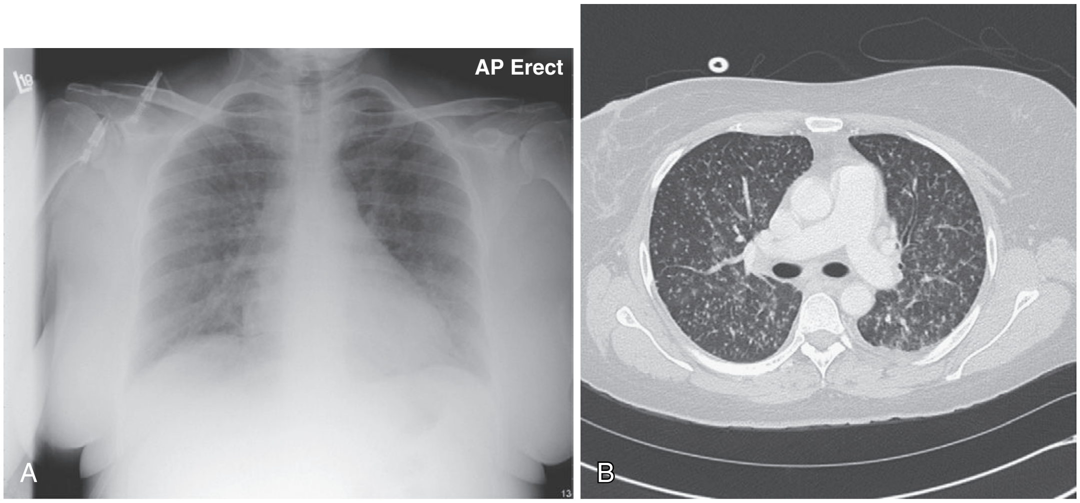

Figure 7-60 Miliary tuberculosis. **A,** Anteroposterior erect chest radiograph demonstrating innumerable 2- to 3-mm soft nodules. **B,** Computed tomography scan showing discrete miliary nodules.

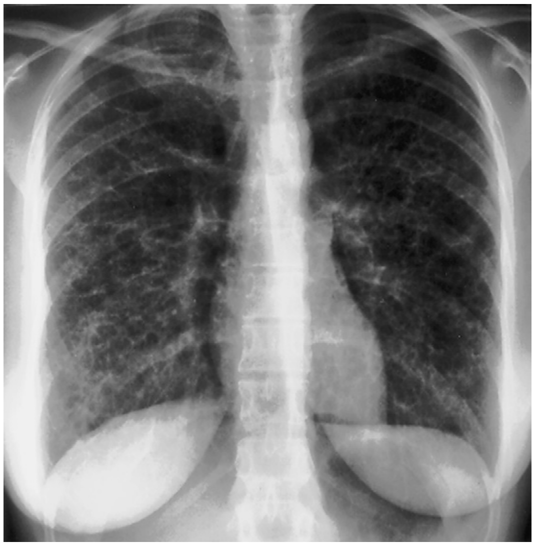

Figure 7-61 Extensive reticular infiltrate in lungs of normal volume. The patient had Langerhans cell histiocytosis.

sometimes a nodular pattern. Occasionally, the linear shadows may be oriented at right angles to the pleural surface, so-called Kerley B lines (Figure 7-62)—a feature that indicates thickening of the interlobular septa. When the linear opacities are extremely profuse or coarse, the impression of a ring or honeycomb pattern is typical.

Nodular Opacities

Nodules may be well or poorly defined and of varying density, ranging from soft tissue to calcific (Figure 7-63). They may be discrete or coalescent, with areas of confluence producing consolidation. When the nodules are greater than a few millimeters in diameter, the differential diagnosis changes. Larger discrete nodules were discussed previously.

Reticulonodular Shadowing

Often, it is impossible to confidently assign a pattern of diffuse shadowing to one of the two previously described categories, because they overlap. The reticulonodular pattern probably is the most common form of diffuse lung shadowing.

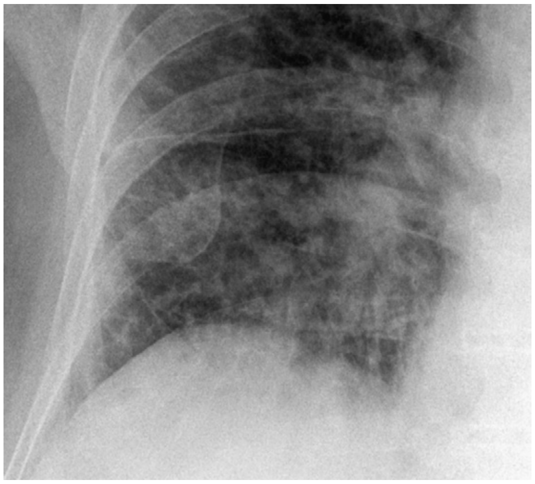

Figure 7-62 Kerley B lines in a patient with heart failure. Of note, the reticular opacities are oriented at right angles to the pleural surface.

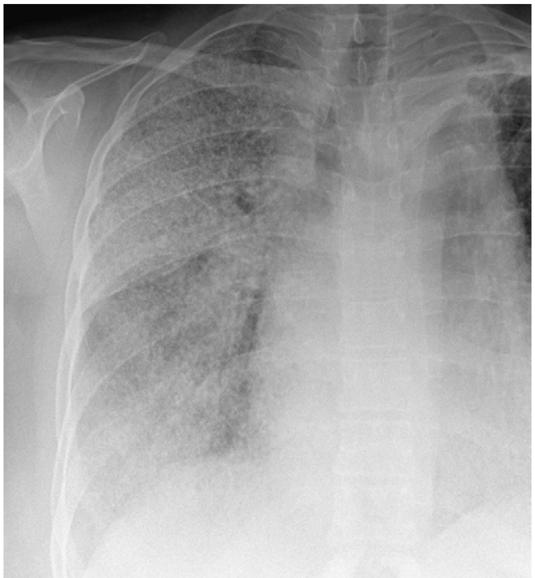

Figure 7-63 Very profuse nodular shadowing. The individual nodules are of high density. The patient had alveolar microlithiasis.

Ground Glass Shadowing

Ground glass shadowing (see Figure 7-33) refers to a generalized increase in density of the lung, which may be diffuse or patchy but most commonly is bilateral and in a middle and lower zone or perihilar location. The underlying vascular branching pattern is not totally obscured as it is in consolidation, but the vessels become less distinct; likewise, the hila and hemidiaphragms may appear less sharp. This subtle abnormality is considerably easier to appreciate with the benefit of a previous normal film for comparison.

In addition to determining the radiographic pattern of diffuse abnormality, a number of other features must be sought, including whether the distribution of disease is central or peripheral, in the upper, middle, or lower zone, and whether distortion of the lung architecture is present. Additional important features include signs of cardiac failure or fluid overload, such as increased heart size, equalization of upper and lower lobe vein size, and pleural effusions. Hilar or mediastinal enlargement caused by lymph node or vascular enlargement also should be specifically sought. In addition, the bones and soft tissues of the chest wall may provide important clues, such as evidence of previous breast surgery or an erosive arthritis. The accuracy of radiographic analysis is reduced in the absence of appropriate clinical information. For example, ascertaining whether the patient is well, acutely or chronically unwell, of normal immune status, or immunocompromised can dramatically narrow a wide range of possibilities in the radiologic differential diagnosis.

AIRWAY DISEASE

Plain tomography has been replaced by CT as the investigation of choice for the examination of airway abnormalities.

Tracheal Narrowing

Tracheal narrowing may be caused by an extrinsic mass, mediastinal fibrosis, or an intrinsic abnormality of the tracheal wall. Chronic inflammatory causes include fibrosing mediastinitis, sarcoidosis, chronic relapsing polychondritis, infection (**Figure 7-64**), and Wegener's granulomatosis. Primary tumors of the trachea are rare. Benign tumors manifest as small, well-defined, intraluminal nodules that are difficult or impossible to visualize on the chest radiograph. Malignant tumors of the trachea tend to occur close to the carina (**Figure 7-65**), although they may be quite extensive and cause a long stricture. Tracheal wall thickening and tracheal luminal narrowing can be detected on the plain chest radiograph, especially when specifically sought, but are best appreciated on CT (**Figure 7-66**). The right lateral

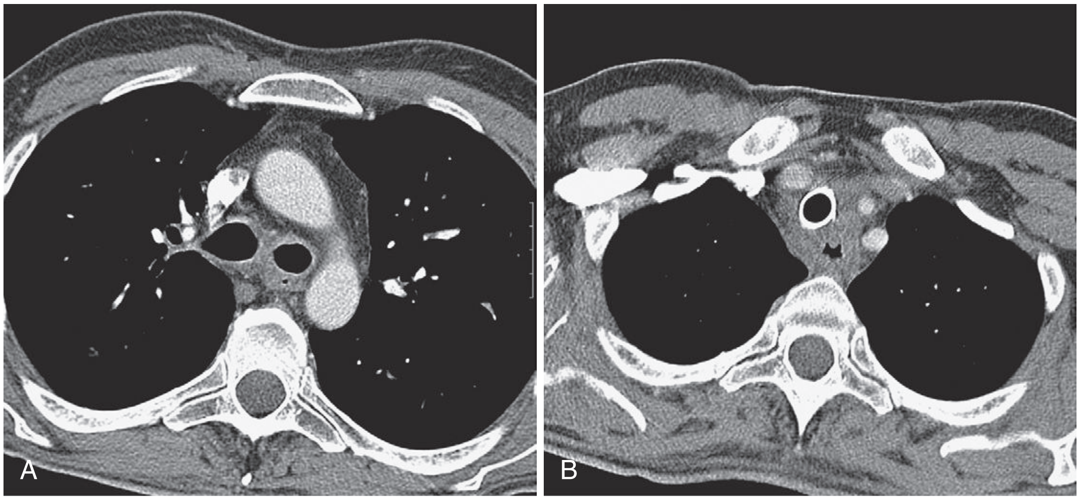

Figure 7-64 **A,** Diffuse wall thickening is present in the left and right main bronchi, just below the level of the carina. **B,** Diffuse tracheal wall thickening is evident at the high level, where a silicone stent is in place.

wall of the trachea (the right paratracheal stripe) above the level of the azygos vein, typically is a 2-mm-thick soft tissue stripe, and tracheal wall thickening can be detected on the plain radiograph if this portion of the airway is involved.

Tracheal Widening

The normal dimensions of the trachea have been assessed by use of a variety of techniques, most recently CT. The trachea becomes slightly larger with increasing age. On CT scanning, the maximal coronal diameter of the trachea is 23 mm in a man and 20 mm in a woman. Dilatation of the trachea is rare and may result from a generalized defect of connective tissue.

Mounier-Kuhn syndrome is the condition that causes the most dramatic tracheal dilatation (Figure 7-67). It is extremely rare and was first described in 1932. On the plain radiograph, shift of the right paratracheal stripe to the right often is the only sign of tracheal widening, and because the trachea frequently is not central in location, tracheal widening can be recognized only if the left wall of the trachea also is identified. The Mounier-Kuhn syndrome is underreported because it may go undiagnosed—clinical signs and symptoms are similar to those of chronic bronchitis, COPD, or bronchiectasis. Other features include marked dilatation of the trachea and major bronchi associated with repeated respiratory infections and copious sputum production. CT scans demonstrate tracheobronchial dilatation; some will often reveal parenchymal scarring secondary to chronic infection. Bronchoscopy demonstrates dilated central airways with thickened walls. Dilatation results in ineffective mucociliary expectoration, and the subsequent chronic inflammation contributes to the cycle of infection and continued inflammation, leading to bronchiectasis and recurrent pneumonia and the development of emphysema.

Histopathologic inspection reveals loss of cartilage and muscle within the airway walls associated with dilatation and saccular diverticulosis. There may be associated connective tissue diseases such as Ehlers-Danlos syndrome in adults and cutis laxa in children. Airways usually return to normal caliber at the fourth or fifth bronchial generation. In some cases, the disease may be acquired, because a complete absence of symptoms until the third or fourth decade of life has been described.

The chest radiograph often is reported to be normal even when extensive disease is evident on CT. Management options are limited, because the central airway involvement prevents extensive surgical intervention. Postural drainage and antibiotic therapy are necessary, in parallel with other forms of bronchiectasis. In some reported cases, bronchoscopy was used to clear secretions, tracheostomy has been necessary, and transplantation has been attempted.

Another unusual form of airway dilatation was described by Williams and Campbell. All patients presented in early childhood with symptoms of cough and wheezing and recurrent pulmonary infections. On examination, the chest was barrel-shaped, and inspiratory and expiratory wheezes and clubbing were noted. In this original cohort, plain radiography and

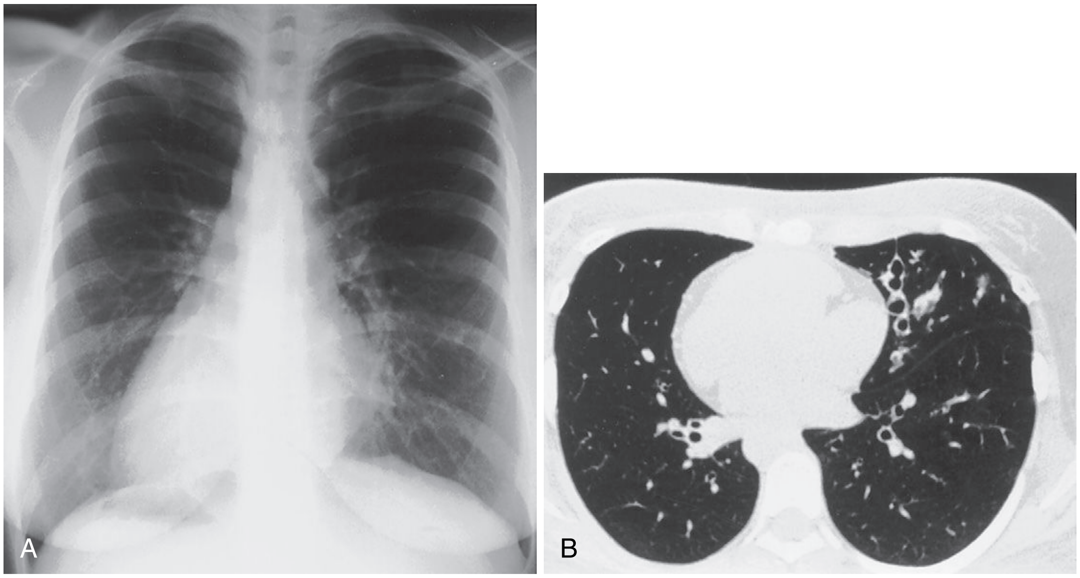

Figure 7-68 Bronchiectasis. **A,** The chest radiograph of a patient with primary ciliary dyskinesia. Dextrocardia is obvious. Some questionable bronchial wall thickening adjacent to the left heart border is obscured. **B,** The changes of bronchiectasis are much more convincingly demonstrated on high-resolution computed tomography.

bronchography demonstrated thin-walled cystic bronchiectasis and ballooning of more peripheral airways on inspiration with collapse on expiration. Inspiratory and expiratory CT images have proved useful in the diagnosis of this syndrome in more recent reports.

Bronchiectasis

The chest radiograph is relatively insensitive for the detection of bronchiectasis, and in most series, a significant proportion of plain radiographs obtained in patients with clinical bronchiectasis are judged to be normal (Figure 7-68). The use of HRCT is discussed later on; this modality is now the investigation of choice for bronchiectasis. Abnormalities present on the chest radiograph are as follows.

Bronchial wall thickening is evident as parallel, linear opacities radiating from the hilum, with lack of the normal convergence more peripherally. Ring shadows occur when the dilated airway is seen end on, may be thick- or thin-walled, and may contain secretions that produce an air-fluid level. Bronchiectatic airways that become plugged with secretions may produce tubular, soft tissue density opacities radiating from the hilum, more commonly in the lower lobes.

Distortion of the lobar anatomy with volume loss and crowding together of bronchovascular structures may be an associated finding. However, patients who have cystic fibrosis, also characterized by bronchiectasis, may have significant air trapping, which results in overexpansion. Even severe bronchiectasis may be invisible within a completely collapsed lobe.

Cylindrical (or tubular) bronchiectasis produces a dilated bronchus with parallel walls, in varicose bronchiectasis the walls are irregular, and in saccular (or cystic) bronchiectasis the airways terminate as round cysts. In an individual patient, presence of more than one pattern is typical. Bronchiectasis usually involves the peripheral bronchi more severely than the central bronchi. Although it has long been held that in allergic bronchopulmonary aspergillosis, this pattern may be reversed, overall the distribution and morphology demonstrated by CT give no more than a clue to the underlying etiology.

MEDIASTINAL ABNORMALITIES

The normal radiographic anatomy of the mediastinum was discussed earlier in this chapter. When a mediastinal abnormality is present on the posteroanterior radiograph, a lateral view should be obtained to aid anatomic localization. Today, the imaging of mediastinal masses depends heavily on CT scanning, which is discussed elsewhere. However, a familiarity with normal anatomy is required to detect mediastinal masses that at first appear as a subtle distortion of the normal mediastinal contours. A considerable volume of mediastinal tumor or lymph node enlargement may be present despite a normal appearance on the chest radiograph.

The most common cause of mediastinal enlargement visible on the chest radiograph in children is the normal thymus, which may enlarge and contract in certain disease states but typically remains relatively prominent, especially on CT scans, until puberty (Figure 7-69). Lymphadenopathy, tumor, hiatal hernia, and vascular abnormalities account for most mediastinal masses seen in adults.

Mediastinal Lymphadenopathy

Lymph nodes are present in all compartments of the mediastinum but are visible on the chest radiograph only when they are calcified or enlarged. Causes of mediastinal nodal enlargement are discussed elsewhere. The chest radiograph is a relatively insensitive indicator of lymphadenopathy. Enlargement of right paratracheal nodes is identified more easily than that of left paratracheal nodes, aortic-pulmonary nodes, and subcarinal lymphadenopathies (Figure 7-70). Barium swallow is a simple method of identifying some cases of subcarinal lymphadenopathy, but CT is the most comprehensive and accurate method of assessing mediastinal nodes.

Abnormalities of the Thoracic Aorta

The thoracic aorta arises in the middle mediastinum and then arches through the anterior, middle, and posterior mediastinal compartments. The greater vessels arise from the aortic arch in the superior mediastinum (Figure 7-71). Dilatation or tortuosity of the aortic arch or its branches may cause widening of the

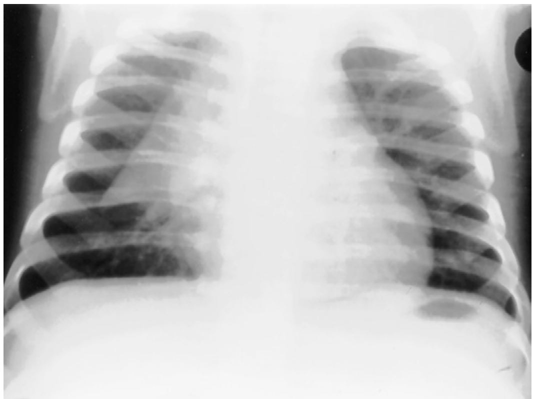

Figure 7-69 A prominent but normal thymic silhouette in an infant. Note the characteristic sail shape of the thymus as it projects over the right lung and the typically slightly lobulated contour as it conforms to the overlying ribs.

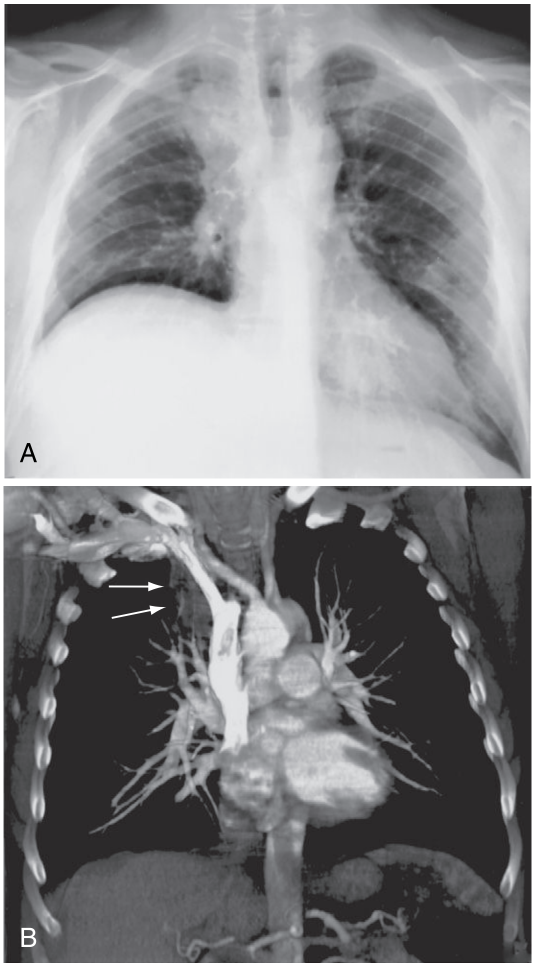

Figure 7-70 Right paratracheal lymph node enlargement caused by bronchogenic carcinoma. **A,** A right phrenic nerve palsy results in elevation of the right hemidiaphragm. **B,** Coronal volume-rendered slab image from a multidetector computed tomography machine obtained in a different patient. As in **A,** right paratracheal lymph node enlargement (*arrows*) abuts but does not distort the right brachiocephalic vein and superior vena cava.

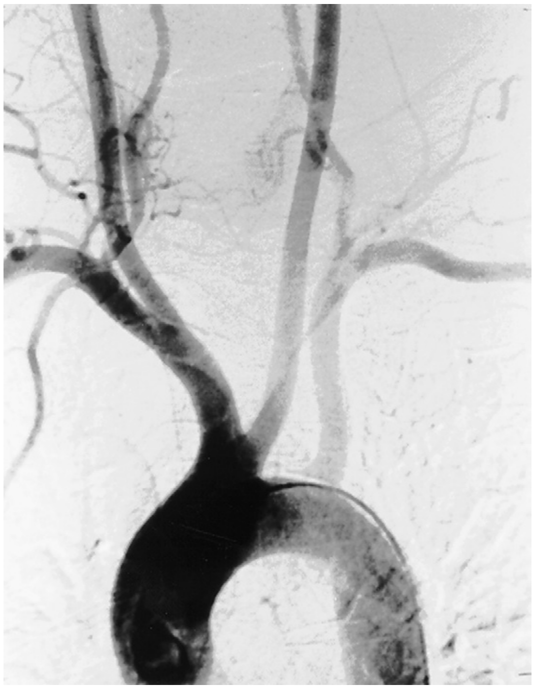

Figure 7-71 Digital subtraction arch aortogram. Two vessels can be seen arising from the arch—a common variant of the normal three-vessel anatomy. The image was obtained with the patient in a 30-degree left anterior oblique position.

mediastinal shadow. So-called unfolding of the aorta is a common chest radiographic finding in elderly or hypertensive patients. Aneurysm of the aorta most often results from atherosclerosis (Figure 7-72). Cystic medial necrosis (Marfan syndrome), infection (mycotic aneurysm), syphilitic aortitis, and a history of trauma are less common causes. Most aortic aneurysms are asymptomatic and manifest as mediastinal opacities on the radiograph, sometimes with curvilinear calcification visible in the wall. Aneurysms of the ascending aorta are best appreciated on the lateral radiograph as a filling in of the retrosternal window. Aneurysms of the arch and descending aorta frequently are evident on the frontal radiograph, but a lateral view often is required for more accurate localization, and cross-sectional imaging may be warranted to confirm that the mediastinal abnormality in question is of vascular origin.

In the acutely injured patient, traumatic aortic rupture may be suspected from the appearance on the chest radiograph, and confirmation of injury usually requires angiography (Figure 7-73). When the chest radiographic findings are equivocal, however, in concert with a degree of trauma less than that usually associated with aortic injury, a spiral CT scan may be performed in the stable patient to exclude a mediastinal hematoma. If any doubt remains, the patient should proceed to angiography. If the aortic injury remains undetected and the patient survives, an aneurysm secondary to the trauma may develop subsequently. Such lesions almost always are confined to the junction of the aortic arch and descending aorta. Aortic abnormalities may produce remodeling due to chronic pressure in adjacent skeletal structures.

Aneurysm of the ascending aorta may be associated with erosion of the posterior surface of the sternum, and descending aortic aneurysms may cause scalloping of the spine. Tortuosity of the innominate artery is a common cause of widening of the superior mediastinum in elderly persons. Right-sided aortic arch (Figure 7-74) and pseudocoarctation of the aorta are two anomalies that may alter the appearance of the mediastinum, suggestive of a mass.

Abnormalities of the Esophagus

Abnormalities of the esophagus are relatively common. They include infection and inflammation, trauma and perforation,

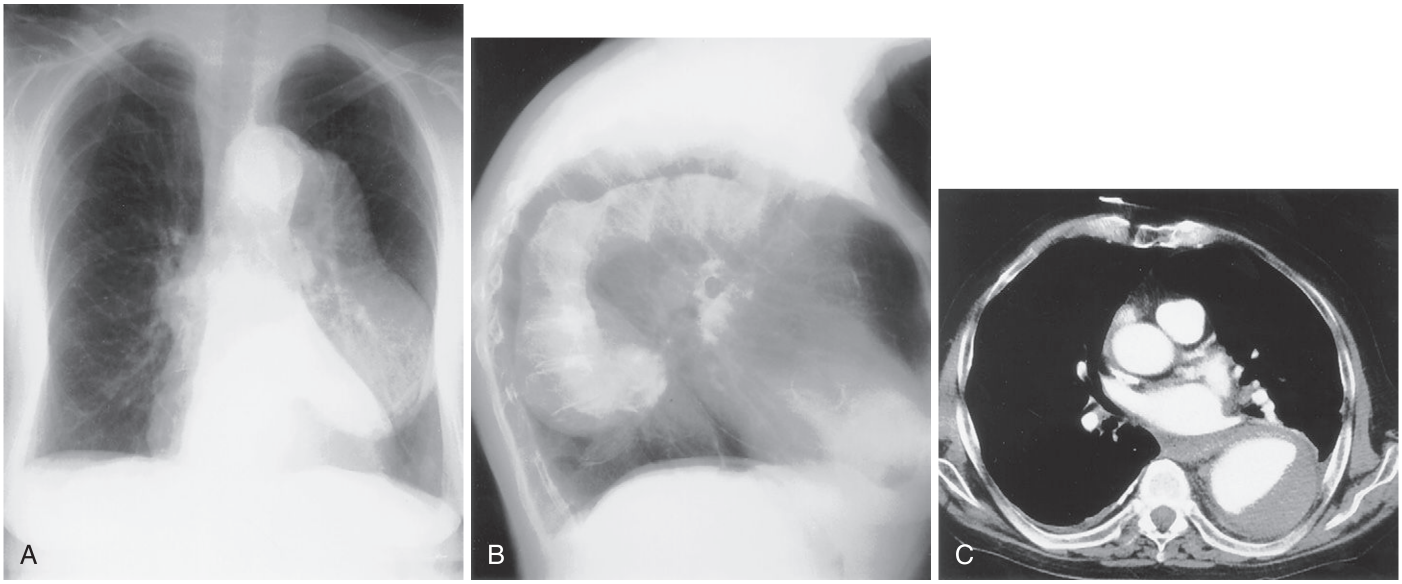

Figure 7-72 Thoracic aortic aneurysm. **A,** On the posteroanterior radiographic view, marked dilatation and tortuosity of the descending thoracic aorta are present. Of note, the left heart border is still evident, indicating the abnormality is likely to lie in the posterior thorax. **B,** Lateral view in the same patient demonstrates that the aneurysm involves the posterior arch and descending thoracic aorta. Note calcification within the ascending aorta. **C,** Computed tomography scan demonstrating extensive mural thrombus.

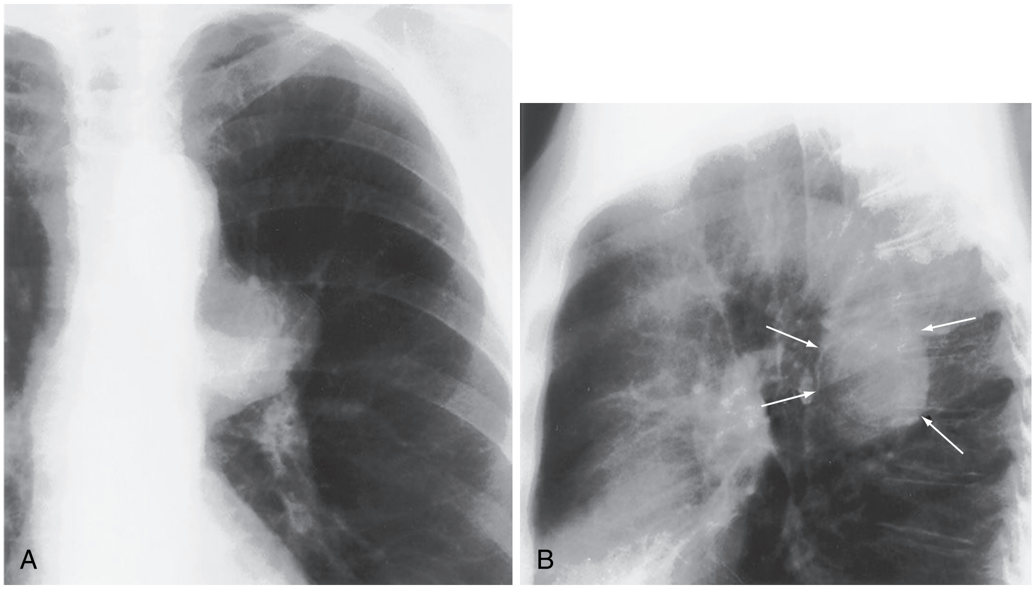

Figure 7-73 Traumatic aortic aneurysm. **A,** On the posteroanterior radiographic view, a soft tissue density mass projects over the left hilum. Of note, the left lower lobe artery is still visible through this mass, indicating that it is separate from the hilum. The medial surface blends smoothly with the mediastinal structures, indicating that it is likely to be extrapulmonary. **B,** The lateral view confirms presence of an aneurysm secondary to previous trauma at the typical site, the junction of the posterior arch and descending thoracic aorta (*arrows*).

and benign and malignant neoplastic processes. Esophageal abnormalities may be associated with diseases that also involve the lungs. Such conditions are best exemplified by achalasia of the cardia (Figure 7-75) or systemic sclerosis (Figure 7-76), in which esophageal motility disorders resulting in significant dilatation and reflux may be encountered in conjunction with pulmonary fibrosis and the sequelae of recurrent aspiration.

Dilatation of Central Veins

The superior vena cava and the azygos vein may dilate because of increased pressure, increased flow, obstruction, or congenital abnormality. Increased flow in the superior vena cava is seen with supracardiac, total, anomalous pulmonary venous drainage (Figure 7-77), and in the azygos vein, with congenital absence of the inferior vena cava. Rarely, aneurysmal dilatation of the superior mediastinal veins produces an abnormal mediastinal silhouette. Likewise, obstruction of the superior vena cava may cause dilatation of the great veins in the superior mediastinum, which results in widening of the mediastinal contour. However, the clinical features are likely to be obvious by the time radiographic abnormalities become significant.

Other Mediastinal Abnormalities

Pneumomediastinum or *mediastinal emphysema* is the presence of air between the tissue planes of the mediastinum. This condition may be secondary to interstitial pulmonary emphysema

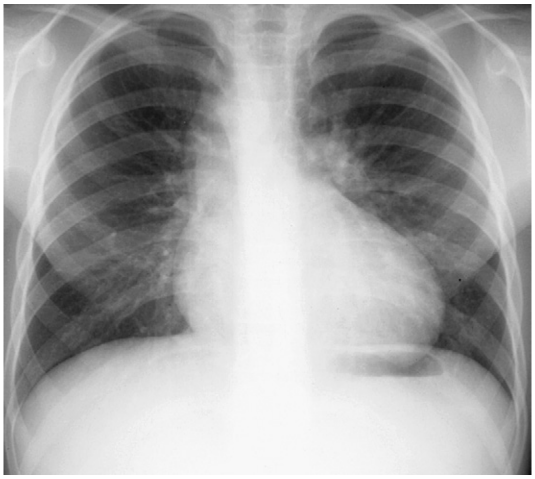

Figure 7-74 Tetralogy of Fallot. A right-sided aortic arch can be seen, in addition to elevation of the ventricular apex secondary to developing ventricular hypertrophy. Note the relatively oligemic lungs.

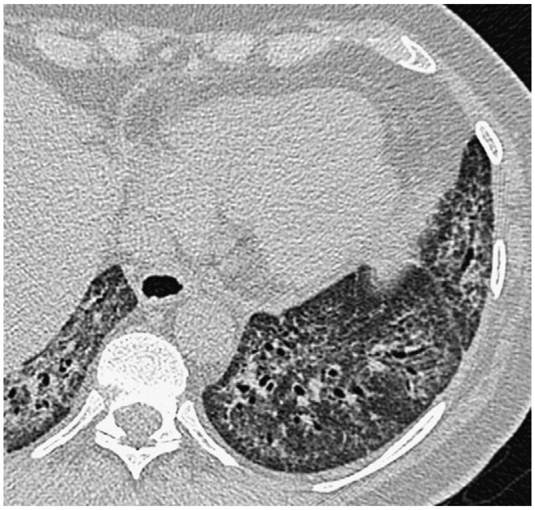

Figure 7-76 Systemic sclerosis with esophageal involvement. HRCT scan shows a coarse bibasal reticular infiltrate with marked traction bronchiectasis. In addition, the esophagus is moderately dilated and contains an air-fluid level.

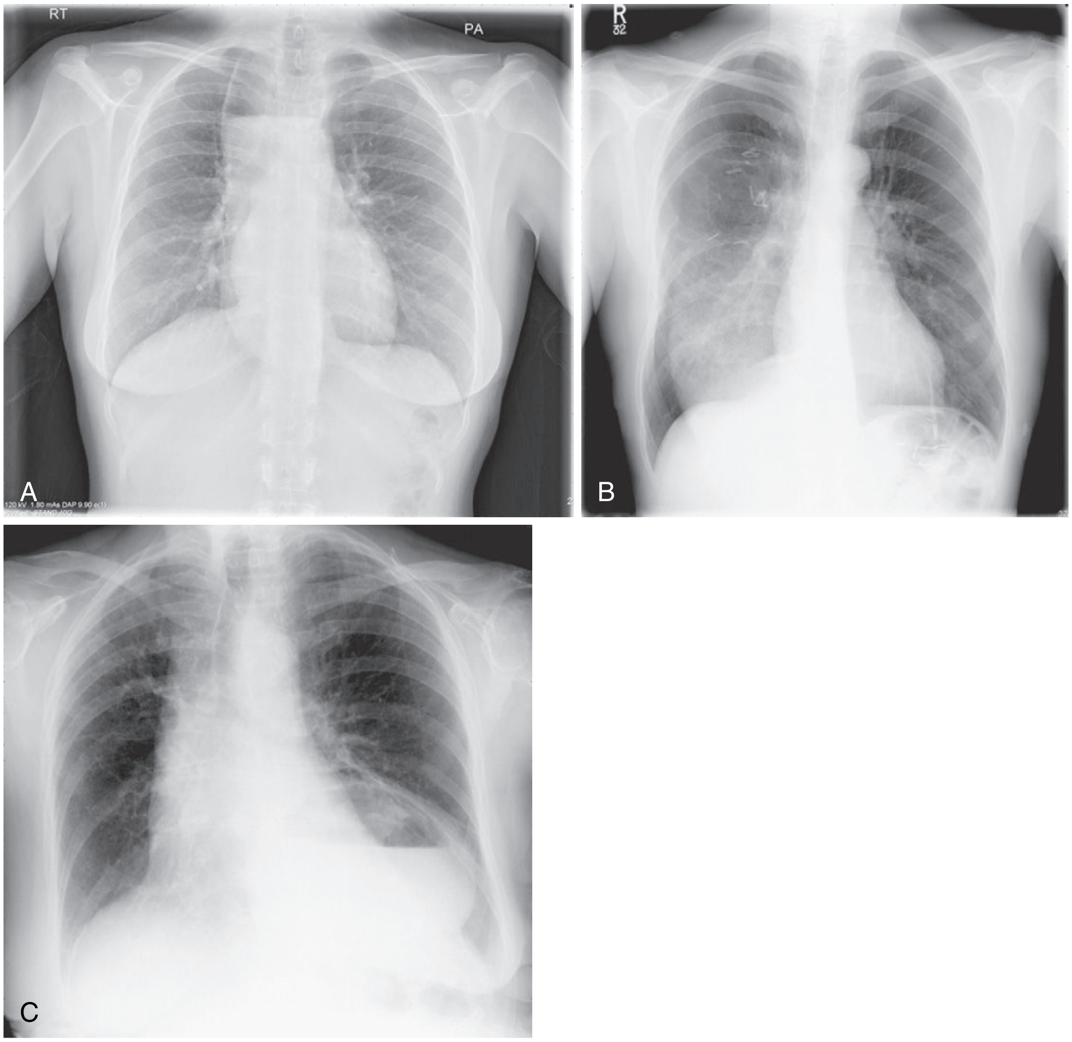

Figure 7-75 Esophageal and gastric intrathoracic abnormalities. **A,** Achalasia of the cardia. The esophagus is empty, but its lateral walls are seen running up the mediastinum. **B,** Chest radiograph obtained in a patient who had a gastric pull-up subsequent to esophagectomy. The wall of the stomach is seen near the right chest wall margin. The stomach contains solid matter in its lower part and mainly air in its upper part. The missing rib was resected for the necessary surgery. **C,** Large hiatal hernia with fluid level more or less overlying the heart. No stomach bubble is seen on the chest film obtained in the conventional site, and the left hemidiaphragm is poorly demarcated. *(**B** and **C** Courtesy of Dr. M. Taylor.)*

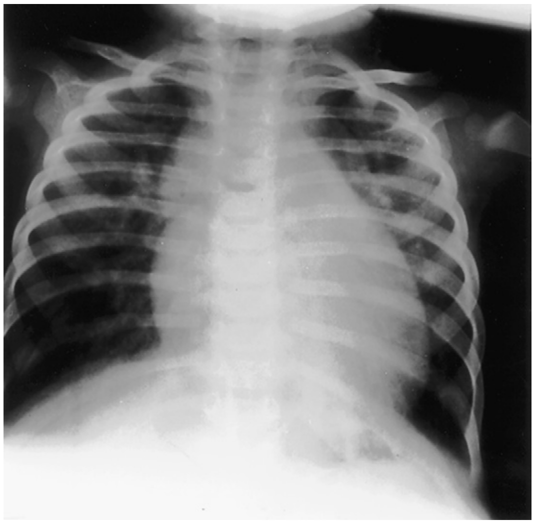

Figure 7-77 Total anomalous pulmonary venous drainage. Widening of the superior mediastinum on the chest radiograph is caused by dilatation of the superior vena cava.

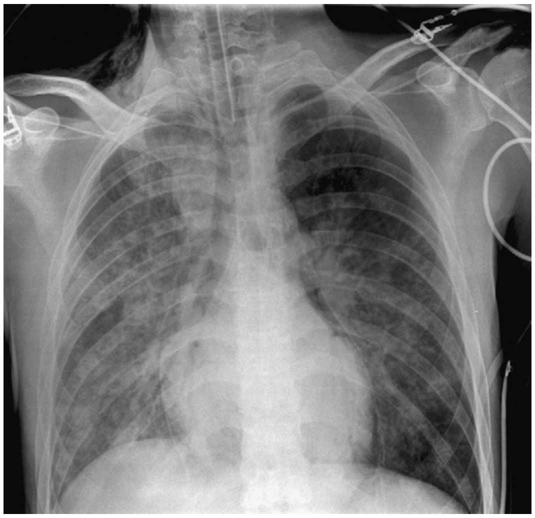

Figure 7-78 Pneumomediastinum. Air separates the tissue planes within the mediastinum and extends into the soft tissues of the neck and chest. A left-sided intercostal drain is in situ. *(Courtesy Dr. M. Taylor.)*

(most often caused by mechanical ventilation); to perforation of the esophagus, trachea, or a bronchus; or to a penetrating chest injury. Chest radiography may show vertical, translucent streaks in the mediastinum, which represent the soft tissue planes separated by air (Figure 7-78). The air may extend up into the neck and over the chest wall (causing subcutaneous emphysema) and also over the diaphragm. The mediastinal pleura may be displaced laterally and then become visible as a thin stripe alongside the mediastinum.

Acute mediastinitis typically is caused by perforation of the esophagus, pharynx, or trachea, and a chest radiograph usually shows widening of the mediastinum. A pneumomediastinum often is apparent, and air-fluid levels may be visible in the mediastinum. Chronic or fibrosing mediastinitis usually manifests as SVCO. Mediastinal hemorrhage may occur from venous or arterial bleeding. The mediastinum appears widened, and blood may be seen to track over the lung apices. It is obviously imperative to identify a life-threatening cause such as aortic rupture.

HILAR ABNORMALITIES

Having identified a hilar abnormality, the observer must differentiate between a vascular and a nonvascular cause. Vascular prominence often is bilateral and accompanied by enlargement of the main pulmonary artery (Figure 7-79). Although the hila are large, they are of relatively normal density, and it usually is possible to trace the pulmonary artery branches in continuity from the adjacent lung to their point of convergence with the interlobar arteries, known as the *hilar convergence sign*. By comparison, enlargement caused by lymph nodes or hilar tumor generally produces a lobulated hilar contour, with discernible lateral or inferior borders. Frequently, the normal hilar point is obliterated, and on the left, the aortopulmonary angle is filled in (Figure 7-80).

Occasionally, a pulmonary lesion is superimposed directly on the hilum on the frontal radiograph, which produces a spuriously large or dense hilum. The true position of the abnormality is revealed on the lateral radiograph (see Figure 7-72). A further pitfall arises when the vessels to the lingula or, more

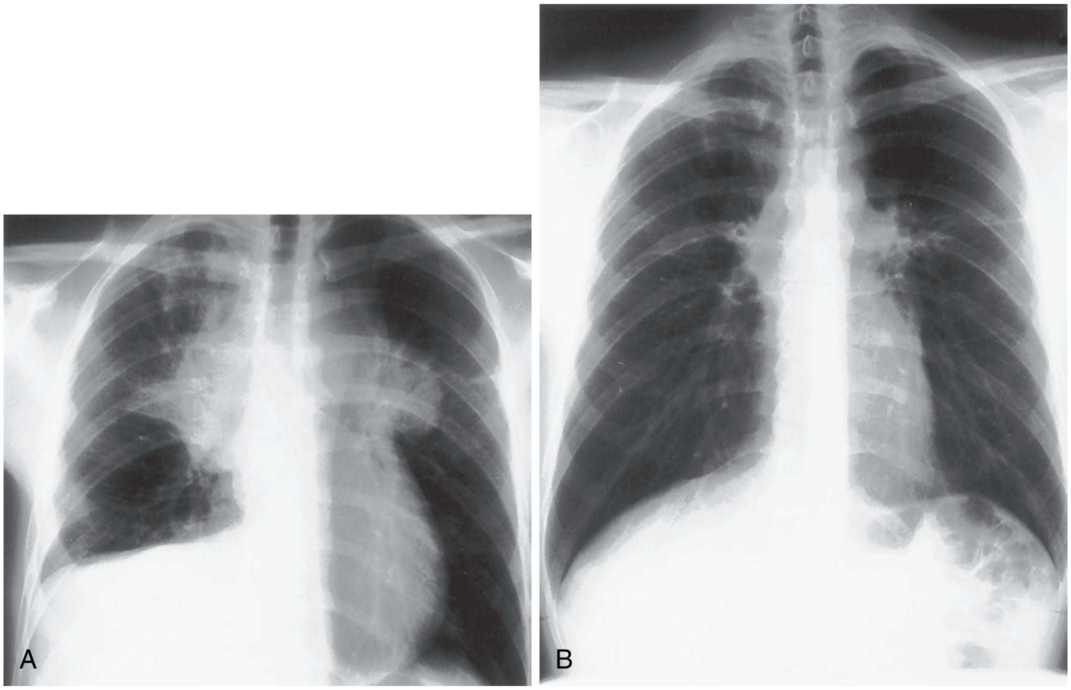

Figure 7-80 Non-Hodgkin lymphoma. **A,** Bilateral hilar lymph node enlargement, with obliteration of the normal aortopulmonary angle and subcarinal nodes. A right-sided pleural effusion is present. **B,** Residual abnormality after chemotherapy.

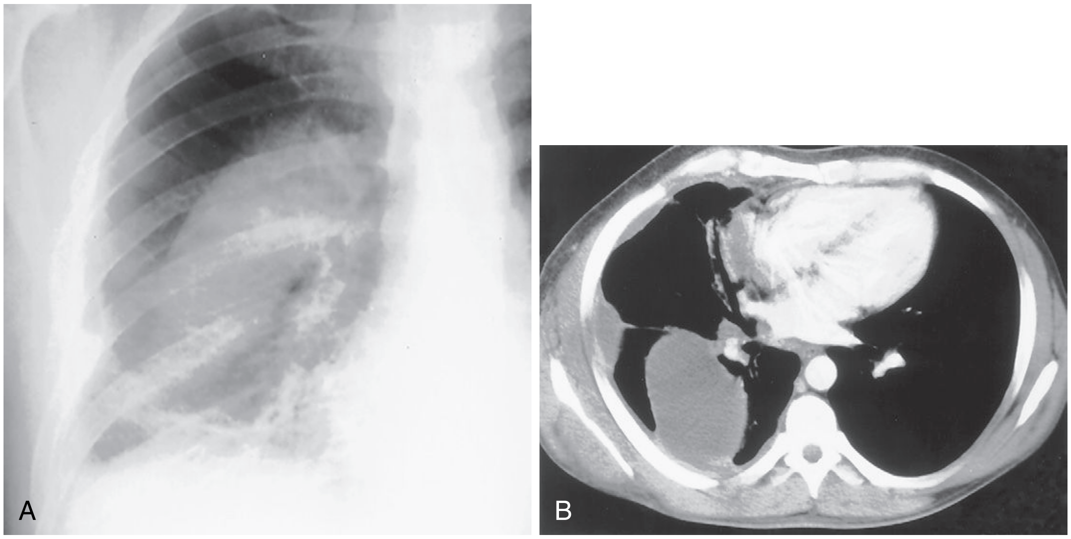

Figure 7-81 Small, right pleural effusion. **A,** The lentiform opacity in the right middle zone is caused by a loculated interlobar effusion. **B,** Computed tomography scan on mediastinal settings demonstrating the position of the loculated fluid within the oblique fissure.

commonly, the right middle lobe are superimposed on the lower part of the hilar shadow, particularly when the film is taken anteroposteriorly, in a lordotic projection, or with a poor inspiratory effort. A lateral radiograph usually confirms the vascular nature of the shadowing.

PLEURAL DISEASE

Pleural Fluid

The most dependent recess of the pleural space is the posterior costophrenic angle, which is where a small effusion tends to collect. As little as 100 to 200 mL of fluid accumulated in this recess can be seen above the dome of the diaphragm on the frontal view. Even smaller effusions may be seen on a lateral radiograph, and it is possible to identify effusions of only a few milliliters by use of decubitus radiographic views made with a horizontal beam, ultrasound imaging, or CT. Eventually, the costophrenic angle on the frontal view fills in, and with increasing fluid a homogeneous opacity spreads upward, obscuring the lung base (Figure 7-81). The fluid usually demonstrates a concave upper edge, higher laterally than medially, and obscures the diaphragm. Fluid may track into the fissures. A massive effusion may cause complete opacification of a hemithorax with passive atelectasis. The space-occupying effect of the effusion may push the mediastinum toward the opposite side, especially when the lung does not collapse significantly (Figure 7-82).

Lamellar effusions are shallow collections between the lung surface and the visceral pleura, sometimes sparing the costophrenic angle. Subpulmonary effusions accumulate between

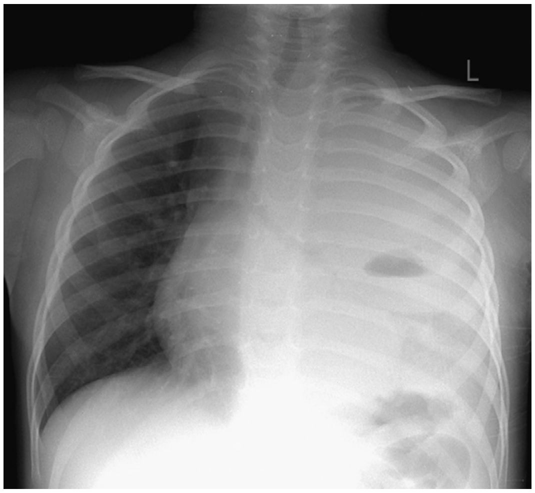

Figure 7-82 Large left pleural effusion. The patient presented with an acute empyema resulting from a lung abscess (note the air-fluid level). The mediastinal shift to the right is due to the space-occupying effects of the fluid.

the diaphragm and undersurface of a lung, mimicking elevation of the hemidiaphragm. Usually, the contour to the top of such an effusion differs from the normal diaphragmatic contour, the apparent apex being more lateral than usual. Also, some blunting of the costophrenic angle or tracking of fluid into fissures may be visible. On the left side, increased distance between the gastric air bubble and lung base may be apparent. A subpulmonary effusion may be confirmed by ultrasound imaging. However, because the fluid is free to shift within the pleural cavity with changes in patient position, a decubitus film may be needed for confirmation.

Encapsulated or encysted fluid may be difficult to differentiate from an extrapleural opacity, parenchymal lung disease, or mediastinal mass. Of note, however, an encysted effusion often is associated with free pleural fluid or other pleural shadowing and may extend into a fissure (see Figure 7-81). Loculated effusions tend to have comparatively little depth but considerable width, rather like a biconvex lens. Their appearance, therefore, depends on whether they are viewed end on, in profile, or obliquely. Extrapleural opacities tend to have a much sharper outline, with tapered, sometimes concave edges where they meet the chest wall. Peripheral, pleurally based lung lesions may show an air bronchogram, which differentiates them from true pleural disease. The differentiation between pleural thickening or mass and loculated pleural fluid may be difficult on plain films; CT and ultrasound imaging are particularly useful in this context.

Fluid may become loculated in the interlobar fissures and most frequently is seen in heart failure. Fluid that collects in the horizontal fissure produces a lenticular, oval, or round shadow, with well-demarcated edges. Loculated fluid in an oblique fissure may be poorly defined on a frontal radiograph, but a lateral film usually is diagnostic, because the fissure is seen tangentially and the typical lenticular configuration of the effusion is demonstrated. Loculated interlobar effusions can appear rounded on two views and may disappear rapidly. Hence, they are sometimes known as pulmonary pseudotumors (**Figure 7-83**). With subsequent episodes of heart failure, they may return at the same site.

Diagnosis of an empyema usually requires thoracentesis. Nevertheless, the diagnosis may be suspected radiographically by the spontaneous appearance on a plain film of an air-fluid level in a pleural effusion, because this feature usually equates with loculation and communication with the tracheobronchial tree or the presence of a gas-forming organism. Loculation is best demonstrated with ultrasound imaging.

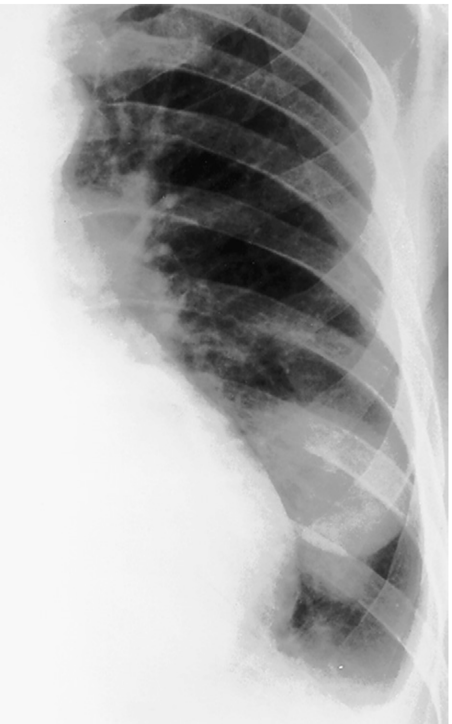

Figure 7-83 Small, left basal pleural effusion. The opacity in the left middle zone is caused by fluid loculated in the oblique fissure.

Pneumothorax

A small pneumothorax is easily overlooked, and in an erect patient, the air usually collects at the apex. The lung retracts toward the hilum, and on a frontal chest film, the sharp white line of the visceral pleura is visible, separated from the chest wall by the radiolucent pleural space, which is devoid of lung markings. This appearance should not be confused with that of a skin fold (**Figure 7-84**). The lung usually remains aerated, although perfusion is reduced in proportion to ventilation, so the radiodensity of the partially collapsed lung remains relatively normal. A closed pneumothorax is easier to see on an expiratory film, although expiratory radiographs are not routinely required to detect clinically significant pneumothoraces. A lateral decubitus film made with the affected side uppermost occasionally is helpful, because the pleural air can be seen along the lateral chest wall. This view is particularly useful in infants, because small pneumothoraces are difficult to see on supine anteroposterior films, because the air tends to collect anteriorly and medially.

A large pneumothorax may lead to complete relaxation and retraction of the lung, with some mediastinal shift toward the normal side (**Figure 7-85**). Because it constitutes a medical emergency, tension pneumothorax often is treated before a chest radiograph is obtained. However, if a radiograph is taken in this situation, it shows marked displacement of the mediastinum (**Figure 7-86**). Radiographically, the lung may be squashed against the mediastinum or herniate across the midline, and the ipsilateral hemidiaphragm may be depressed.

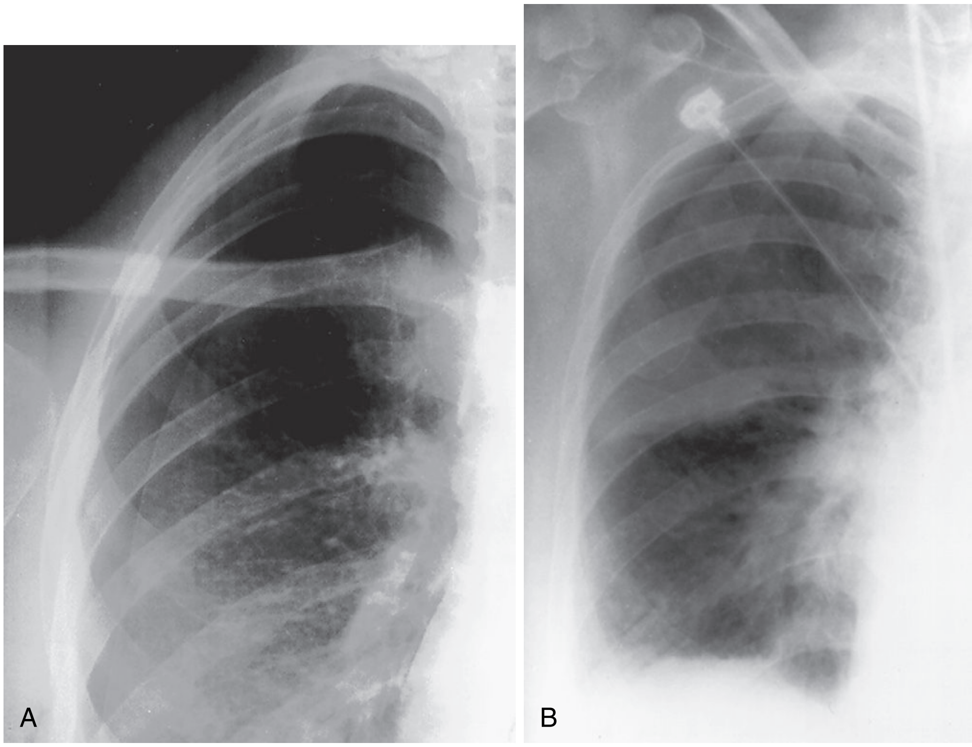

Figure 7-84 Shallow right pneumothorax. **A,** A discrete pleural white line is seen. Peripheral to this line, lung markings are absent. **B,** In this skin fold, although a change in density parallels the chest wall, no discrete pleural line is present, and lung markings are seen to extend beyond the apparent lung edge. This appearance is caused by a superficial fold of skin produced by the x-ray cassette.

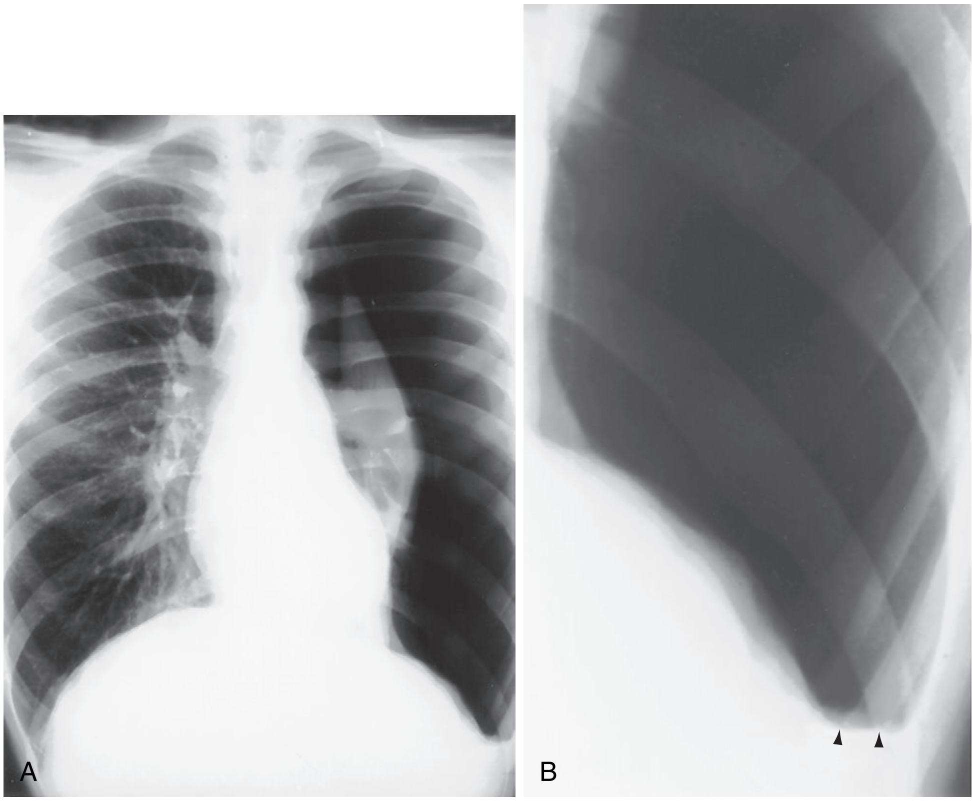

Figure 7-85 Left-sided pneumothorax. **A,** Complete collapse of the left lung, which is retracted to the left hilum. **B,** Magnified view of the left lower zone demonstrates the "short" air-fluid level commonly seen in a costophrenic angle when a pneumothorax is present (*arrowheads*).

Complications of Pneumothorax

Pleural adhesions may limit the distribution of a pneumothorax and result in a loculated or encysted pneumothorax. The usual appearance is an ovoid air collection adjacent to the chest wall, which may be radiographically indistinguishable from a thin-walled, subpleural pulmonary cyst or bulla. Pleural adhesions occasionally are seen as line shadows that stretch between the two pleural layers; they prevent relaxation of the underlying lung. Rupture of an adhesion may produce a hemopneumothorax. Collapse or consolidation of a lobe or lung in association with a pneumothorax is important because it may delay reexpansion of the lung.

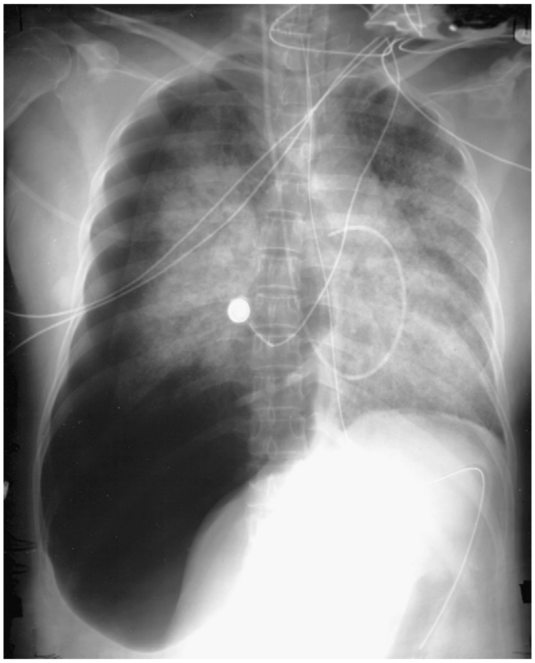

Figure 7-86 Tension pneumothorax that developed after insertion of a Swan-Ganz catheter. Note the shift of the mediastinum toward the left and reversal of the normal contour of the right hemidiaphragm.

Because the normal pleural space contains a small volume of fluid, blunting of the costophrenic angle by a "short" fluid level commonly is seen on radiographs of a pneumothorax (see Figure 7-85). In a small pneumothorax, this fluid level may be the most obvious radiologic sign. A higher fluid level usually signifies a complication and represents exudate, pus, or blood, depending on the etiology of the pneumothorax (**Figure** 7-87).

The usual radiographic appearance of a hydropneumothorax is that of a pneumothorax containing a horizontal fluid level that separates opaque fluid below from lucent air above. A hydrothorax or pyopneumothorax may arise as a result of a bronchopleural fistula (an abnormal communication between the bronchial tree and the pleural space). This may be a complication of surgery but also may occur as a complication of a subpleural lung tumor (**Figure** 7-88).

Pleural Thickening

Blunting of a costophrenic angle is a common observation and usually is caused by localized pleural thickening secondary to previous pleuritis. In the asymptomatic patient and in the absence of other radiologic abnormalities, it is of no significance other than that it may simulate a pleural effusion. When relevant, the possibility of pleural fluid may have to be excluded by other techniques. Localized pleural thickening that extends into the inferior end of an oblique fissure may produce so-called tenting of the diaphragm and is of similar significance, although a similar appearance may result from scarring caused by previous pulmonary infection or infarction.

Bilateral apical pleural thickening is common, usually symmetric in distribution, and more frequent in elderly patients and does not necessarily indicate previous tuberculosis. The

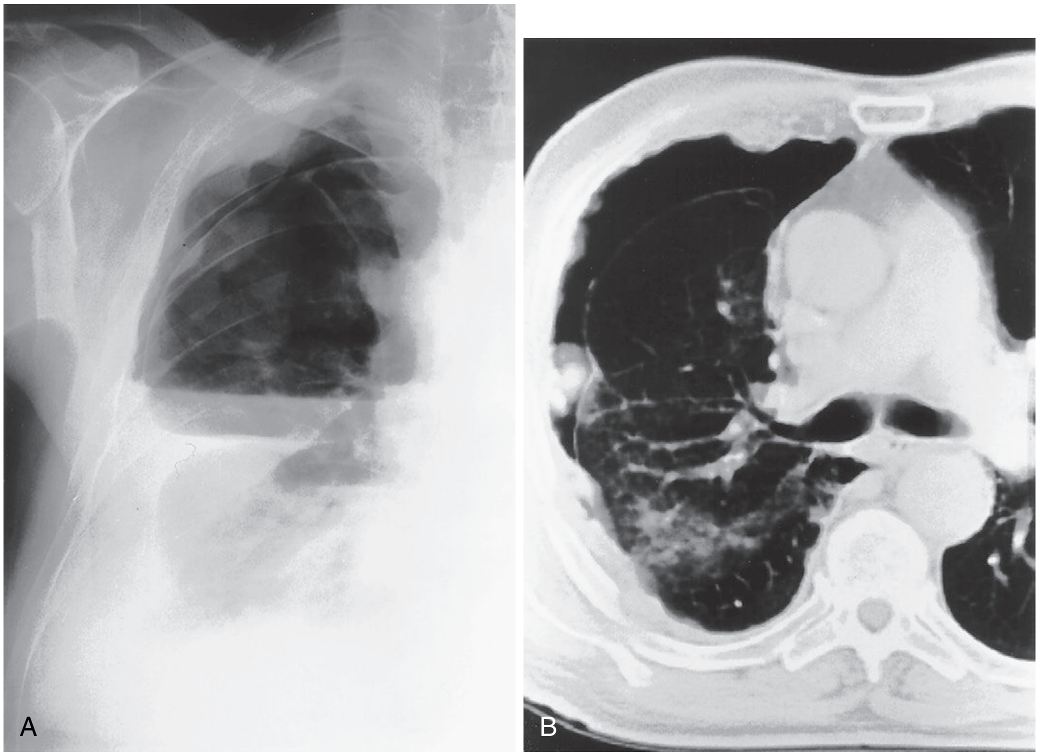

Figure 7-87 Hydropneumothorax in a patient with a mesothelioma. **A,** Chest radiograph shows normal thickness of the visceral pleura, but with lobulated soft tissue shadowing caused by tumor within the parietal pleura. **B,** Computed tomography scan demonstrates the lobulated pleural tumor.

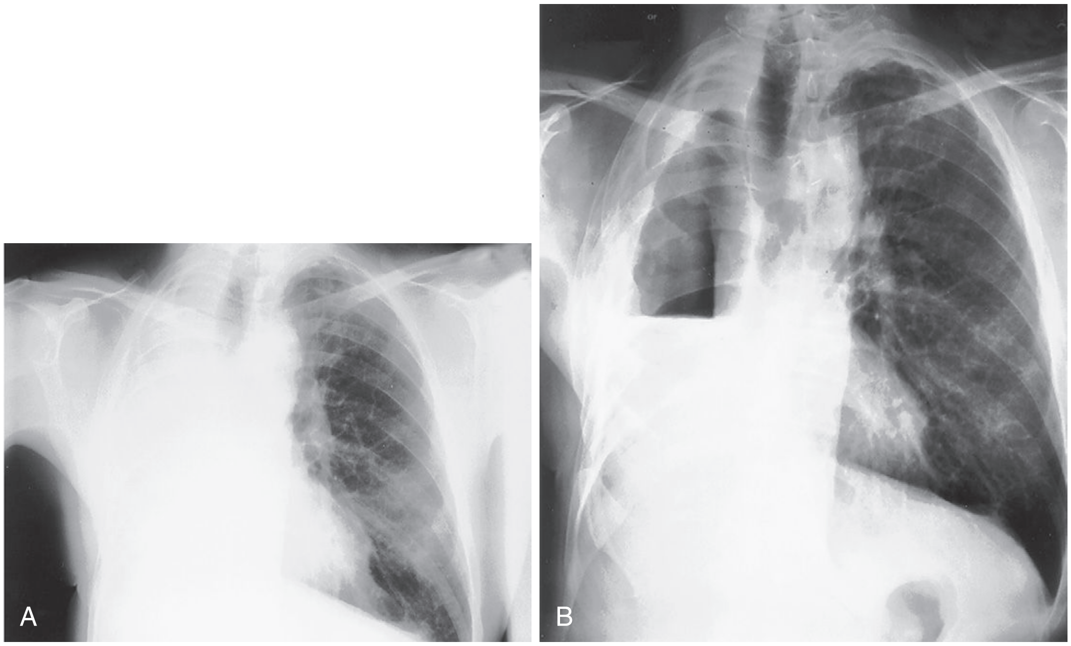

Figure 7-88 Pneumonectomy: appearances and complications. **A,** Chest radiograph showing the normal appearances after a right pneumonectomy. **B,** Spontaneous development of an air-fluid level, caused by a bronchopleural fistula from local recurrence.

etiology is uncertain, but in some affected persons, the "caps" represent extrapleural fat that has descended because of scarring and consequent retraction of the upper lobes. By contrast, asymmetric or unilateral apical pleural thickening may be highly significant, especially if associated with pain. Asymmetric apical pleural shadowing may represent a Pancoast tumor, and bone destruction should be specifically sought (Figure 7-89).

More extensive unilateral pleural thickening usually is the result of a previous thoracotomy or an exudative pleural effusion. A simple transudate typically resolves completely, but empyema and hemothorax are more likely to resolve with residual pleural fibrosis. The thickened pleura may calcify (Figure 7-90), and the entire lung may become surrounded by fibrotic pleura, which may be as much as a few centimeters thick (Figure 7-91). Bilateral (parietal) pleural plaques are a common manifestation of asbestos exposure, and occasionally more diffuse, visceral pleural thickening is seen.

Pleural Calcification

In general, pleural calcification has the same causes as for pleural thickening. Unilateral pleural calcification is therefore likely to be the result of previous empyema or hemothorax, and bilateral calcification occurs after asbestos exposure (Figure 7-92). Pleural calcification may be discovered in a patient who was not aware of previous chest disease.

The calcification associated with previous pleurisy, empyema, or hemothorax occurs in the visceral pleura (Figure 7-93); associated pleural thickening is almost always present and separates the calcium from the ribs. The calcium may be in a continuous sheet or in discrete plaques, which usually produce dense, coarse, irregular shadows, often sharply demarcated

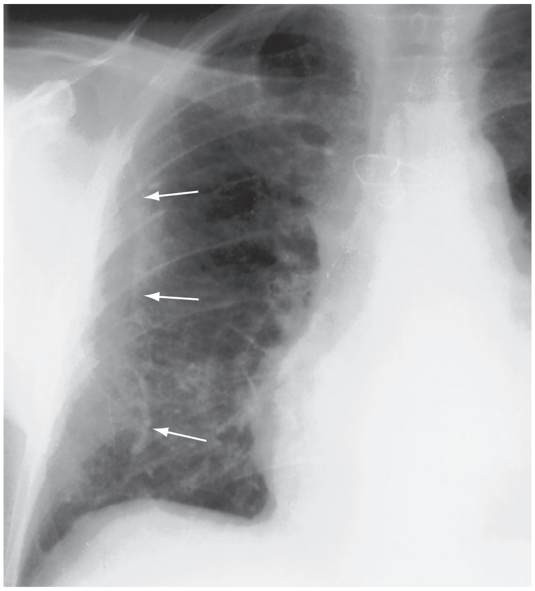

Figure 7-90 Previous thoracotomy (note sternotomy sutures) for mitral valve replacement. Pleural calcification is seen on the right side (*arrows*).

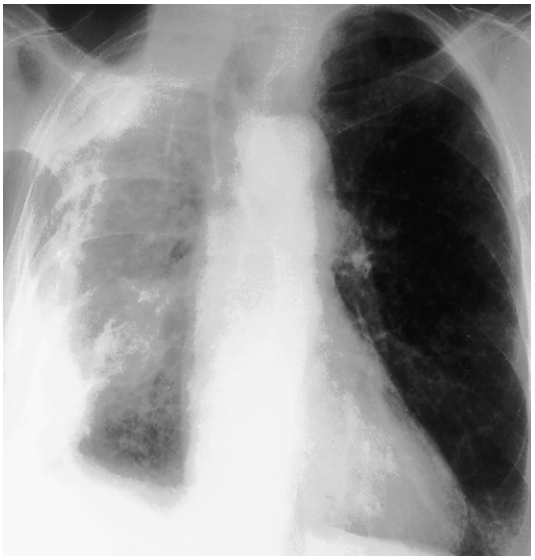

Figure 7-91 Previous tuberculosis. Extensive right-sided pleural thickening and calcification, with reduction in volume of the right hemithorax, are evident.

laterally. When a plaque is viewed end on, it may be less well defined, mimicking a pulmonary infiltrate.

Pleural Masses

Primary tumors of the pleura are rare. Benign tumors of the pleura include pleural fibroma and lipoma (Figure 7-94). The most common malignant disease of the pleura is metastatic, usually adenocarcinoma from the bronchus or breast (Figure 7-95). Malignant mesothelioma typically is associated with previous asbestos exposure.

COMPUTED TOMOGRAPHY

ANATOMY OF THE MEDIASTINUM

The soft tissue contrast provided by CT, as well as its cross-sectional nature, makes the diagnostic information available from CT far superior to that provided by two-dimensional radiography. Modern CT scanners can acquire a volume of imaging information that includes the whole of the mediastinum within the time of a single breath-hold. This three-dimensional dataset can then be displayed as continuous or overlapping axial slices, free from breathing movement artifact. Usually, a collimation and slice width of between 5 and 10 mm is used, and it is usual, but not always essential, to give intravenous contrast. The normal mediastinal anatomy is demonstrated in Figures 7-96 to 7-101.

Great Vessels

The great vessels constitute the most familiar anatomic landmarks within the mediastinum. Knowledge of the relationship of these vessels to other mediastinal components allows accurate description of the location of pathology and has important implications for planning the approach to either an open operation or mediastinoscopy. The most common branching pattern of the aortic arch is for three arteries to arise from the upper arch—the right innominate, left common carotid, and left subclavian (see Figure 7-96). However, many variations to this basic anatomy exist (see Figures 7-71, 7-74, and 7-77). The transverse portion of the aortic arch is the most readily recognizable vascular structure within the mediastinum (see Figure 7-97). The great veins lie anterior to the arterial structures. The left brachiocephalic vein is situated above and anterior to the aortic arch and aortic branches, although its position is variable. The right brachiocephalic vein descends more directly in the anterior right mediastinum to merge with its counterpart to form the superior vena cava. Because CT contrast is given from one arm, one brachiocephalic vein is heavily opacified, whereas the other remains of soft tissue density.

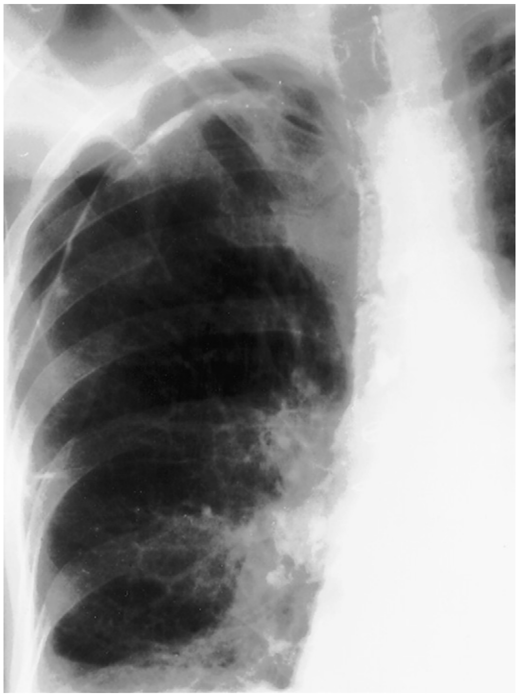

Figure 7-93 Previous sternotomy resulting in pleural thickening and calcification. A small pneumothorax is visible. Of note, the pleural thickening is associated with the visceral pleura.

The pulmonary outflow tract ascends, usually outlined by fat within the pericardium, to divide adjacent and just posterior to the ascending aorta. The main pulmonary artery diameter typically is equal to or less than that of the ascending aorta as measured on CT. When the pulmonary artery diameter exceeds the aortic diameter, underlying pulmonary hypertension is likely. The right pulmonary artery swings dorsally and to the right, behind the ascending aorta and the superior vena cava and anterior to the right main bronchus (see Figure 7-99). After giving a branch to the upper lobe, it descends posterolaterally to the bronchus intermedius. The left pulmonary artery follows a shorter course and arches up and over the left main bronchus.

Hilar anatomy is well demonstrated on contrast-enhanced CT, especially when vascular structures are traced sequentially over contiguous images. Knowledge of normal anatomy enables differentiation of vascular structures from normal or enlarged mediastinal lymph nodes, even on unenhanced scans; however, if there is any cause for doubt, intravenous contrast always clarifies the situation (see Figure 7-101).

Airways

The trachea descends through the thoracic inlet, where reduction in caliber may occur, and usually appears rounded on scans obtained in full inspiration. If scans are obtained during expiration, the membranous posterior wall of the trachea is seen to bow forward into the tracheal lumen. The wall of the trachea is only 2 mm thick, and any intramural thickening is well demonstrated on CT. Modern scanners also allow reformatting of

the data in sagittal or coronal planes, thus allowing more elegant demonstration of tracheal abnormalities. The anatomy of the bronchial tree can be traced from the tracheal carina out into the lungs, at least to the segmental level, with excellent correlation between CT and bronchoscopic findings. Furthermore, the three-dimensional dataset acquired on modern spiral scanners can be manipulated to provide a computer simulation of the bronchoscopic appearances (see Figure 7-7, *D*).

Thymus

The thymus, in the normal state, is not visible on the chest radiograph of the adult patient, but the thymic remnant frequently is evident on CT. The thymus decreases in size after puberty. It lies in the anterior mediastinum, just in front of the root of the aorta; it is bilobed, with the left lobe usually being the larger. Generally, the thymus is assessed by examining the contours of the gland, which should be concave, and the thickness of the individual lobes. In childhood, the thymus is of soft tissue density on CT scanning, but after puberty, it starts to involute, and the gland undergoes atrophy and fatty replacement. Traces of thymic tissue within the anterior mediastinal fat frequently are identifiable on CT in young adults.

Thyroid

Usually, the thyroid is confined to the neck, but mediastinal extension frequently occurs with thyroid enlargement (see further on). Typically, the thyroid lies on either side of the extrathoracic trachea and is bounded laterally by the carotid artery and internal jugular vein. On contrast enhancement, normal thyroid tissue enhances avidly; it usually is of relatively high attenuation on unenhanced scans because of its relatively high iodine content.

Esophagus

The esophagus often is completely collapsed on CT scanning and is thus inconspicuous, but it is easily identified if it contains air or contrast. Initially, the esophagus lies directly posterior to the trachea; below the bifurcation, it usually deviates slightly to the left and lies adjacent to the aorta. The esophageal wall typically is only 2 to 3 mm in thickness.

Lymph Nodes

Numerous lymph nodes occur within the mediastinum, usually less than 1 cm in long axis and discrete; they may not be visible on CT scanning. Previous granulomatous disease may result in extensive mediastinal lymph node calcification, which reveals the true extent of normal mediastinal lymph node distribution (**Figure 7-102**). An extensive chain of lymph nodes also accompanies the internal mammary vessels bilaterally. Additional nodes are present in the intercostal chain adjacent to the heads

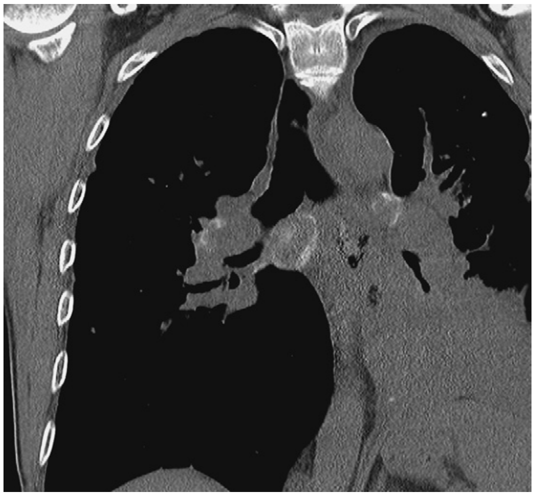

Figure 7-102 Unenhanced computed tomography scan through the thorax showing faint eggshell calcification in mediastinal lymph nodes secondary to previous granulomatous disease.

of the ribs in a posterior, paraspinal position and alongside the esophagus and descending thoracic aorta. These merge with the retrocrural lymph node chain and the paraaortic nodes in the abdomen.

Pericardium

The pericardial membrane is composed of visceral and parietal layers and surrounds the heart. The visceral layer is separated from the myocardium by a variable amount of epicardial fat. The parietal layer is variably fused with the mediastinal pleura. Where they are separate, mediastinal fat may accumulate (such as in the epiphrenic fat pad). Fluid within the pericardial sac may be evident on the chest radiograph, CT scan, or ultrasound image.

COMPUTED TOMOGRAPHIC EVALUATION OF MEDIASTINAL MASSES

Most patients who have a mediastinal mass present with symptoms from the local compressive or invasive effects of the mediastinal mass, but in a surprising number, the mass is discovered on a chest radiograph taken for an unrelated cause. Generally, the PA and lateral chest radiographs enable localization of the mass to one of the compartments of the mediastinum, which refines the differential diagnosis. However, current practice is for patients who present with a mediastinal mass to undergo a contrast-enhanced CT scan or sometimes MRI.

The differential diagnosis of a mediastinal mass is wide in scope. Masses can arise from any of the normal structures in the mediastinum, as well as from metastatic disease from a distant primary tumor. In addition, mediastinal abscesses also may manifest as a mass. The diagnosis is considerably narrowed by CT, which enables the organ of origin of the mass to be assessed, defines the attenuation and enhancement characteristics, and detects evidence of invasion of adjacent structures. It is usual to classify mediastinal masses according to the anatomic portion of the mediastinum from which they appear to arise (Figure 7-103).

Figure 7-103 Distribution and classification of mediastinal masses depending on density derived from computed tomography scan.

Superior Mediastinal Masses

Thyroid

An enlarged thyroid may extend inferiorly into the superior mediastinum and may be large enough to reach into the middle mediastinum. However, this picture rarely presents a diagnostic problem, because the mass is obviously continuous with the cervical thyroid tissue and enhances avidly after intravenous contrast. Frequently, the enlarged gland contains low-density cysts and areas of calcification, particularly within cyst walls. Large thyroid masses may cause tracheal deviation or narrowing and may enlarge acutely with hemorrhage into the gland (Figure 7-104). Although the thyroid originates anterior to the trachea, extension to the right and even posterior to the trachea within the upper mediastinum may be observed.

Lymphatic Malformations

Lymphatic malformations are rare and may arise in the superior mediastinum. The most common of these is the cystic hygroma, which usually manifests in infants as a cervical mass with an extensive intrathoracic component. Although these lesions are considered benign, complete resection is difficult to

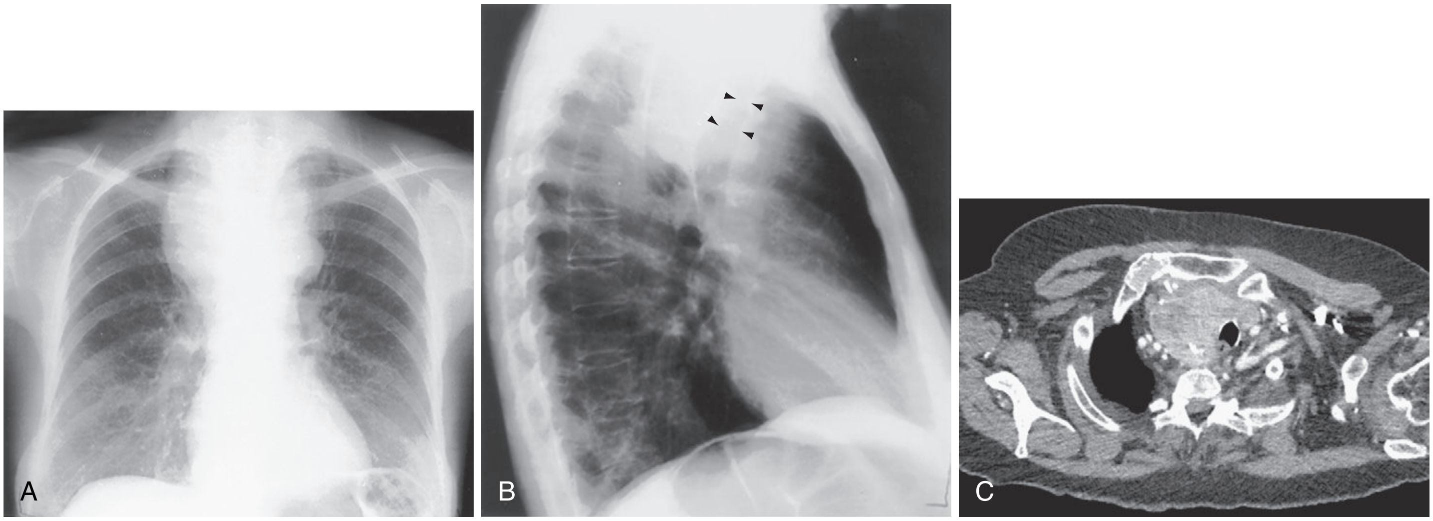

Figure 7-104 Retrosternal thyroid mass. **A,** Posteroanterior chest radiograph shows a large superior mediastinal mass mainly to the right of the trachea. **B,** The lateral view demonstrates an extension behind the trachea, which is narrowed in its anteroposterior dimension (*arrowheads*). **C,** The thyroid frequently extends into a retrotracheal position in the upper mediastinum, as demonstrated on this computed tomography scan from a different patient.

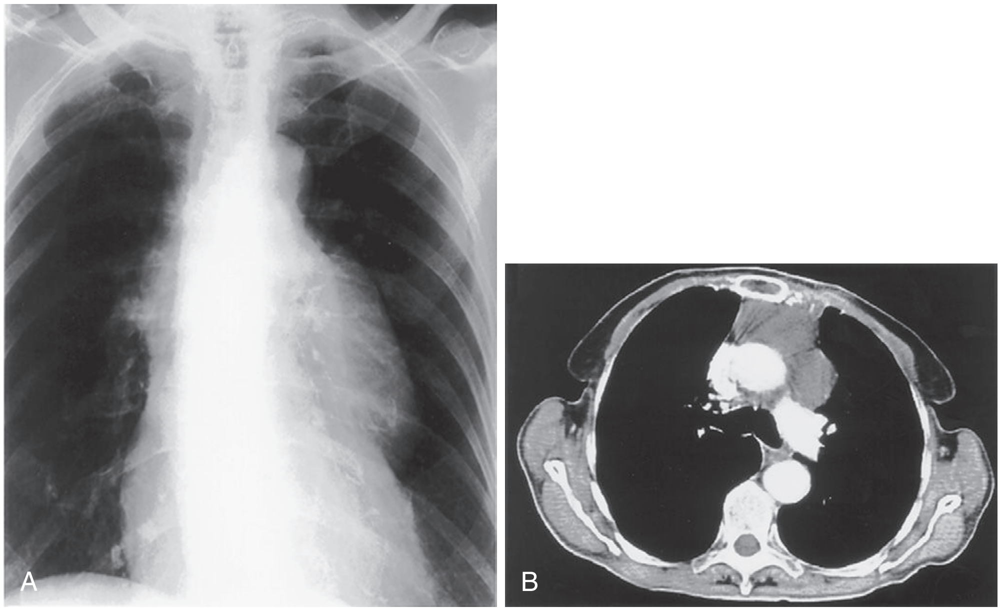

Figure 7-105 Thymic cyst. **A,** Anteroposterior chest radiograph shows mediastinal widening. **B,** Contrast-enhanced computed tomography scan confirms an anterior mediastinal abnormality of fluid density.

accomplish because of their tendency to spread around normal structures.

Anterior Mediastinal Masses

Most anterior mediastinal masses arise from the thymus, thyroid (see earlier), germ cell tumors, and enlarged lymph nodes.

Thymus

The normal thymus involutes after puberty but may show reactive enlargement in certain disease states or after chemotherapy. Intrinsic neoplasia of the thymus, however, is a relatively common cause of an anterior mediastinal mass in adult life. Causes of thymic neoplasia include thymoma, thymic carcinoma, thymic cysts (Figure 7-105), thymic lipoma, thymic carcinoid, and thymic lymphoma. With CT, fat or fluid elements may be identified within a thymic mass, and invasion of adjacent structures can be shown. With the exception of thymolipoma and thymic cysts, histopathologic examination usually is required for definitive diagnosis.

Teratomas and Germ Cell Tumors

Teratomas and germ cell tumors originate from primitive stem cell rests. It is useful to separate these neoplasms into benign and malignant forms—the former is the benign cystic teratoma (synonymous with dermoid cyst). Benign cystic teratomas (Figure 7-106) may contain differentiated elements and consequently may display a variety of densities on CT, ranging from fat to calcified tissue, and even that of teeth. The malignant teratomas comprise a variety of tumors that usually arise in the testes—namely, seminomas, teratocarcinoma, embryonal

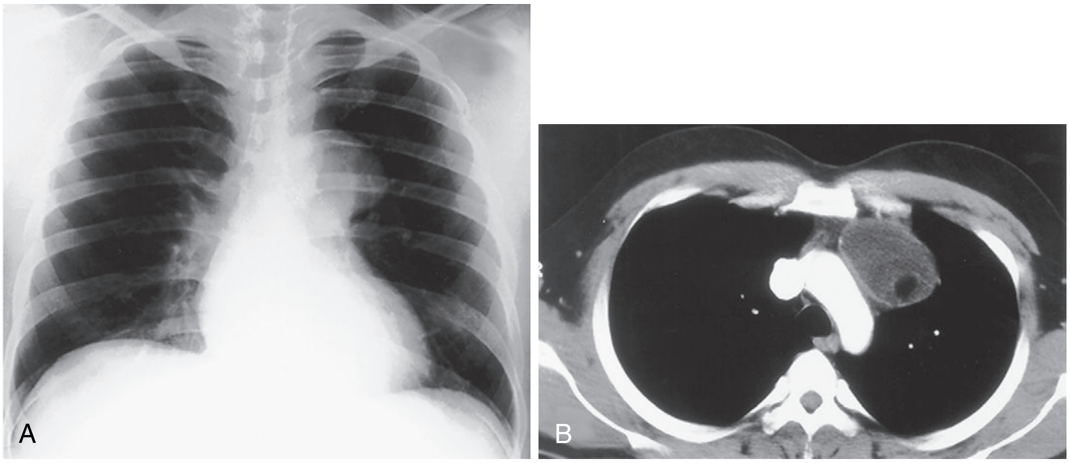

Figure 7-106 Cystic teratoma. **A,** Posteroanterior, erect chest radiograph demonstrates a mass arising from the mediastinum. Note that the posterior aortic arch and descending aorta are still visualized, which indicates an anterior position. **B,** Computed tomography scan shows fluid and fat elements within an anterior mediastinal mass.

carcinoma, yolk sac tumors, and choriocarcinoma. Some mediastinal germ cell tumors may be secondary to a primary tumor arising within the gonads. Malignant germ cell tumors usually are found in young men, secrete tumor markers, and are chemosensitive.

Lymph Node Enlargement

Lymph node enlargement is a common cause of an anterior mediastinal mass, although many processes that involve lymph nodes cause generalized mediastinal nodal enlargement. These processes may be infective (such as tuberculosis or histoplasmosis), neoplastic, reactive, or of unknown etiology (such as sarcoidosis).

Lymphoma

Hodgkin disease and, to a lesser extent, non-Hodgkin lymphoma and lymphatic leukemia frequently involve the mediastinum, especially the paratracheal, tracheobronchial, and anterior mediastinal nodes. The lymph node enlargement typically is asymmetric.

Middle Mediastinal Masses

Middle mediastinal masses most frequently are malignant, usually from metastatic nodal enlargement. The presence of enlarged nodes, however, is not an accurate predictor of malignancy, because reactive enlargement also is common. The classification of mediastinal lymph node enlargement is discussed under staging of lung cancer.

Some important developmental middle mediastinal masses are recognized. These lesions frequently are identified as an incidental abnormality in adult life, although they may manifest earlier if complications supervene. Bronchogenic cysts may arise anywhere along the course of the trachea but usually are found close to a carina. On the chest radiograph they appear as well-defined, round masses that may, on rare occasion, calcify. On CT scans they may appear as either cystic or solid masses. MRI may be diagnostic.

Posterior Mediastinal Masses

The posterior mediastinum contains neural elements, which give rise to a range of benign and malignant neural tumors. These may attain considerable size by the time of clinical presentation, and modeling abnormalities may occur in the adjacent ribs and spine, which provide a clue to their chronicity. On CT scanning, they typically are paraspinal in location and of soft tissue density, with patchy calcification. Also, CT may show the typical dumbbell extension of a neurofibroma, from an extraspinal position through an intervertebral foramen. In the assessment of neurogenic tumors, MRI has a distinct advantage over CT in that it can definitively confirm or exclude tumor extension into the spinal canal (Figure 7-107).

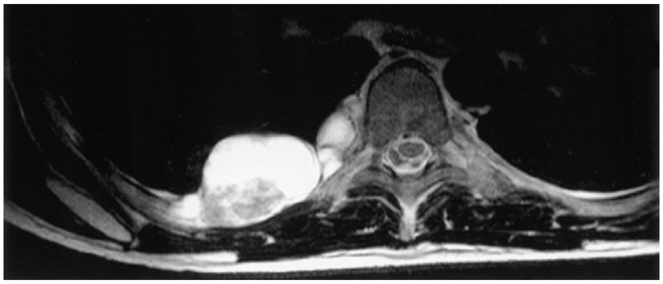

Figure 7-107 Paraganglionoma in an adult: appearance on magnetic resonance imaging. A right paraspinal T2-weighted high-signal-intensity lobulated mass is present. There is no extension into the soft tissues of the chest wall or through the neural foramina into the spinal canal.

The esophagus lies in the posterior mediastinum. Esophageal carcinoma usually manifests with dysphagia or weight loss, without presence of a mass on the chest radiograph. CT usually is reserved for the staging of esophageal malignancy, in addition to the assessment of local tumor bulk. Benign esophageal lesions may reach a considerable size before the onset of symptoms, so at initial detection on the plain radiograph, the mass may be quite large. Such tumors include fibroma, leiomyoma, and lipomas.

Neuroenteric cysts are rare congenital masses that occur in the posterior mediastinum, usually inseparable from the esophagus, and sometimes within the esophageal wall. If a vertebral or neural canal abnormality is present, these are known as neuroenteric cysts, but if not, they are termed esophageal duplication cysts. Posterior mediastinal masses may arise directly from the spinal column and may represent primary or secondary tumors, infective processes, or sequelae of trauma or degeneration.

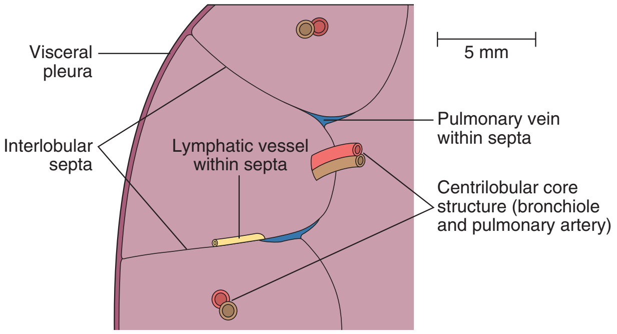
INTERPRETATION OF HIGH-RESOLUTION COMPUTED TOMOGRAPHY SCANS OF THE LUNGS

APPEARANCE OF NORMAL LUNG ANATOMY

Accurate interpretation of HRCT scans of the lung requires an understanding of the normal appearance of the bronchi, blood vessels, and the secondary pulmonary lobule. The close correspondence between gross pathologic specimen appearance and HRCT features enables the use of anatomic terms to describe the patterns of lung disease depicted by HRCT.

Throughout the lung, the bronchi and pulmonary arteries run together and taper slightly as they travel radially; this anatomic feature is easiest to appreciate in the bronchovascular bundles that run within and parallel to the plane of HRCT section. At any given point, the diameter of the bronchus is the same as its accompanying pulmonary artery. The bronchovascular bundle is surrounded by connective tissue from the hilum to the bronchioles in the lung periphery. The concept of connected components making up the lung interstitium is useful for the understanding of HRCT findings in interstitial lung disease—the peripheral interstitium around the surface of the lung beneath the visceral pleura extends into the lung to surround the secondary pulmonary lobules. Within the lobules, a finer network of septal, connective tissue fibers supports the alveoli. The "axial" fibers form a sheath around the bronchovascular bundles. Thus, the connective tissue stroma of these three separate components is in continuity, forming a fibrous skeleton for the lungs.

In normal persons, HRCT shows a clear and definite interface between the bronchovascular bundle and surrounding lung. Any thickening of the connective tissue interstitium results in apparent bronchial wall thickening and blurring of this interface. The size of the smallest subsegmental bronchi visible on HRCT scans is determined by the thickness of the bronchial wall, rather than by the bronchial diameter. In general, bronchi with a diameter less than 3 mm and walls less than 300 mm thick are not consistently identifiable on HRCT scans. Airways reach this critical size at approximately 2 to 3 cm from the pleural surface. The secondary pulmonary lobule is the smallest anatomic unit of the lung that is surrounded by a connective tissue septum (Figure 7-108). Within the septa lie lymphatic vessels and venules. The lobule contains between 5 and 12 acini, which each measure approximately 6 to 10 mm in diameter. Each lobule is approximately 2 cm in diameter and polyhedral in shape and often resembles a truncated cone. In the lung periphery, the bases of the cone-shaped lobules lie on a visceral pleural surface. In the central parts of the lung, the interlobular septa and thus the lobules are less well developed. The centrilobular bronchiole and accompanying pulmonary artery enter through the apex of the lobule.



Visceral pleura
Interlobular septa
Lymphatic vessel within septa
5 mm
Pulmonary vein within septa
Centrilobular core structure (bronchiole and pulmonary artery)

Figure 7-108 Anatomy of the secondary pulmonary lobule.

The interlobular septa measure approximately 100 µm in thickness. The lower limit of resolution with HRCT is approximately 200 µm, so normal septa are infrequently identified on HRCT scans. The few interlobular septa that are visible in normal persons are seen as straight lines 1 to 2 cm in length that terminate at a visceral pleural surface. Sometimes several septa that join end to end are seen as a nonbranching, linear structure, which can measure up to 4 cm in length; these are most frequent at the lung bases, just above the diaphragmatic surface.

The secondary pulmonary lobule is supplied by a centrilobular artery and bronchiole that are approximately 1 mm in diameter as they enter the lobule. In the normal state, the core structures, effectively the 500-µm-diameter centrilobular artery, are visible as dots 1 cm deep to the pleural surface. On standard window settings, the lung parenchyma is of almost homogeneous low density, marginally greater than that of air.

Patterns of Parenchymal Disease

Vague terms traditionally used in the lexicon of plain chest radiography can be replaced by precise descriptions derived from an understanding of HRCT anatomy. Abnormal patterns on HRCT scans that represent pulmonary disease usually can be categorized into one of four patterns: reticular and linear opacities, nodular opacities, increased lung density, and cystic air spaces with areas of decreased lung density.

Although each of these patterns generally has a corresponding pattern on chest radiography, they are seen with much greater clarity on cross-sectional HRCT images, and the precise distribution of disease can be more readily appreciated. Increasing conformity is emerging in the terminology used to describe the HRCT abnormalities of diffuse infiltrative lung diseases.

Reticular Pattern

A reticular pattern on HRCT scans always indicates significant pathology. A reticular pattern caused by thickening of interlobular septa is a cardinal sign of many interstitial lung diseases. Numerous interlobular septa that join up to form an obvious network indicate an extensive interstitial abnormality caused by infiltration with fibrosis, abnormal cells, or fluid (e.g., fibrosing alveolitis, lymphangitis carcinomatosa, or pulmonary edema, respectively). Interlobular septal thickening that results from fibrosing alveolitis often is associated with intralobular, interstitial thickening (beyond the resolution of HRCT) and a coarse reticular pattern that contains cystic air spaces and produces the honeycomb pattern of destroyed lung. Thickening of the interlobular septa may be smooth or irregular, but this distinction is not always obvious. Irregular septal thickening is a feature of lymphangitic spread of tumor, whereas pulmonary edema and alveolar proteinosis cause smooth thickening. Sarcoidosis is typified by some nodular septal thickening, although widespread septal thickening is not characteristic of this condition.

Because the various parts of the lung interstitium are in continuity, widespread interstitial disease that causes interlobular septal thickening also results in bronchovascular interstitial thickening (e.g., by lymphangitis carcinomatosa). The bronchovascular thickening seen on HRCT is equivalent to the peribronchial "cuffing" seen around bronchi in end-on views on chest radiography. The HRCT finding of peribronchovascular thickening in isolation must be interpreted with caution, because it may be seen in reversible pure airway disease, for example, asthma. With thickening of the subsegmental and segmental bronchovascular bundles caused by lymphangitis carcinomatosa, for example, the interface between the thickened bronchial wall and surrounding lung sometimes has a “feathery” appearance (**Figure 7-109**).

The coarseness of the network that makes up the reticular pattern on HRCT is determined by the level at which the interstitial thickening is most severe. Thickening of the intralobular septa results in a very fine reticular pattern on HRCT, visible only on an optimal HRCT scan. Some of the very delicate linear structures that make up such a fine reticular pattern are so small as to be below the resolution limits of HRCT, even with the narrowest collimation. The result is an amorphous increase in lung density (“ground glass” opacification) (see further on) caused by volume averaging within the section.

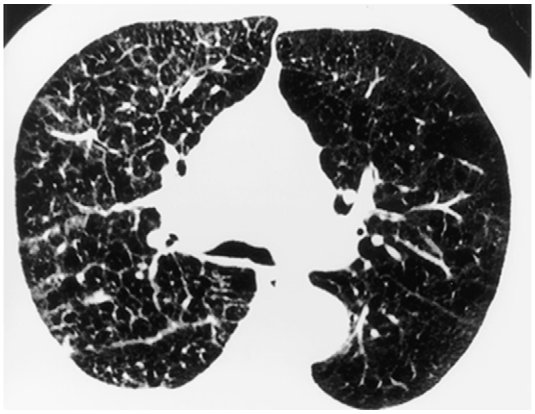


Figure 7-109 High-resolution computed tomography scan showing generalized, irregular thickening of the interlobular septa in the right lung. The patient had lymphangitis carcinomatosa.

Extensive pulmonary fibrosis causes complete destruction of the architecture of the secondary pulmonary lobules, which results in a coarse reticular pattern made up of irregular, linear opacities. The reticular pattern of end-stage fibrotic or honeycomb lung mirrors the appearance on chest radiographs and is characterized by cystic spaces that measure a few millimeters to several centimeters across and are surrounded by discernible walls (**Figure 7-110**). Paradoxically, thickened interlobular septa are not an obvious feature of advanced fibrosing alveolitis, probably because of the severe disturbance of the normal lung architecture. The distortion that accompanies interstitial fibrosis may result in irregular dilatation of the segmental and subsegmental bronchi without honeycomb change, a phenomenon termed *traction bronchiectasis* (see Figure 7-110).

Nodular Pattern

A nodular pattern on HRCT consists of innumerable, small, discrete opacities that range in diameter from 1 to 10 mm and is a feature of both interstitial and air space diseases. The location of nodules in relation to the lobules and bronchovascular bundles, as well as their density, clarity of outline, and uniformity of size, may indicate whether the nodules lie predominantly within the interstitium or air spaces. Because most

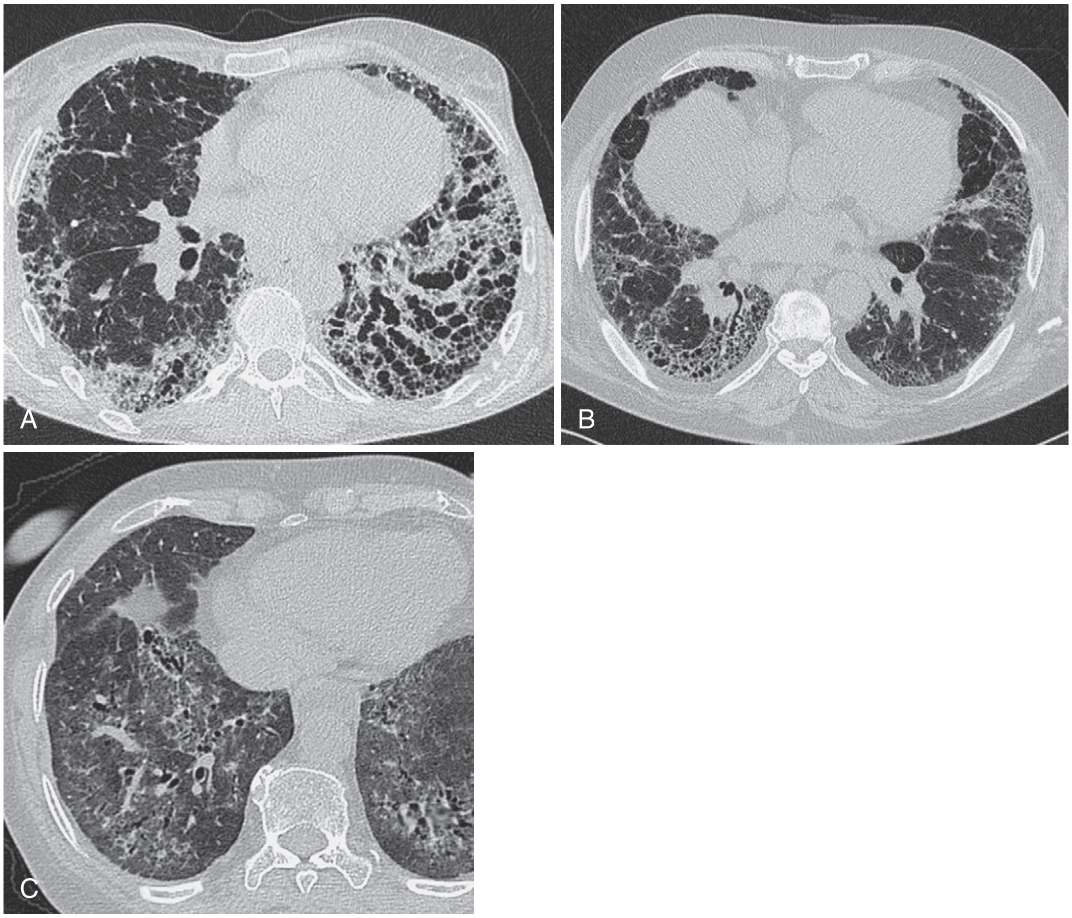

Figure 7-110 High-resolution computed tomography in fibrosing alveolitis. **A,** In the first patient, coarse cystic spaces are visible throughout the lung bases. **B,** In a second patient, finer fibrotic changes are seen. Traction bronchiectasis is evident in both cases, which is a typical feature of the usual interstitial pneumonitis (UIP) pattern. **C,** In a third patient, the much more marked ground glass changes are characteristic of nonspecific interstitial pneumonia (NSIP) pattern.

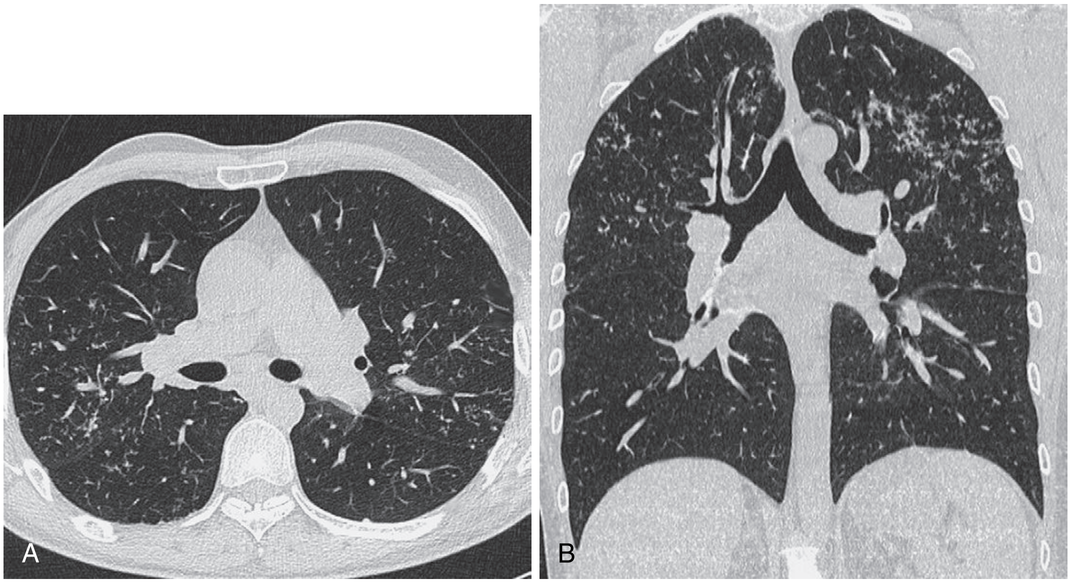

Figure 7-111 High-resolution computed tomography imaging of the lungs in a patient with sarcoidosis. **A,** Parenchymal nodularity together with thickening and beading of the bronchovascular bundles is typical of sarcoidosis. **B,** Coronal reformatted image through the lungs of the same patient demonstrates the middle and upper zone predominance of disease.

diffuse lung pathoses have both interstitial and air space components, this distinction does not always aid in the diagnosis. Whether pulmonary nodules can be detected on CT depends on their size, profusion, and density and on the scanning technique. Narrow-collimation HRCT clearly is superior to conventional CT for the detection of micronodular disease because it is associated with less partial volume effect, which can average out the attenuation of tiny nodules. A further refinement is the use of maximum-intensity projection images obtained with spiral CT to detect extremely subtle micronodular disease. Nodules within the lung interstitium are seen in the interlobular septa, subpleural regions (particularly in relation to the fissures), and in a peribronchovascular distribution. Nodular thickening of the bronchovascular interstitium results in an irregular interface between the margins of the bronchovascular bundles and the surrounding lung parenchyma. These features are most pronounced in cases of sarcoidosis, in which coalescent, perilymphatic granulomas cause a beaded appearance of the thickened bronchovascular bundles. The bronchovascular distribution of nodules, in conjunction with a perihilar concentration of disease, is virtually pathognomonic for sarcoidosis (Figure 7-111).

The nodular pattern seen in coal worker's pneumoconiosis and silicosis generally is more uniform in distribution. Centrilobular nodules may be more numerous in the upper zone and in subpleural regions, but overall they tend to be more evenly spread throughout the lung parenchyma than those seen in sarcoidosis.

When the air spaces are filled, or partially filled, with exudate, individual acini may become visible as poorly defined nodules approximately 8 mm in diameter. Acinar nodules may merge with areas of ground glass opacification and sometimes are seen around the periphery of areas of dense parenchymal consolidation (Figure 7-112). Such nodules usually are centrilobular, although this localization may be difficult to appreciate if the nodules are very profuse. Conditions in which this nonspecific pattern is seen include organizing pneumonia, hypersensitivity pneumonitis (Figure 7-113), endobronchial spread of tuberculosis, idiopathic pulmonary hemorrhage, and some cases of bronchoalveolar cell carcinoma.

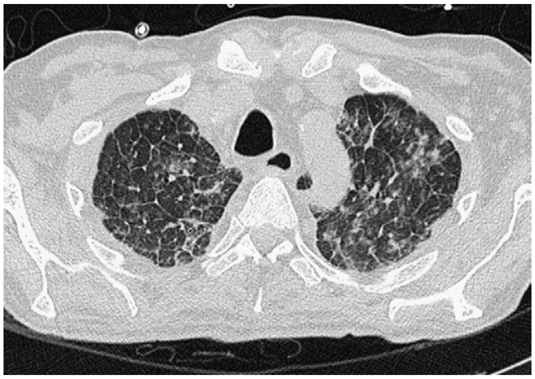

Figure 7-112 Poorly defined acinar nodules. Generalized ground glass density and interlobular septal thickening also are evident. The patient had cardiogenic pulmonary edema.

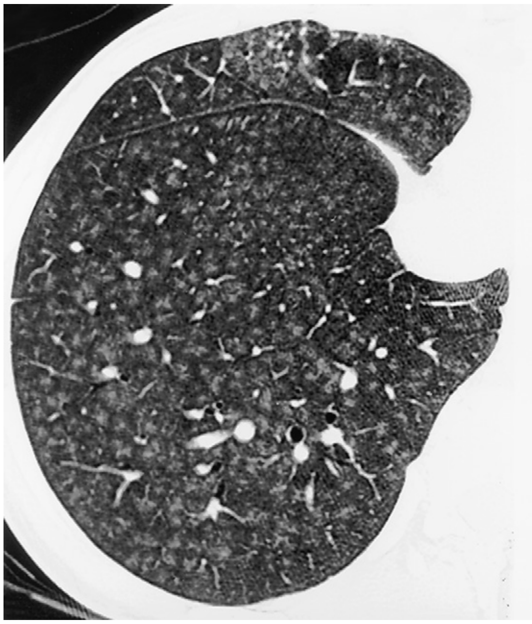

Figure 7-113 High-resolution computed tomography scan showing poorly defined nodular opacities merging with ground glass opacification. The patient had subacute hypersensitivity pneumonitis.

Increased Lung Density

An amorphous increase in lung density on HRCT often is described as a ground glass opacification appearance (Figure 7-114). Unlike the equivalent abnormality on chest radiography, in which the pulmonary vessels often are indistinct, a ground glass pattern on HRCT does not obscure the pulmonary vasculature. In cases in which the presence of a ground glass pattern is equivocal, HRCT often is useful to compare the density of the lung parenchyma with air in the bronchi—in the normal state, the difference in density is marginal. Although this HRCT abnormality usually is easily recognizable, particularly when it is interspersed with areas of normal lung parenchyma, subtle degrees of increased parenchymal opacification may not be obvious. It is important to recognize that a normal increase in parenchymal density, indistinguishable from a generalized opacification caused by infiltrative lung disease, results in a ground glass pattern in patients who breath-hold at end expiration.

On a pathologic level, the changes responsible for ground glass opacification are complex and include partial filling of the air spaces and thickening of the interstitium, or a combination of the two (Figure 7-115). Conditions that are characterized by these pathologic changes and result in the nonspecific pattern of ground glass opacification include fibrosing alveolitis in the active cellular phase, *Pneumocystis* pneumonia, subacute hypersensitivity pneumonitis, sarcoidosis, drug-induced lung damage, diffuse pulmonary hemorrhage, and acute lung injury. The amorphous ground glass density seen on HRCT in these conditions usually represents a potentially reversible process. However, mild thickening of the intralobular interstitium by irreversible fibrosis may rarely produce a ground glass appearance in fibrosing alveolitis. Furthermore, ground glass opacification may be seen in areas of bronchoalveolar cell carcinoma, usually in conjunction with patches of denser, consolidated lung (Figure 7-116).

A pitfall in identifying a ground glass pattern on HRCT occurs when regional differences in pulmonary perfusion are present—regional alterations in pulmonary blood flow, caused by thromboembolism, for example, may result in striking differences in lung density (Figure 7-117). The density difference between the underperfused lung and normal lung may give the appearance of a ground glass density in normal (but relatively overperfused) lung parenchyma. These areas of different density have often been termed mosaic oligemia. A similar appearance is seen in patients who have patchy air trapping caused by small airway disease, such as in an obliterative bronchiolitis: The relatively transradiant areas of underventilated and thus underperfused lung make the normal lung parenchyma appear more than usually dense and thus simulate a ground glass infiltrate. This potential pitfall often can be recognized for what it is by the relative paucity of vessels in the underventilated parts of the lungs caused by hypoxic

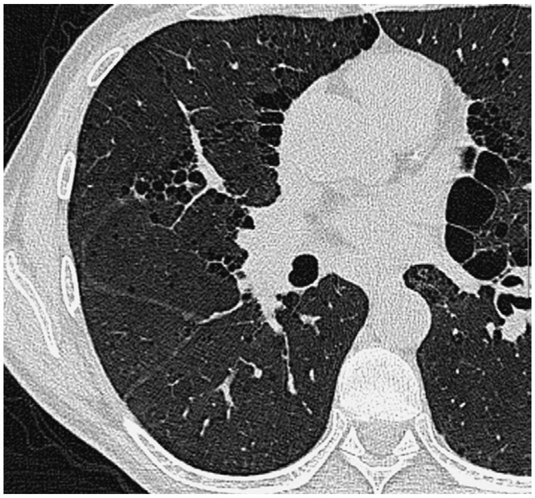

Figure 7-114 Ground glass appearance on high-resolution computed tomography. Extensive ground glass opacification in a patient with desquamative interstitial pneumonitis. Note that the vessels are visible within the areas of ground glass opacification.

Established pulmonary fibrosis
A
B
C

Figure 7-115 Normal and diseased lung voxels. **A,** In the normal state, most of the volume of these voxels is made up of air. **B,** Gross thickening of the interstitium and some cells within the air spaces causes displacement of air and a corresponding increase in density within the voxels—this produces ground glass opacification on a high-resolution computed tomography image. **C,** In established pulmonary fibrosis, the strands of fibrotic lung occupy much of the volume of individual voxels, which is reflected in their density; pulmonary fibrosis thus has a reticular pattern on high-resolution computed tomography.

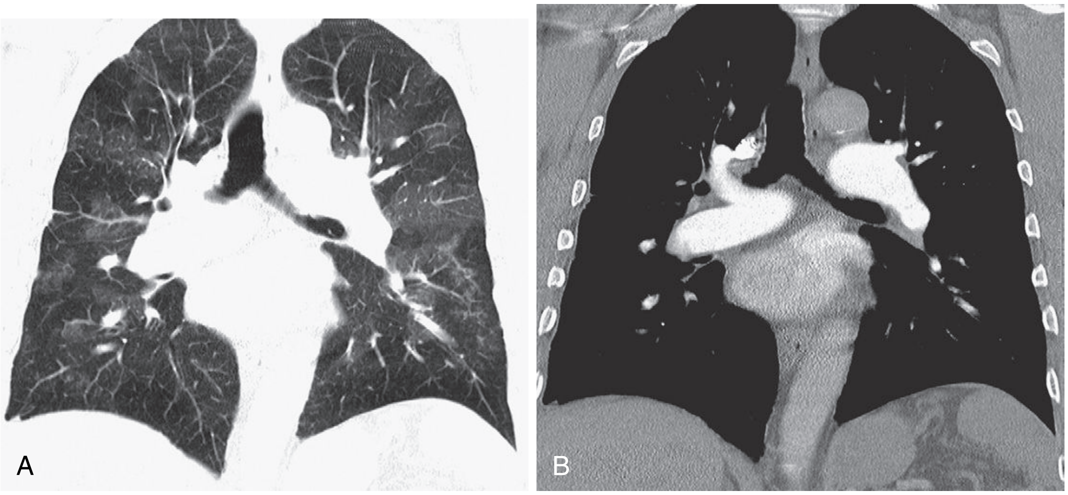

Figure 7-117 Coronal reformatted images from MDCT dataset. Uneven density of the lung parenchyma caused by perfusion inhomogeneity. The patient had chronic thromboembolism. **A,** Coronal reformatted image using lung window settings demonstrates the mosaic attenuation pattern. **B,** On mediastinal window settings, the large central pulmonary arteries are evident.

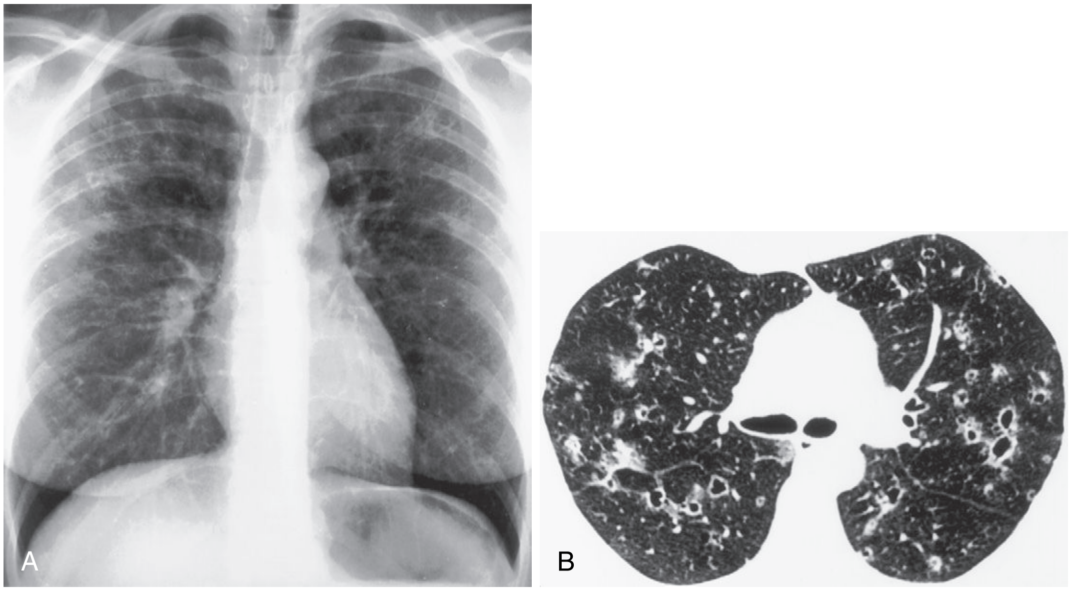

Figure 7-118 Cystic air spaces. **A,** Nonspecific shadowing on a chest radiograph, with the suggestion of a cavitating nodule in the right upper zone. **B,** High-resolution computed tomography scan through the upper lobes reveals multiple curious-shaped, cavitating lesions, typical of Langerhans cell histiocytosis.

vasoconstriction. The vessels in the relatively normal lung of higher density are engorged because of shunting of blood to these regions (see Figure 7-117).

Cystic Air Spaces

The term *cystic air space* describes a clearly defined, air-containing space that has a definable wall 1 to 3 mm thick. Many conditions are characterized by a profusion of cystic air spaces, which may not be recognizable as such on chest radiography (**Figure 7-118**), whereas the size and distribution of these cysts on HRCT may suggest the diagnosis.

The destruction of alveolar walls that characterizes emphysema produces areas of low attenuation on HRCT, which often merge imperceptibly with normal lung (**Figure 7-119**). In patients who have predominantly centrilobular emphysema, circular areas of lung destruction may resemble cysts; however, the centrilobular core usually is visible as a dotlike structure in the center of the apparent cyst. Although bullae of varying sizes are clearly seen on HRCT in patients who have emphysema, usually a background permeative, destructive parenchyma prevents confusion with other conditions in which cystic air spaces are a prominent feature.

Cystic air spaces as the dominant abnormality are seen in only a few conditions, which include lymphangioleiomyomatosis, Langerhans cell histiocytosis, end-stage fibrosing alveolitis, and postinfective pneumatoceles. In lymphangioleiomyomatosis, the cysts usually are uniformly scattered throughout the lungs, with normal lung parenchyma intervening; the individual cysts rarely are larger than 4 cm in diameter (**Figure 7-120**). As the disease progresses, the larger cystic air spaces coalesce; the circumferential, well-defined walls of the cysts become disrupted; and the HRCT pattern in advanced lymphangioleiomyomatosis, and indeed in Langerhans cell histiocytosis, may be practically indistinguishable from that in severe centrilobular emphysema. Distinction of the delicate, "lacelike" reticular pattern of lymphangioleiomyomatosis on HRCT from that of

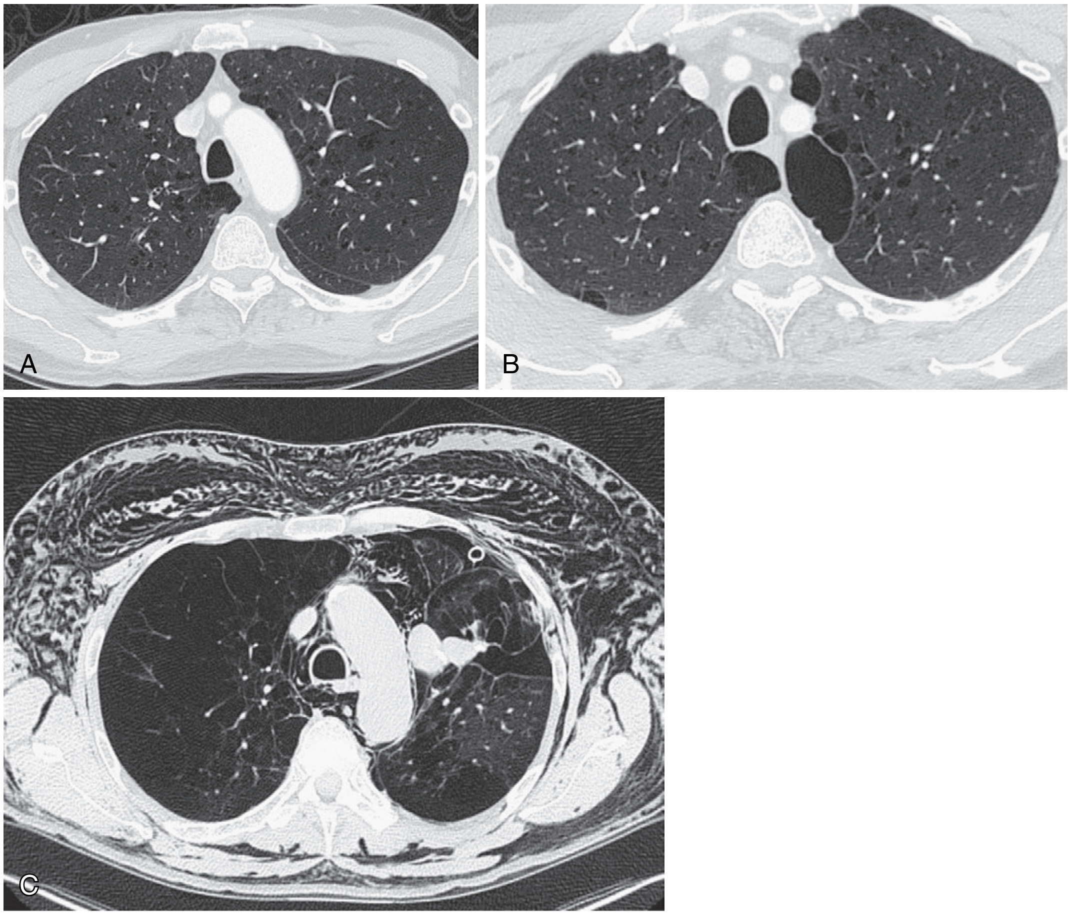

Figure 7-119 High-resolution computed tomography in centrilobular versus other forms of emphysema. **A,** Centrilobular emphysema. Note the permeative destruction of the lung parenchyma with scattered centrilobular lucent areas. **B,** Paraseptal emphysema. The disease is concentrated in the subpleural lung. **C,** Panacinar emphysema. Large swathes of completely destroyed lung are evident, with almost no vascular or soft tissue structures demonstrated within.

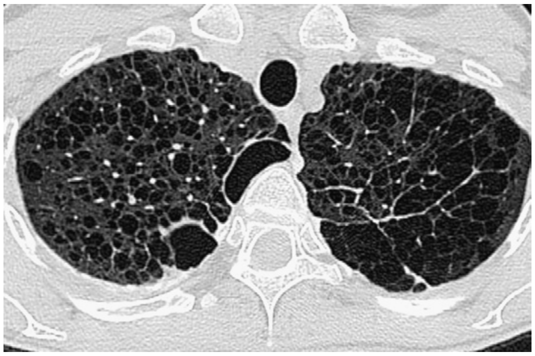

Figure 7-120 High-resolution computed tomography in advanced lymphangioleiomyomatosis. Note the coalescence of cystic air spaces, which resembles that in severe centrilobular emphysema.

end-stage fibrosing alveolitis usually is possible, because the cystic air spaces in a fibrotic honeycomb lung are smaller and have thicker walls. Furthermore, the tendency for fibrosing alveolitis to have a peripheral distribution, even in its end stage, usually is still obvious in the upper zones.

Similar, confluent cystic air spaces that give a delicate pattern on HRCT are seen in images obtained in patients who have advanced Langerhans cell histiocytosis. Earlier in the disease, however, a nodular component is present, and some of the nodules cavitate. The combination of cavitating nodules, some of which have curious shapes (e.g., cloverleaf shape), and cystic air spaces with a predominantly upper zone distribution is virtually pathognomonic for this diagnosis (see Figure 7-118). Serial HRCT scans show the natural history of nodules, which cavitate, become cystic air spaces, and, in end-stage disease, coalesce. In a few cases, these pathologic changes may resolve, with the lung parenchyma reverting to a normal appearance. Some of the cavitating nodules in Langerhans cell histiocytosis superficially resemble bronchiectatic airways, but a lack of continuity between these lesions will be observed on adjacent sections, and the segmental bronchi, when they can be identified, do not have any of the HRCT features of bronchiectasis.

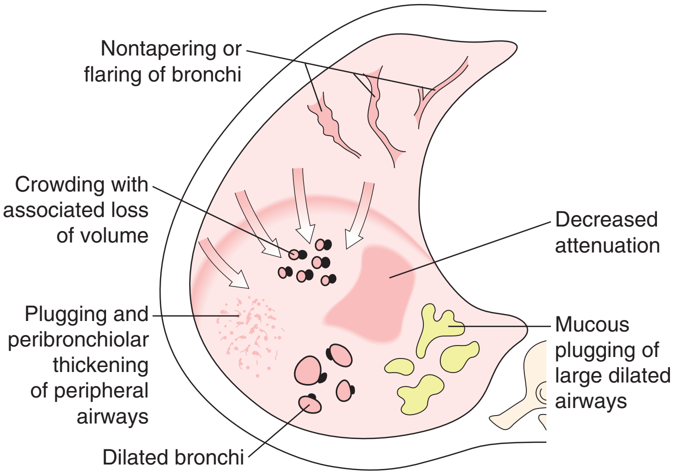
DISEASES OF THE AIRWAYS

Now that bronchography is rarely performed, the imaging modality of choice to diagnose bronchiectasis is HRCT. *Bronchiectasis* is defined as damage to the bronchial wall that results in irreversible dilatation of the bronchi, whatever the cause. Thus, the main feature of bronchiectasis on HRCT is dilatation of the bronchi with or without bronchial wall thickening. Criteria for the HRCT identification of abnormally dilated bronchi depend on the orientation of the bronchi in relation to the plane of the HRCT section (**Figure 7-121**).

Vertically oriented bronchi are seen in transverse section, so reference can be made to the accompanying pulmonary artery, which in normal persons is of approximately the same caliber; any dilatation of the bronchus results in the so-called signet ring sign (**Figure 7-122**). Although this generally constitutes reliable evidence of abnormal bronchial dilatation, care must be taken in comparing the diameter of the bronchi and adjacent pulmonary arteries just below the division of the lower lobe bronchus. At this level, pairs of segmental and sometimes subsegmental bronchi converge, and the resulting fusion of the two bronchi may give the spurious impression of an abnormally dilated bronchus. Bronchi that have a more horizontal course on CT scans, particularly the anterior segmental bronchi of the upper lobes and the segmental bronchi of the lingula and right middle lobe, are demonstrated along their length, and abnormal dilatation is seen as nontapering parallel walls or even flaring of the bronchi as they course distally (Figure 7-123). In more severe cases of bronchiectasis, the bronchi are obviously dilated and have a varicose or cystic appearance.

Bronchial wall thickening is a frequent but not invariable feature of bronchiectasis. The definition of what constitutes abnormal bronchial wall thickening remains contentious, particularly because mild degrees of wall thickening are seen in normal subjects, asymptomatic smokers, asthmatic individuals, and patients affected by an acute, lower respiratory tract, viral infection. In brief, no robust and reproducible criterion for the identification of abnormal bronchial wall thickening has been identified, so bronchial wall thickening remains a subjective sign with an attendant high variation in observer interpretation. However, it is the presence of peribronchial thickening that renders the smaller peripheral airways visible on HRCT. Although there is no exact level beyond which visualization of the bronchi can be regarded as abnormal on HRCT, normal bronchi should not be visible within 2 to 3 cm of the pleural surface. Large elliptical and circular opacities, which represent secretion-filled, dilated bronchi, constitute a sign of gross bronchiectasis and are almost invariably seen in the presence of other obviously dilated bronchi, some of which may contain air-fluid levels (Figure 7-124). When mucous plugging of the smaller airways occurs, minute branching structures or dots in the lung periphery may be identifiable. In some cases, plugging of the numerous centrilobular bronchioles gives a curious nodular appearance to the lungs (Figure 7-125).

Supplementary HRCT evidence of bronchiectasis includes crowding of the affected bronchi, with obvious volume loss of the lobe as shown by the position of the major fissures. In many lobes affected by bronchiectasis, areas of decreased attenuation of the lung parenchyma adjacent to the abnormal airways can



Nontapering or flaring of bronchi

Plugging and peribronchiolar thickening of peripheral airways
Dilated bronchi
Decreased attenuation
Mucous plugging of large dilated airways

Figure 7-121 High-resolution computed tomography features of bronchiectasis: nontapering or flaring of bronchi lying within the plane of section; “signet ring” sign of dilated bronchi running perpendicular to the plane of computed tomography section; mucous plugging of large, dilated airways; plugging and peribronchiolar thickening of small peripheral airways; crowding with associated loss of volume (see position of oblique fissure); and areas of decreased attenuation, which reflect associated small airway disease.

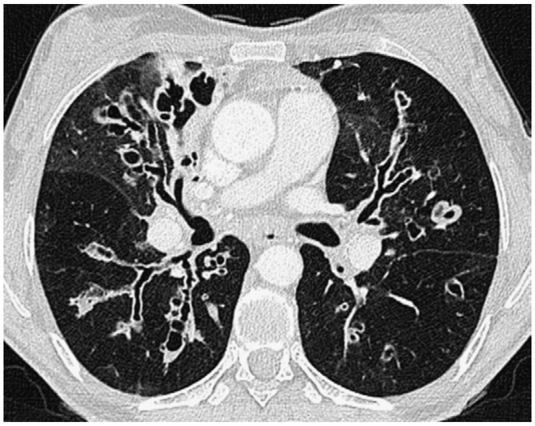

Figure 7-123 High-resolution computed tomography scan obtained in a patient with cystic fibrosis. Nontapering and flaring of the bronchiectatic airways are evident in the apical segment of the right lower lobe. In addition, mosaic perfusion is present, reflecting associated small airway disease.

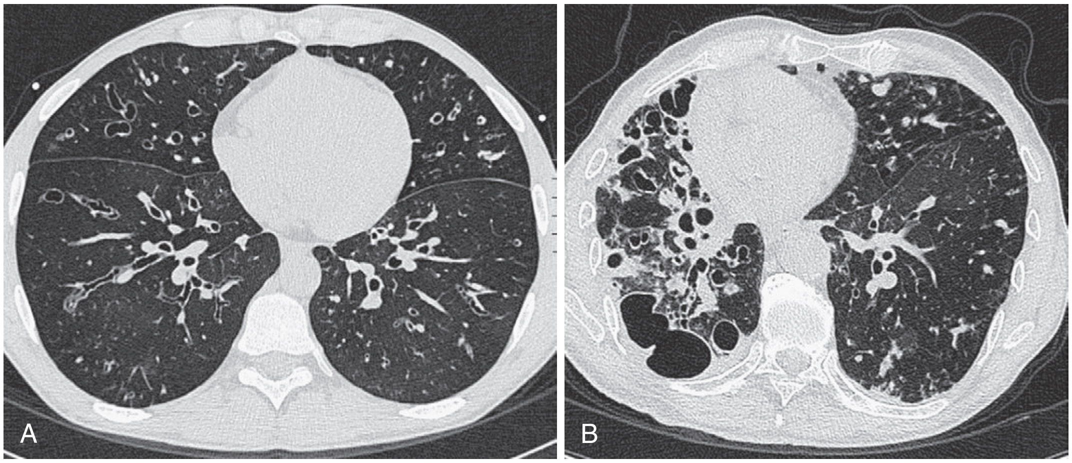

Figure 7-122 Bronchiectasis in two different patients. **A,** Cylindrical bronchiectasis without plugging has a characteristic signet ring appearance. **B,** With more severe disease, some airway plugging is seen in the tip of the lingula.

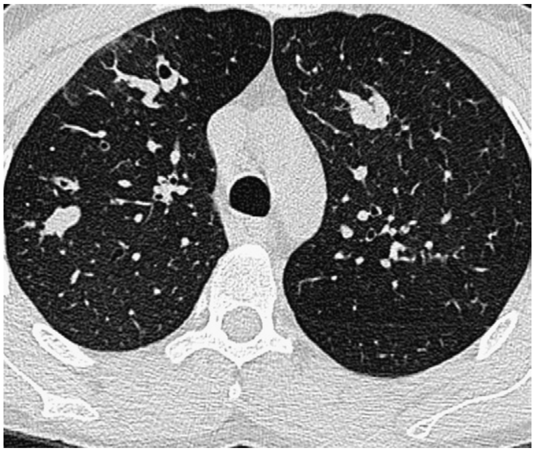

Figure 7-124 Severe bronchiectasis in the left upper lobe. Some bronchi are filled with secretions, which results in multiple tubular and elliptical opacities. The patient had allergic bronchopulmonary aspergillosis.

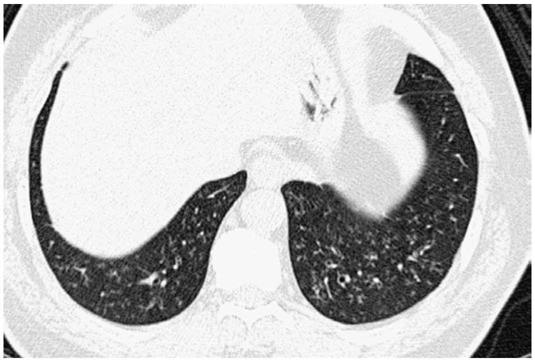

Figure 7-125 Numerous small irregular opacities in the left lower lobe representing plugged bronchioles. The patient had panbronchiolitis.

Table 7-2 **Causes of False-Positive and False-Negative Diagnosis of Bronchiectasis on High-Resolution Computed Tomography**

False-Negative Factors	False-Positive Factors
Inappropriately thick computed tomography section	Cardiac pulsation causing "double vessels"
Movement artifact obscuring lung detail	Confluence of subsegmental bronchi leading to spurious impression of bronchiectasis, at a single level (particularly in the lower lobes)
Focal, inconspicuous, thin-walled bronchiectasis	Cavitating nodules mimicking bronchiectasis (e.g., Langerhans cell histiocytosis)
Masking of bronchiectatic airways by surrounding fibrosis	Reversible dilatation of bronchi with acute pneumonic consolidation

be identified; this pattern of mosaic attenuation is thought to reflect accompanying small airway disease, and the extent of the pattern correlates well with functional evidence of airflow obstruction, particularly indices of small airway dysfunction.

A positive diagnosis of bronchiectasis on HRCT is straightforward in patients who have moderate and severe disease. In some situations, however, subtle signs of bronchiectasis may be obscured by technical artifacts. Conversely, the HRCT appearance of bronchiectasis may be mimicked by other lung pathoses. Some of the causes of false-negative and false-positive diagnoses of bronchiectasis are listed in Table 7-2.

Interest in the ability of HRCT to detect small airway disease is increasing. In the exudative form of bronchiolar disease (typified by Japanese panbronchiolitis), HRCT directly shows the plugged small airways as small, irregularly branching opacities. The HRCT signs of constrictive obliterative bronchiolitis (e.g., in patients with rheumatoid arthritis or postviral obliterative bronchiolitis) are indirect—areas of decreased attenuation occur within which the vessels are of reduced caliber (but not distorted, in contrast with emphysema). The areas of decreased attenuation may merge with those of more normal lung or may have sharply demarcated, "geographic" boundaries (mosaic attenuation pattern). The density differences that characterize constrictive obliterative bronchiolitis may be extremely subtle, but because they represent areas of reduced ventilation with consequent air trapping, they may be dramatically emphasized on scans performed at end expiration. Most patients affected by small airway disease ill exhibit some bronchiectatic changes on HRCT, which tend to be more severe in those who have immunologically mediated obliterative bronchiolitis.

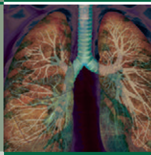
DIAGNOSTIC TECHNIQUES



Chapter 8

Positron Emission Tomography Imaging

Johan Vansteenkiste • Christophe Dooms • Christophe Deroose

Conventional imaging relies on differences in the *structure* of tissues, measured by differences in density, as in chest radiography and computed tomography (CT); surface reflectivity, as in ultrasonography; or chemical environment, as in magnetic resonance imaging (MRI). With the exquisite anatomic detail they provide, these modalities play a crucial role in the evaluation of many respiratory diseases. Nonetheless, assessment of structural differences often does not lead to a definitive diagnosis; in such instances, invasive tests with tissue sampling also are needed.

Positron emission tomography (PET) brought a revolutionary and novel aspect to imaging: It allows accurate, noninvasive measurement of *metabolism* of tissues, a valuable complement to the structural information provided on conventional imaging. This combined information allows better distinction between malignant and benign tissues and also can be used in monitoring of disease by the study of metabolic alterations, which can be different from or even precede the anatomic changes.

USE OF POSITRON EMISSION TOMOGRAPHY IN RESPIRATORY MEDICINE

PET with ^{18}F-fluorodeoxyglucose (FDG) tagging is a noninvasive imaging technique with high sensitivity for detection of both oncologic and nononcologic disorders in respiratory medicine. It has been suggested that FDG-PET might be useful in several diseases associated with FDG uptake based on inflammatory mechanisms, such as granulomatous diseases (e.g., sarcoidosis) or other proliferative inflammatory disorders (e.g., idiopathic pulmonary fibrosis, posttransplantation lymphoproliferative disorders).

Classical forms of sarcoidosis with intrathoracic nodal and/or pulmonary disease are in general assessed by combining clinical examination, pulmonary function and laboratory tests, and a CT scan of the chest. The extent and activity of the disease can be more accurately assessed by FDG-PET–CT than by gallium 67 single photon emission CT (^{67}Ga-SPECT) scintigraphy. FDG-PET–CT in sarcoidosis is better at identifying occult sites of extrathoracic disease and has a superior spatial and contrast resolution, as well as better interobserver agreement, compared with ^{67}Ga-SPECT. FDG-PET–CT currently is undergoing further evaluation of its clinical utility to monitor disease activity during treatment of interstitial pulmonary diseases such as sarcoidosis and idiopathic pulmonary fibrosis.

Posttransplantation lymphoproliferative disorder (PTLD) is a serious complication occurring after solid organ or bone marrow transplantation. The incidence of PTLD in lung transplant recipients is 5%. In this disorder, FDG-PET–CT allows more accurate evaluation of disease extent, with better follow-up after treatment, than that achievable with conventional CT imaging.

The most common application of FDG-PET is in investigation of respiratory malignancies. The indications for PET in this setting are listed in Box 8-1.

PRINCIPLES OF POSITRON EMISSION TOMOGRAPHY IMAGING

POSITRON EMISSION TOMOGRAPHY CAMERAS

A PET camera produces three-dimensional images that represent the distribution of radioactivity in the body. Any molecule that can be labeled with a positron-emitting radioisotope can be used to generate PET images (more than 400 PET tracers are listed in the NIH Molecular Imaging and Contrast Agent Database [MICAD], available at www.ncbi.nlm.nih.gov/books/NBK5330/).

The spatial resolution of older PET cameras was 6 mm or higher; for contemporary PET cameras, this is around 4 mm. Lesions with a diameter up to twice that resolution can be characterized with virtually no size-related (partial volume effect) underestimation of the tracer uptake, whereas for smaller lesions, the tracer uptake will gradually be underestimated as the size becomes smaller. In practice, lesions larger than 8 to 10 mm will be well characterized, whereas smaller ones, other than strongly FDG-avid lesions, cannot be accurately depicted.

The main difference between standard radionuclide imaging with gamma cameras and imaging with dedicated PET cameras is that the latter type of camera has a full ring of several thousands of scintillation detectors and does not need lead collimators—which absorb more than 99% of the emitted photons—to generate the image, resulting in higher sensitivity to radioactivity and higher spatial resolution.

Historically, PET cameras were “stand-alone” machines, either dedicated PET cameras or specially designed gamma cameras with which dual-head gamma camera coincidence imaging was performed. To overcome the lack of anatomic information of PET imaging, this type of camera has been replaced by hybrid systems in which a dedicated PET camera is combined with an anatomic tomograph—mostly with a computed tomography (CT) camera but sometimes a magnetic resonance imaging (MRI) camera. These fusion PET-CT cameras are considered the new standard (“stand-alone” PET cameras are not manufactured anymore), whereas PET-MRI is an emerging technology. The use of hybrid PET-CT cameras offers three main advantages: (1) attenuation correction (AC), which is needed to correct the image for the fact that some of the

Box 8-1 **Current and Innovative Indications for Positron Emission Tomography in Respiratory Oncology**

Diagnosis of Single Pulmonary Nodules or Masses
- Differentiation of malignant versus benign nodules
  - Reduce the need of unwanted invasive procedures
  - Reduce cost
  - Aid in decision algorithms in screening studies
- False-negative results
  - Small or ground glass opacity tumors
  - Low-metabolism tumors (carcinoid, bronchioloalveolar carcinoma)
- False-positive results
  - Inflammatory respiratory disorders

Mediastinal Lymph Node Staging
- High negative predictive value for lymph node metastasis
  - Reduction in number of invasive tests, without loss of accuracy
  - Reduction in cost
  - Better guidance of invasive procedures
- False-negative results
  - Low FDG uptake in primary tumor
  - Centrally located tumors
  - Major hilar lymph node involvement
- False-positive results
  - Inflammatory lymph nodes

Extrathoracic Staging
- Significant complement to conventional imaging
  - Detection of unexpected metastasis
  - Characterization of equivocal lesions
- False-negative results
  - Low FDG uptake in primary tumor
  - Small metastatic deposits
- False-positive results
  - Inflammatory/benign: always confirm single suspect lesion
  - Second primary tumor

Innovative Indications
- Selective use in lung cancer screening
- Assessment of pleural mesothelioma
- Diagnosis of recurrence after radical therapy
- Prognosis and assessment of therapy
  - Prognostic information
  - Early response evaluation during chemotherapy
  - Restaging after induction treatment
- Radiotherapy planning
- Response prediction in molecular therapy

FDG, ^{18}F-fluorodeoxyglucose.

photons coming from radioactive decay are absorbed by the body, can be performed with the CT dataset, resulting in significant time reduction (approximately 10 minutes gained per patient); (2) increased accuracy of the exact position of the lesion and morphologic characterization of the underlying correlate, reducing equivocal findings; and (3) significantly increased confidence in reported findings. Typical scan times for modern PET-CT are in the 6- to 20-minute range for a skull-to-thigh image (i.e., whole-body scan). The data reported in this chapter derive from either dedicated PET or PET-CT applications.

The advent of PET-CT has resulted in two different strategies: so-called *low-dose CT*, which is used only for AC and localization, and “one-stop shopping” *high-dose, contrast-enhanced diagnostic CT* together with PET. It has been demonstrated that the use of oral or intravenous contrast agents does not induce clinically significant changes in the PET images. The combination of contrast-enhanced CT with PET changes tumor-node-metastasis (TNM) staging in 8% of patients and is nowadays mandatory for applications such as radiation therapy planning. The drawback is an increase in radiation dose, with low-dose techniques adding about 3 mSv to the approximately 8 mSv from the radiopharmaceutical, whereas contrast-enhanced CT adds some 10 to 20 mSv.

METABOLIC TRACERS

For cancer imaging, 2-^{18}F-fluoro-2-deoxy-D-glucose (FDG), described in 1978, is by far the most commonly used metabolic tracer. The usefulness of this tracer relates to the increased cellular uptake of glucose (due to an increased expression of glucose transporter proteins) and a much higher rate of glycolysis in cancer cells. FDG, a glucose analogue in which the oxygen molecule in position 2 is replaced by a positron-emitting fluorine 18 atom, undergoes the same uptake as for glucose but is metabolically trapped and accumulated in the neoplastic cell after phosphorylation by hexokinase.

INTERPRETATION OF POSITRON EMISSION TOMOGRAPHY IMAGES

GENERAL PRINCIPLES

If the aim of the FDG-PET study is just to stage the patient’s cancer, visual analysis of non-AC images (i.e., “hot spots” with higher-than-background activity not caused by physiologic processes are positive for tumor) probably is just as good as AC images, as has been pointed out by different prospective studies, both for the discrimination of nodules and for the evaluation of mediastinal involvement. Non-AC images should be examined to detect small lung lesions, because they are better visualized, owing to higher contrast, than are AC images.

THE NORMAL FDG-PET IMAGE

High physiologic FDG uptake occurs in brain, kidney, and urinary tract (urinary excretion) and can be present in the heart. Particularly in the brain, this interferes with lesion detection. A low degree of physiologic uptake of FDG has been noted in thoracic structures, including the lung, the heart, the aorta and large arteries, esophagus, thymus, trachea, thoracic muscles, bone marrow, and joints and soft tissues. This low background tracer activity builds the image contour.

FALSE-POSITIVE RESULTS

FDG uptake is not tumor-specific and may be observed in all active tissues with high glucose metabolism, in particular, those in which inflammation is present. Therefore, a finding of clinically relevant FDG uptake, especially if isolated and decisive for patient management, requires confirmation. The differentiation between metastasis and a benign or inflammatory lesion, or even an unrelated second malignancy, should be made by means of other tests or tissue diagnosis.

The major causes of false-positive results (Box 8-2) in chest pathology are infectious, inflammatory, and granulomatous disorders. Iatrogenic procedures, such as thoracocentesis, placement of a chest tube, percutaneous needle biopsy, mediastinoscopy, thoracoscopy, and talc pleurodesis, also may give false-positive results.

Box 8-2 Causes of False-Positive and False-Negative Results on Positron Emission Tomography

False-Positive Findings

Infection/Inflammation
(Postobstructive) pneumonia/abscess
Mycobacterial or fungal infection
Granulomatous disorders (sarcoidosis, Wegener granulomatosis)
Chronic nonspecific lymphadenitis
(Rheumatoid) arthritis
Occupational exposure (anthracosilicosis)
Bronchiectasis
Organizing pneumonia
Reflux esophagitis

Iatrogenic Causes
Invasive procedure (puncture, biopsy)
Talc pleurodesis
Radiation esophagitis and pneumonitis
Bone marrow expansion post chemotherapy
Colony-stimulating factors
Thymic hyperplasia post chemotherapy
FDG embolism

Benign Mass Lesions
Salivary gland adenoma (Warthin tumor)
Thyroid adenoma
Adrenal adenoma
Colorectal dysplastic polyps

Focal Physiologic FDG Uptake
Gastrointestinal tract
Muscle activity
Brown fat
Unilateral vocal cord activity
Atherosclerotic plaques

False-Negative Results

Lesion-Dependent
Small-sized lesion
Bronchioloalveolar carcinoma
Carcinoid tumors
Ground glass opacity neoplasms

Technique-Dependent
Hyperglycemia
Paravenous FDG injection
Increased time between injection and scanning

FDG, ^{18}F-fluorodeoxyglucose.

FALSE-NEGATIVE RESULTS

False-negative results are less common and may be due to lesion-dependent or technical factors (see Box 8-2). A critical mass of metabolically active malignant cells is required for PET detection. Interpretation thus is a critical process with tumors exhibiting decreased FDG uptake such as small, very well-differentiated adenocarcinoma, bronchioloalveolar carcinoma, or carcinoid tumors. FDG-avid lesions smaller than 5 mm may be false-negative as a consequence of the limitations in spatial resolution and partial volume effect. In the lower lung fields, the detection limit may even go down to 10 mm, owing to additional respiratory motion. CT-based AC can cause artifacts in the event of misregistration between the CT and the PET data, which can lead to occultation of liver metastasis on the AC images.

Factors related to technique are paravenous FDG injection and high baseline glucose serum levels. Blood glucose levels should be checked, and it is advised to proceed only if the glucose level is within an acceptable range before tracer injection (typically 60 to approximately 180 mg/dL). Although diabetic patients often were excluded in the prospective studies, FDG uptake probably is not significantly influenced in these patients if the blood glucose levels are under reasonable control.

POSITRON EMISSION TOMOGRAPHY IN DIAGNOSIS

The value of FDG-PET in differentiating benign from malignant lung lesions (**Figure 8-1**) has been studied in many prospective studies and documented in different metaanalyses. In these series, in which a *standardized uptake value* (SUV) cutoff of 2.5 often was used to suggest malignancy, a sensitivity of about 90% to 95% (range, 83% to 100%), a specificity of about 80% (range, 52% to 100%), and an accuracy of about 90% (range, 86% to 100%) were reported. Differences in the results can be explained mainly by the prevalence of malignancy in the study population, which is the result of the varying epidemiology of solitary pulmonary nodules (SPNs) in different areas of the world (e.g., regions with more tuberculosis or histoplasmosis), and by the inclusion criteria of the different series (e.g., a lower sensitivity can be expected in series with smaller nodules). The causes for false-negative and false-positive findings in SPNs are listed in Box 8-2.

Studies listed in the metaanalyses included only solid nodules of at least 1 cm in diameter. Therefore, use of a threshold SUV above 2.5 is questionable for smaller or ground glass lesions. In mostly Japanese series with smaller or faint lesions, use of the 2.5 threshold missed malignancy in a quarter of the cancerous lesions. Many of these could, however, be diagnosed on the basis of weak FDG uptake on visual analysis (corresponding to an SUV of about 1.5).

FDG-PET should be used in relation to other clinical (age, smoking history) and radiologic (spiculation) factors determining the likelihood of malignancy. In clinical decision algorithms, FDG-PET will mostly add information for SPNs with an intermediate probability of malignancy. It is important to be aware of possibilities and limitations (see Box 8-2). Strong data point to use of FDG-PET for characterization of solid pulmonary nodules larger than 2 cm in diameter. Sensitivity is around 95%, negative predictive value (NPV) is very high, malignancy can be excluded correctly in the vast majority of cases, and unnecessary invasive procedures can be avoided. In order to minimize the chance of missing malignancy in smaller or faint SPNs, any lesion with FDG uptake resulting in higher-than-background activity should be considered suspect, and the overall use of the “magic” SUV threshold of 2.5 should be abandoned.

Finally, specificity and positive predictive value (PPV) are suboptimal, and clinicians should be aware that a false-positive scan is possible in the conditions listed in Box 8-2, which should be evaluated by appropriate tests. In case of doubt, lesions with increased FDG uptake should be considered to be malignant until proven otherwise and should be managed accordingly.

POSITRON EMISSION TOMOGRAPHY IN STAGING

TUMOR-NODE-METASTASIS STATUS

On the basis of extension of the primary tumor (T), spread to locoregional lymph nodes (N), and presence of distant metastasis (M), patients with lung cancer can be grouped according to different disease stages. Stage is the most important factor in prognosis and choice of treatment. Therefore, reliable

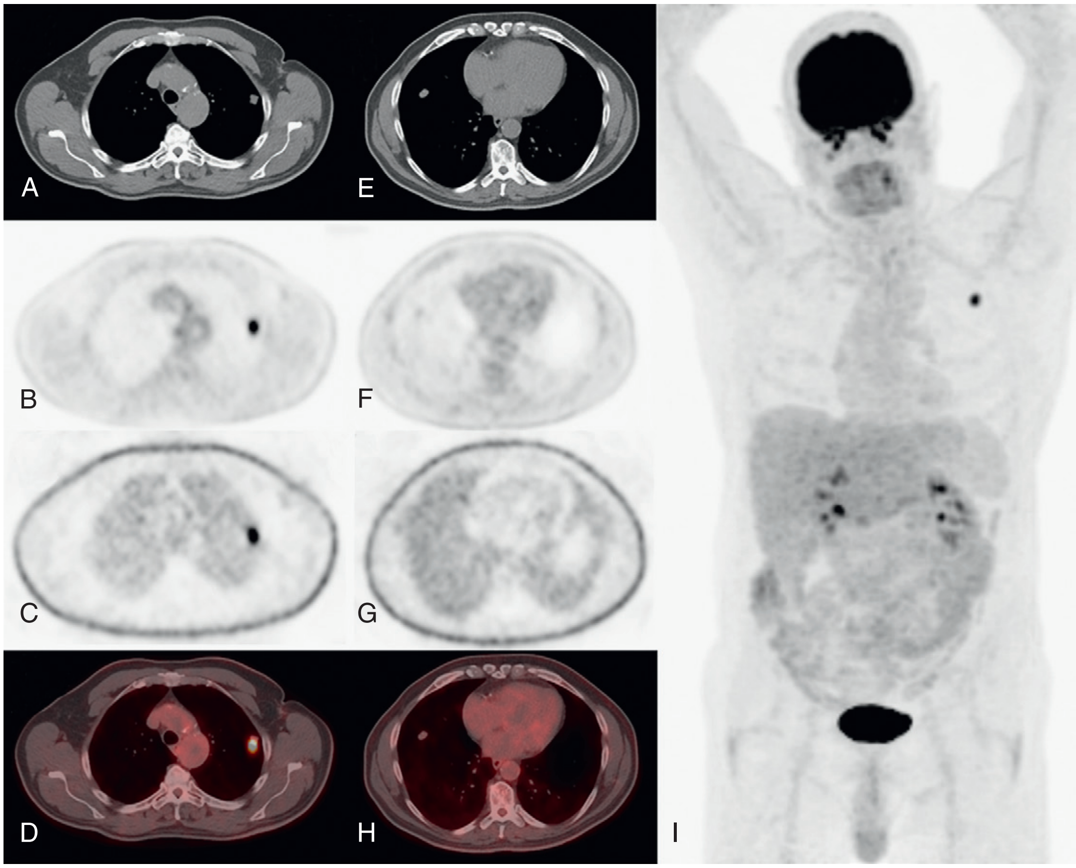


Figure 8-1 ^{18}F-fluorodeoxyglucose (FDG) positron emission tomography–computed tomography (PET–CT) for investigation of coin lesions. Patient with focal nodular lesion in right lung on chest radiograph (*not shown*). CT showed two coin lesions 13 mm in diameter, one in the right middle lobe and one in the left upper lobe. **A,** CT image of left lung coin lesion. **B,** Intense focal FDG uptake ($SUV_{max} = 11.3$) at the site of the lesion on transverse attenuation coefficient (AC) images. **C,** Transverse non-AC image also demonstrates intense FDG uptake. **D,** Fusion image shows colocalization of PET signal and coin lesion. **E,** CT image of right lung lesion. **F,** A transverse AC PET image shows only faint uptake ($SUV_{max} = 1.2$) at the site of the lesion, less intense than the blood pool activity seen in the mediastinum. **G,** A transverse non-AC image shows no increased uptake at all. **H,** Fusion image shows lack of uptake in the lesion. **I,** Maximum intensity projection PET image showing FDG-uptake in the left lung lesion only. At resection, the lesion on the left was found to be a well-differentiated primary lung adenocarcinoma. The lesion in the right lung was regarded as postinfectious scarring and did not change during further years of follow-up. *SUV*, standardized uptake value.

noninvasive methods for accurate staging are very important. CT scan, endoscopic techniques, and surgical staging procedures are key staging tools, but addition of FDG-PET to these conventional methods has been shown to improve the staging process substantially, by distinguishing patients who are candidates for radical approaches such as surgical resection or intense multimodality treatments from those who are not.

For the *T factor,* the detailed images of modern multislice CT allow evaluation of the relationship of the tumor to the fissures (which may determine the type of resection), to mediastinal structures, or to the pleura and chest wall. The integrated FDG-PET–CT images (Figure 8-2) may allow more precise evaluation of chest wall and mediastinal infiltration or correct differentiation between tumor and peritumoral inflammation or atelectasis.

FDG-PET–CT has been used to assess pleural disease with variable results, because small pleural deposits can be missed on PET-CT, owing to their low tumor load or partial volume effect, whereas false-positive results have been documented in patients with inflammatory pleural lesions. If pleural abnormalities determine the chance for radical treatment, often histopathologic verification with cytologic analysis or thoracoscopic biopsy is needed.

For the *N factor*, the addition of FDG-PET to CT results in more accurate lymph node staging than CT alone, with an overall sensitivity of 80% to 90% and a specificity of 85% to 95% in metaanalyses.

On the one hand, the absence of mediastinal lymph node disease on FDG-PET–CT has a high NPV, so that invasive lymph node staging tests can be omitted, and the patient can proceed to straightforward surgical resection. Restrictions on this NPV apply in case of insufficient FDG uptake in the primary tumor, central location of the tumor, or presence of important hilar nodal disease that may obscure coexisting N2 disease on PET images.

On the other hand, the combination of FDG-PET and CT illustrates the location of suspect lymph nodes, thereby helping to direct tissue sampling procedures such as endobronchial ultrasound–guided transbronchial needle aspiration or cervical mediastinoscopy. Because false-positive results are possible with lymph node imaging (under the conditions listed in Box 8-2), histopathologic proof of lymph node involvement should be sought in most patients with imaging-positive mediastinal nodes on FDG-PET, except those with obvious bulky nodes on imaging (Figure 8-3).

For the *M factor*, FDG-PET added to CT is almost uniformly superior to CT alone, except in brain imaging, for which sensitivity is unacceptably low owing to the high glucose uptake in normal surrounding brain tissue. CT and, even better, MRI remain the methods of choice for brain imaging.

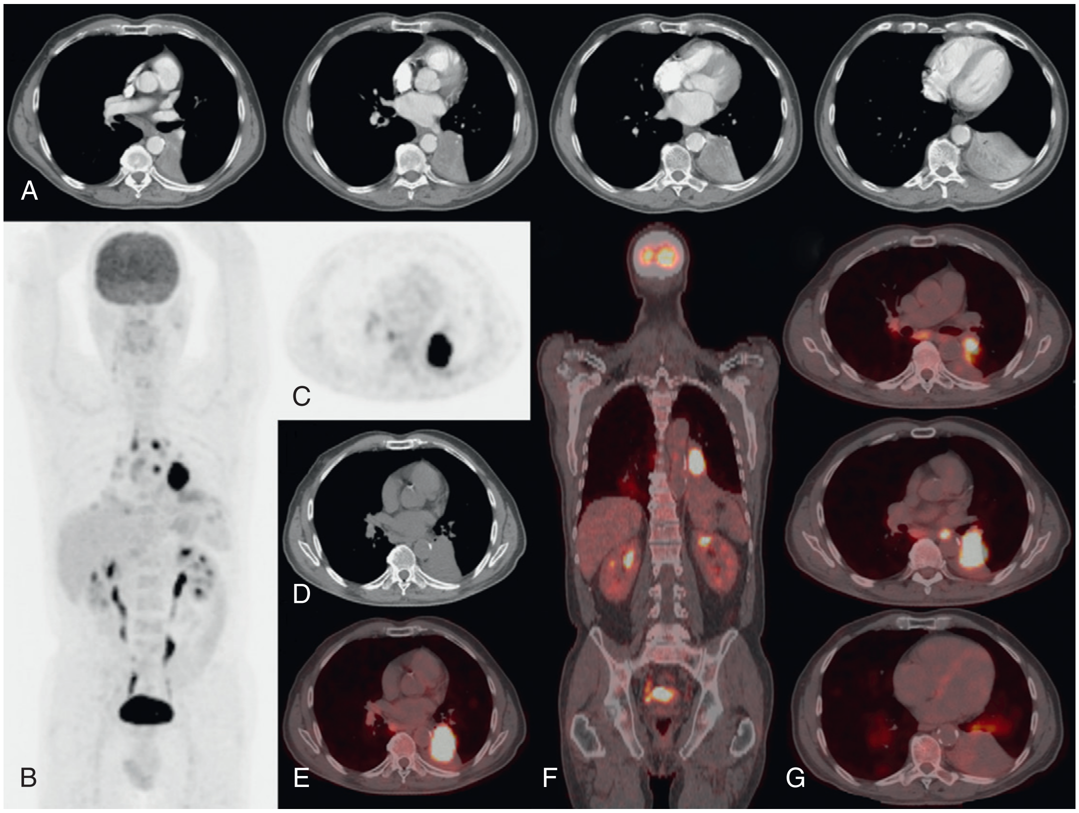

Figure 8-2 ^{18}F-fluorodeoxyglucose positron emission tomography–computed tomography (FDG-PET–CT) aids in the determination of T stage. Patient with adenocarcinoma of the left lower lobe. **A,** CT images show densification of the left lower lobe due to a solid lesion with accompanying retro-obstructive atelectasis, without clear delineation between tumor and benign parenchyma. **B,** Coronal image of the FDG-PET–CT shows a large rounded hypermetabolic lesion in the left lower lobe with smaller foci of intense activity in the mediastinum medial and cranial to the tumor, corresponding to lymph nodes. **C,** Transverse PET image showing a nicely delineated rounded tumor mass, allowing appropriate size determination (47 mm, or T2a). **D,** Corresponding low-dose CT image. **E,** Corresponding fusion image. **F,** Coronal image showing limited size of tumor compared with the atelectatic region. **G,** Consecutive fusion images allowing determination of involved and spared tissue, which are of high value in radiation therapy planning.

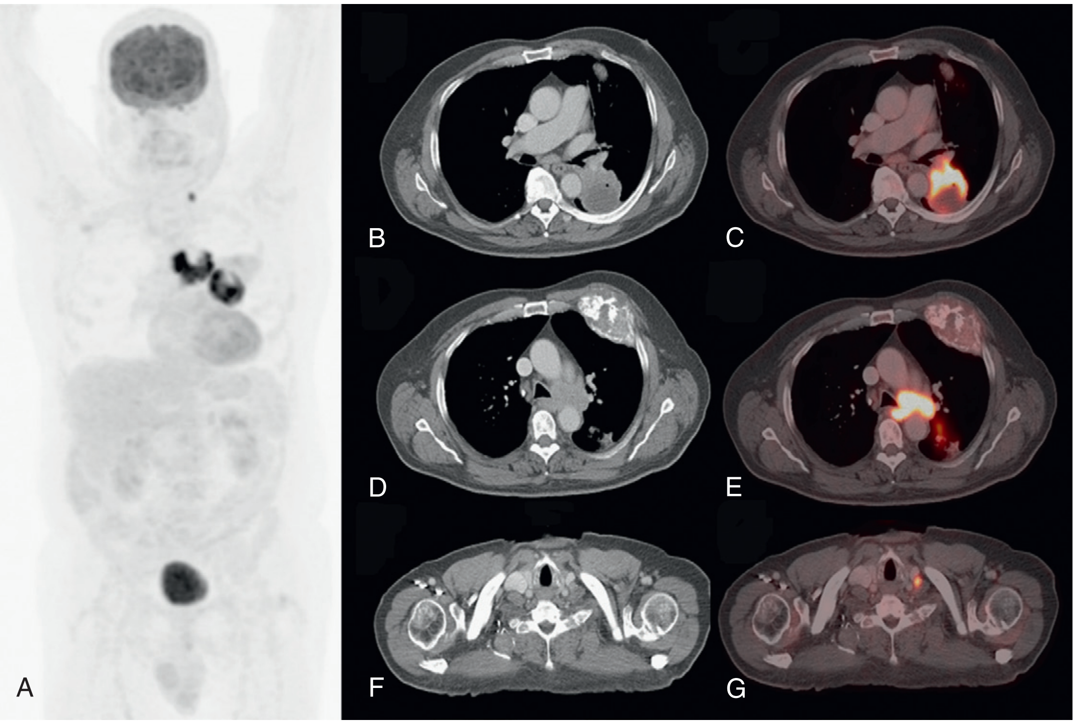

Figure 8-3 ^{18}F-fluorodeoxyglucose positron emission tomography–computed tomography (FDG-PET–CT) in the determination of nodal (N) stage. Patient with a squamous cell carcinoma of the left lower lobe. **A,** Coronal image shows hypermetabolic tumor in left lower lobe with a hypometabolic area at the cranial part indicating necrosis, hypermetabolic bulky mediastinal nodes, and focal increased uptake in the left supraclavicular region. **B,** CT image of primary tumor. **C,** Fusion image of primary tumor. **D,** CT image of bulky enlarged subaortic nodes and calcified rib lesion. **E,** Fusion image demonstrates hypermetabolic nodes and absence of metabolic activity in the rib. **F,** Nonenlarged supraclavicular lymph node behind the jugular vein. **G,** Focal intense FDG uptake in this node ($SUV_{max} = 12.2$) is indicative of N3 involvement. The benign nature of the rib lesion was confirmed through biopsy, and the malignant nature of the supraclavicular node, by fine needle aspiration. *SUV,* standardized uptake value.

For bone metastases, FDG-PET is more accurate than technetium 99m–tagged medronate disodium (formerly methylene diphosphonate) (^{99m}Tc-MDP) bone scan: Sensitivity is at least as good (90% to 95%), and specificity is far better (95%, versus 60% for bone scan). Limitations are the restricted area of imaging for PET (only from the head to just below the pelvis) and possibility of a false-negative result with osteoblastic lesions (rare in lung cancer). For adrenal gland metastases, FDG-PET has a high sensitivity for detection of such disease, so an equivocal-appearing lesion on CT without FDG uptake usually will not be metastatic. FDG-PET also can be of help for investigation of hepatic lesions that remain indeterminate by conventional studies. PET also may reveal metastases in sites that escape attention on conventional staging (e.g., soft tissue lesions, retroperitoneal lymph nodes, barely palpable supraclavicular nodes, painless bone lesions). Exclusion of malignancy requires caution in case of smaller lesions (less than 1 cm in diameter) (see Box 8-2). In this respect, the small contralateral lung nodule(s)—a common finding in the era of spiral multislice CT—often still requires invasive sampling, such as by thoracoscopy.

INFLUENCE ON TREATMENT CHOICES

FDG-PET has a significantly complementary role to that of CT for two reasons: First, PET may detect unexpected lymph node or distant organ metastatic spread (Figure 8-4). After a negative result on conventional staging, unknown metastases are found on PET-CT in 5% to 20% of the patients, in increasing numbers from clinical stage I to III tumors. Second, FDG-PET is able to determine the nature of some equivocal lesions on conventional imaging. Consequently, PET induces a change of stage in 27% to 62% of patients with non–small cell lung carcinoma (NSCLC), in general more upstaging than downstaging, related mainly to the detection of unexpected distant lesions (Table 8-1). Such findings lead to a change in management in 25% up

Table 8-1 **Impact of Positron Emission Tomography on Stage Designation and Patient Management in Non-Small Cell Lung Carcinoma**

Study	*N*	Change of Stage	Change in Management
Lewis et al., 1994	34	NR	41%
Bury et al., 1997	109	34%	25%
Saunders et al., 1999	97	27%	37%
Pieterman et al., 2000	102	62%	NR
Hicks et al., 2001	153	43%	35%

Hoekstra et al., 2003	57	30%	19%

NR, not reported.

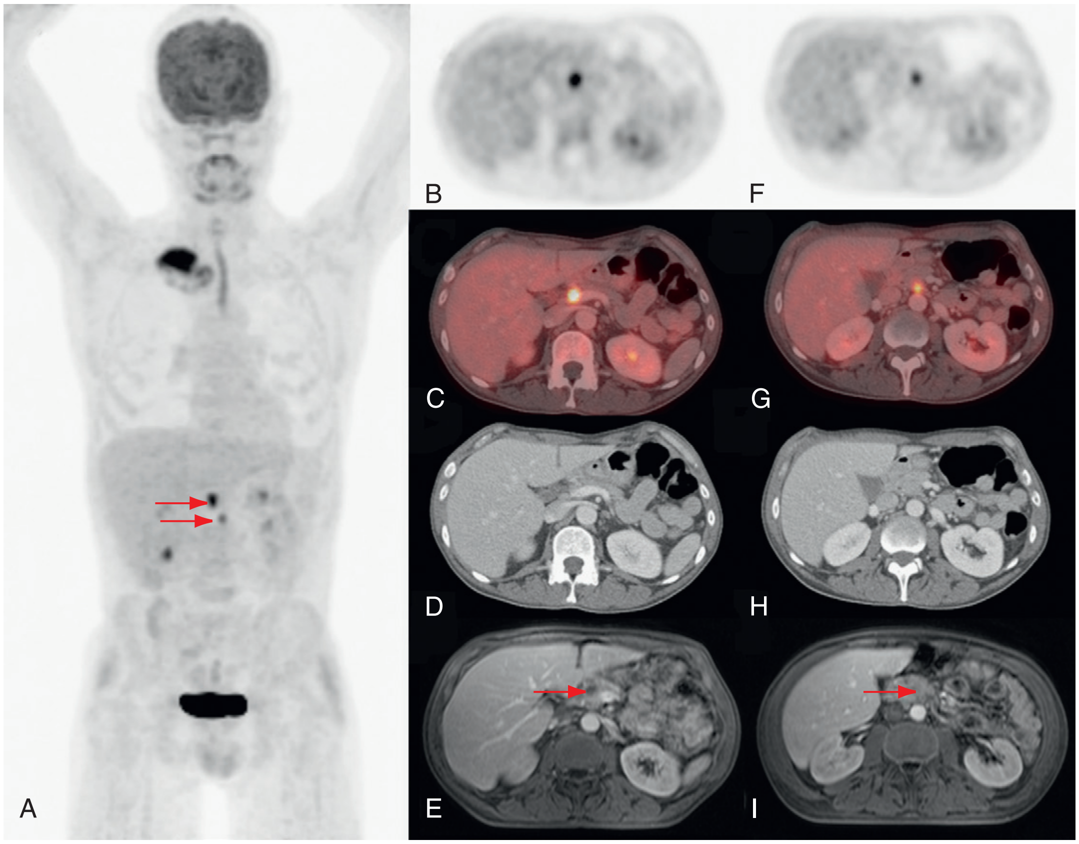

Figure 8-4 ^{18}F-fluorodeoxyglucose positron emission tomography–computed tomography (FDG-PET–CT) may detect unsuspected metastases. Patient with large cell carcinoma of the right upper lobe assessed with FDG-PET–CT after concurrent chemotherapy and radiotherapy. **A,** Coronal image shows a persistent, intensely hypermetabolic mass in the right upper lung. Pronounced linear FDG uptake in the esophagus corresponded to treatment-induced inflammation. Two additional foci project on the midline of the epigastrium *(arrows).* **B,** Transverse PET image of the cranial epigastric lesion. **C,** Fusion image shows an intra- or juxtapancreatic location, highly suspicious for metastasis. **D,** Corresponding CT image shows no significant lesion. **E,** Hypointense focal intrapancreatic lesion on a subsequent contrast-enhanced T1-weighted MRI study, compatible with metastasis *(arrow).* **F-I,** Similar findings in the caudal lesion. Echoendoscopy-directed fine needle aspiration confirmed metastasis. *MRI,* magnetic resonance imaging.

to 52% of the patients. Documented changes have involved both treatment intent (curative versus palliative) and choice of treatment modalities (chemotherapy versus radiotherapy, radical radiotherapy versus surgery).

No problem arises in interpretation when whole-body FDG-PET shows multisite metastases, but presence and character of an isolated suspect lesion that determines radical treatment intent should always be verified by other tests or tissue sampling, because of the ever-present risk of false-positive lesions (see Box 8-2) or a second primary tumor. In one large retrospective series, solitary extrathoracic lesions were documented in approximately 20% of the patients. About half of these were metastatic; the other half were not related to lung cancer, as either inflammatory or other benign lesions, or were second primary tumors (**Figure 8-5**).

Before the advent of integrated FDG-PET–CT, it remained unclear if PET alone could *replace* conventional imaging. One randomized study compared staging with upfront FDG-PET alone (i.e., directly after first presentation) versus guideline-based CT imaging in 465 patients. Patients with FDG-avid, noncentrally located tumors without signs of mediastinal or distant spread on PET proceeded directly to surgical resection. Frequency of noninvasive tests to reach a clinical TNM diagnosis was about the same in both treatment groups, but that of invasive tests (i.e., mainly mediastinoscopy) was significantly reduced with PET. With the contemporary use of integrated FDG-PET–CT, this question has become an academic one.

The effect of *adding* FDG-PET or FDG-PET–CT was investigated in several randomized controlled trials (**Table 8-2**). Two earlier trials that looked at the addition of PET alone reported seemingly contradictory results. Clear differences in trial design probably accounted for this finding. In the Dutch trial, the end point "futile thoracotomy" was clearly defined (benign disease, explorative thoracotomy, pathologic stage IIIA-N2/IIIB, or postoperative relapse or death within 12 months), whereas in the Australian study, there were no benign lesions, surgery was considered to be of use in some patients with stage IIIA-N2

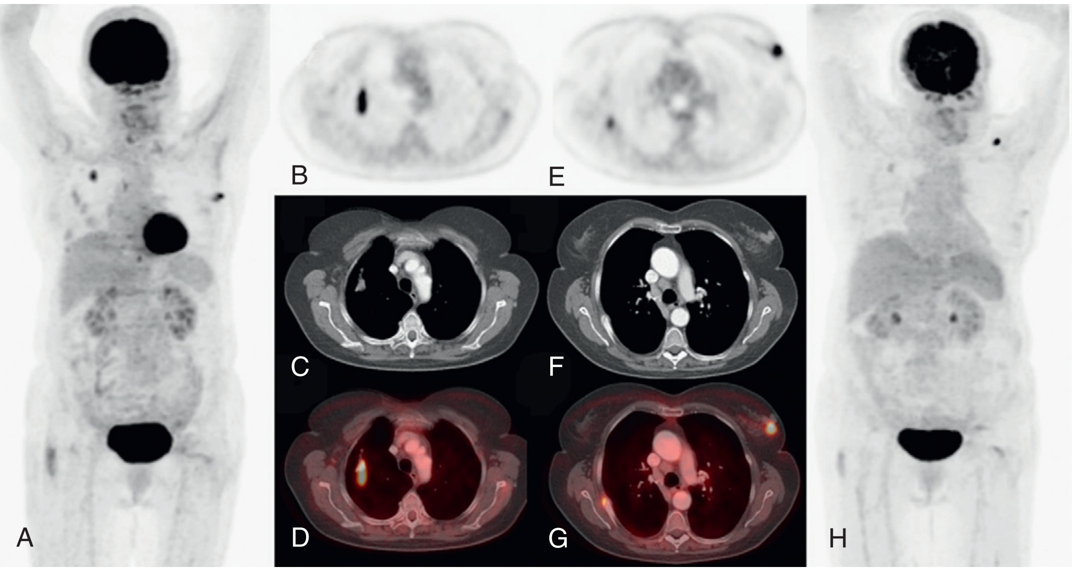

Figure 8-5 ^{18}F-fluorodeoxyglucose positron emission tomography–computed tomography (FDG-PET–CT) detects synchronous tumors, as in this patient with adenocarcinoma in the right upper lobe. **A,** Coronal image shows focal intense uptake in the right upper lobe as well as in the left breast. Moderately increased uptake is apparent in a right paratracheal lymph node. Note multifocal, moderately increased uptake in the right ribs (secondary to inflammation due to recent fractures) and next to the right trochanter femoris (enthesopathy). **B,** Transverse PET image shows the intensely FDG-avid lung lesion, compatible with the known malignancy. **C,** CT image of lung lesion. **D,** Fusion image. **E,** Transverse PET image of the intensely FDG-avid focal lesion in the left breast, highly suspicious for malignancy. **F,** CT shows an enhancing solid lesion at the site of FDG uptake. **G,** Fusion image of breast lesion that proved to be an invasive ductal adenocarcinoma. **H,** Coronal image after induction chemotherapy for the pulmonary adenocarcinoma and antihormonal therapy for the breast lesion. Note the strong decrease in uptake in both primary tumors, indicating a partial metabolic response. The intense focus in the left supraclavicular region is an artifact due to tracer retention in the patient's Portacath.

Table 8-2 Effects on Outcome With Addition of FDG-PET or FDG-PET–CT to Clinical Assessment

Study	*N*	Population	Study Question	Comparison	Outcome	Findings
Van Tinteren et al., 2002	188	Proven/suspected resectable NSCLC	Reduction in "futile thoracotomies"?	CS → surgery	Yes	Futile thoracotomy 41% vs. 21% (*P* = .003)
Viney et al., 2004	184	Proven stage I-II NSCLC	Impact on "decision to operate"?	CS → surgery CS + PET → surgery	No	No difference in avoided thoracotomies (*P* = .20)
Fischer et al., 2009	189	Proven/suspected resectable NSCLC	Reduction in "futile thoracotomies"?	CS → surgery PET-CT → surgery	Yes	Futile thoracotomy 52% vs. 35% (*P* = .05)
Maziak et al., 2009	337	Proven stage I-IIIA NSCLC	Improvement in correct upstaging?	CS PET-CT	Yes	Correctly upstaged pts 7% vs. 14% (*P* = .05)

CS, conventional staging; *CT*, computed tomography; *FDG*, ^{18}F-fluorodeoxyglucose; *NSCLC*, non-small cell lung carcinoma; *PET*, positron emission tomography.

disease, and no strict follow-up terms were predefined. The Australian trial focused on patients with clinical stage I and II disease only, where less additional benefit of PET was demonstrated in previous nonrandomized accuracy studies. The later trials used FDG-PET–CT imaging in addition to standard workup. The study by Fischer and colleagues largely reproduced the Dutch experience, with a significant reduction in futile thoracotomies. However, the number of nonfutile thoracotomies and the overall survival rate were similar in both treatment groups. Finally, the study reported by Maziak and associates mainly looked at correct upstaging and met this primary end point. Even in this study, which was the largest, no significant survival difference at 3 years was noted. This apparent lack of improvement was attributed by the investigators to the fact that larger patient numbers may be needed, and to the fact that some patients did not have their planned surgery.

The overall evidence thus points at significantly more accurate TNM staging with PET-CT compared with conventional imaging alone. This improved accuracy leads to more appropriate treatment policies, such as the avoidance of futile surgery in more patients than when only conventional imaging is used. In nonrandomized settings, this also has been reported to lead to other treatment adaptations—for example, a change between radical and palliative intent of radiotherapy, or adaptations in the radiation fields. Although all of this evidence certainly leads to true benefits such as stage migration and better patient management, it remains unknown if survival of individual patients has improved since the introduction of FDG-PET.

SURVIVAL

Indeed, several FDG-PET staging studies clearly demonstrated stage migration. The possible effects of stage migration may account in part for improvements in survival of patients treated for both early- and advanced-stage disease, widely referred to as the "Will Rogers phenomenon." Examples are the prospective multicenter trials on the use of FDG-PET in patients with stage III NSCLC, in which upstaging was confirmed in about 25% to 30% of the patients, and in which overall survival was significantly longer ($P = .006$) in patients whose disease was staged by PET than in those who did not undergo PET. The aforementioned randomized controlled trials were underpowered to evaluate the potential real survival benefit brought by PET.

FDG-PET also has been shown to predict the prognosis for patients with NSCLC. A recent systematic review and meta-analysis including retrospective studies demonstrated that the SUV, a semiquantitative measure of FDG uptake, for the primary tumor at diagnosis may predict outcome in NSCLC, especially at earlier stages. These studies almost consistently found a better overall survival among patients with a metabolic activity lower than the threshold SUV value, calculated from either the most discriminative log-rank SUV value or the median SUV. However, although SUV may be a way to assess prognosis, no true cutoff point has been recognized as suitable for broad clinical use. Rather, a continuous SUV spectrum of a gradually worsening prognosis might be a more realistic concept. Baseline SUV, incorporated as a continuous variable in a Cox proportional hazards model, showed a 7% increase in hazard of death after a one-unit increase in SUV in patients with resected stage I to III NSCLC and a 6% increase in hazard of death after a one-unit increase in SUV in patients with inoperable NSCLC treated with radiotherapy.

HEALTH ECONOMICS

Today's respiratory oncologists aim for the best-quality health care for the patient, but in acknowledgment of the need for financial prudence. The major cost of modern oncology practice, however, does not lie in the baseline diagnostic process but is attributable to the delivery of expensive treatments and the morbidity related to possible side effects. Therefore, application of economic modeling in the use of FDG-PET has to be based on both diagnostic and therapeutic aspects of health care expenditure within the day-to-day clinical setting.

In a recent overview of all economic evaluations on FDG-PET in oncology performed between 2005 and 2010, the strongest evidence for cost-effective use of PET alone was for the staging of NSCLC. Studies suggested that PET for staging of NSCLC may benefit patients in terms of a (slight) increase in life expectancy and may benefit the health care system in terms of cost savings resulting from the number of invasive procedures avoided. Since the introduction of PET-CT technology into clinical medicine in 2001, only a few additional studies in respiratory oncology have evaluated the cost-effectiveness of this integrated scanning method. Taking into account the superior accuracy of FDG-PET–CT over that of PET alone in lung cancer staging, the health economic impact in terms of cost-effectiveness probably can be extended to PET-CT. Furthermore, FDG-PET is cost-effective for characterizing and diagnosing solitary pulmonary nodules and constitutes the most cost-effective strategy for assessment of nodules of low to moderate pretest probability of malignancy on CT.

OTHER INDICATIONS FOR POSITRON EMISSION TOMOGRAPHY

Small Cell Lung Cancer

Small cell lung cancer (SCLC) typically shows very high FDG accumulation. In a systematic analysis of seven studies, FDG-PET or PET-CT provides more accurate staging of SCLC, mainly based on high sensitivity rates ranging from 92% to 100%. In one study, involved nodes were detected in 14% of patients in whom results on CT were negative. This increased lesion detection resulted in stage migration in a median of 13% of patients, 9% (0 to 33%) upstaged from limited stage (LS) to extensive stage (ES), and 4% (0 to 17%) downstaged from ES to LS. The data on the use of FDG-PET in the management of SCLC are less robust than for NSCLC, because the emphasis on systemic and radiation therapy provides less histologic data to serve as gold standard. Furthermore, most studies were rather small (mean $n = 40$) and retrospective in nature. Detection of brain metastases also is poor, so additional specific brain imaging with conventional methods is still mandatory. Nevertheless, the use of FDG-PET information is associated with considerable changes in patient management, ranging from 27% to 47% across studies. The use of FDG-PET–CT resulted in changes to the three-dimensional conformal radiation therapy plan in 58% of patients, mainly by decreasing the target volume (in case of atelectasis) or by detecting unsuspected nodal or pulmonary foci.

Mesothelioma

Integrated FDG-PET–CT imaging is playing an increasing role in the assessment of suspected or known malignant pleural mesothelioma (MPM) (**Figure 8-6**). PET-CT is useful in the correct differentiation of malignant (mainly MPM) from benign pleural diseases in asbestos-related CT findings, with an overall

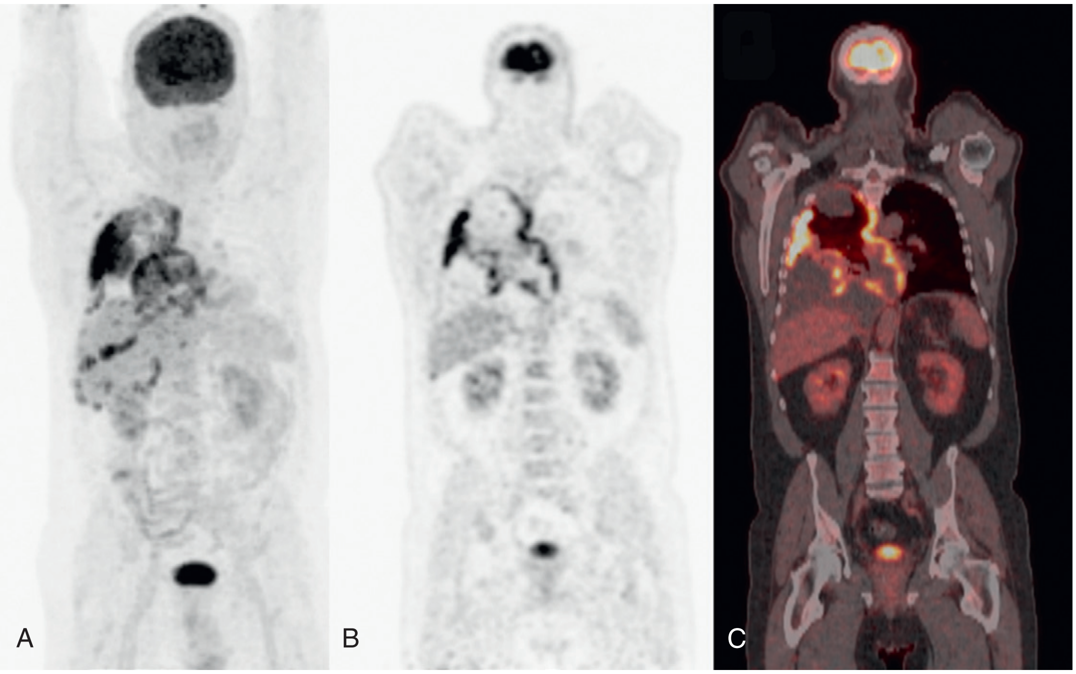

Figure 8-6 ^{18}F-fluorodeoxyglucose positron emission tomography–computed tomography (FDG-PET–CT) for evaluation of a patient with right-sided epithelioid pleural mesothelioma. Pleuroscopy with talc pleurodesis was performed before the PET scan. **A,** Coronal image showing diffuse and irregular area of intense FDG uptake in the right hemithorax, mainly in the apical part but with also demonstrating multiple foci in the costodiaphragmatic sinus. **B,** Coronal PET image showing hypermetabolic activity in the lateral and medial right pleura. **C,** Fusion images show areas of pleural effusion without increased FDG uptake.

accuracy greater than 90% and a high NPV of more than 90%. PET-CT is significantly more accurate in baseline TNM staging in patients who are appropriate candidates for multimodality therapy based on spiral CT findings alone. Although PET-CT does not provide additional information about the primary tumor beyond that supplied by CT alone, it identifies a higher number of metastatic mediastinal lymph nodes and/or unknown distant metastatic disease in up to two thirds of patients, with a significant clinical impact on treatment planning. Early evidence also suggests that PET-CT may have a role in evaluating response to therapy in MPM. This is an interesting possibility, because the assessment of response in patients with MPM according to standard response criteria on CT is far from simple. More work to define response criteria for MPM on FDG-PET is needed. Furthermore, a prospective study in patients with nonsarcomatoid malignant pleural mesothelioma observed that baseline total glycolytic volume on PET was more predictive of survival than CT-assessed TNM stage on multivariate analysis. These observations of prognostic capability still require prospective validation.

Therapy Assessment

FDG uptake in tumors is related to (1) the number of viable cancer cells, (2) their metabolic activity and proliferation capacity, and (3) the presence of inflammatory cells. In many clinical settings, the metabolic changes caused by cancer therapy precede the morphologic changes. This discrimination of viable from nonviable tumor is the basis for the use of FDG-PET for the determination of response to therapy.

Restaging of locally advanced lung cancer after neoadjuvant or induction therapy has been extensively studied (Table 8-3). In the restaging of mediastinal lymph nodes, FDG-PET added to CT was more accurate than CT alone but with more moderate results than when used for baseline nodal staging (sensitivity of 50% to 80% and specificity of 60% to 90%). Later studies using integrated PET-CT found better sensitivity (up to 77%) with an increase in specificity (up to 92%). Mediastinal restaging with PET-CT thus reaches an accuracy level of some clinical value but is especially useful in directing additional tissue sampling techniques such as endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA), esophageal ultrasound–guided fine needle aspiration (EUS-FNA), or mediastinoscopy, which usually need to be added to certify the nodal status.

The findings on outcome prediction in this setting are even more interesting. The classic prognostic parameters for surgery in these patients are obtained from the resection specimen—(1) downstaging of mediastinal nodes and (2) the pathologic response in the primary tumor. Outcomes are poorly predicted by the evolving clinical or CT imaging characteristics during therapy. In the prospective studies, both the residual FDG uptake in the primary tumor after induction and the change in FDG uptake in comparison of pre- and postinduction values had strong power to predict outcome after combined-modality treatment. With the advent of endoscopic baseline mediastinal staging (EBUS-TBNA and EUS-FNA) to confirm N2 or N3 disease, the postinduction assessment can be based on primary tumor response information on (serial comparison of) FDG-PET and lymph node assessment by a first mediastinoscopy after induction therapy. In one model, the combination of lymph node involvement and primary tumor response on FDG-PET could discriminate patients with a good prognosis (defined as a 5-year survival rate of 62%) from those with a poor prognosis (survival rate of only 6%; hazard ratio, 0.18) in a cohort of patients with surgical multimodality treatment.

Targeted therapies are advancing at a rapid pace in the treatment of NSCLC, and conceptually FDG-PET might be of great interest in the assessment of these cytostatic rather than cytotoxic drugs. Two recent independent studies have shown that early FDG-PET can predict progression-free and overall

Table 8-3 **Results of PET and Integrated PET-CT in Restaging After Induction Treatment for Locally Advanced Non-Small Cell Lung Carcinoma**

Study	*N*	Stage	CTRT	Imaging	Sensitivity	Specificity
Vansteenkiste et al., 2001	31	IIIA-N2	0	PET + CT (visual corr.)	71%	88%
Akhurst et al., 2002	56	I-III	29%	PET + CT (visual corr.)	67%	61%
Ryu et al., 2002	26	III	100%	PET + CT (visual corr.)	58%	93%
Cerfolio et al., 2003	34	IB-IIIA	21%	PET + CT (visual corr.)	71%	77%
Hellwig et al., 2004	37	III	70%	PET + CT (visual corr.)	50%	88%
Port et al., 2004	25	I-IIIA	0	PET + CT (visual corr.)	20%	71%

survival in patients treated with erlotinib, even in the absence of a Response Evaluation Criteria in Solid Tumors (RECIST) response.

For patients managed with the newer locoregional treatment strategy of radiofrequency ablation, FDG-PET may potentially be useful in the assessment of the therapeutic success and prediction of prognosis. This specific setting, however, necessitates a careful pattern analysis next to semiquantitative determination of the glucose metabolism, because there can be a strong and persisting inflammatory response.

For all settings in which FDG-PET scans at different time points are to be compared, it is crucial to perform the PET procedure according to a consistent methodology, including interval from last therapy, patient preparation, camera setting, reconstruction parameters, and image analysis. Recommendations on this very crucial point of standardization in a multicenter setting have been published recently.

Radiotherapy Planning

Just as careful TNM staging is important to select patients who are candidates for surgical options, the accurate delineation of target volumes for radiotherapy is crucial to avoid geographic treatment misses leading to treatment failures.

It has been shown in many radiotherapy planning studies that use of FDG-PET or FDG-PET–CT influences the target volumes. The PET-based volume delineations were in general smaller than those with CT alone, mainly to permit potentially more precise nodal irradiation. This approach allowed for radiation dose escalation to the tumor in a substantial number of patients. Prospective clinical trials using PET-CT–based selective nodal irradiation reported isolated nodal failures in less than 5% of patients treated with (chemo)radiotherapy. This rate is lower than the 13% rate of false-negative PET results in CT-positive lymph nodes in a metaanalysis, which might be explained by the incidental irradiation of lymph nodes adjacent to the planning target volume. Because of the possibility of false-positive lymph nodes on PET, invasive nodal staging using endosonography or mediastinoscopy may be warranted, if the nodes concerned would have a major impact on the radiation treatment field. The clinical gain with PET-based delineation of the primary tumor compared with CT-based delineation is in general smaller, except in situations with postobstructive atelectasis.

In recent studies, automated PET-CT delineation also reduced the interobserver variability in treatment planning compared with that for CT alone. Furthermore, FDG-PET also may have a role in monitoring treatment during the course of radiotherapy. PET may identify radioresistant areas within the primary tumor before and during treatment, with high accuracy. Work is in progress on how to use this information to plan higher radiation doses to these areas, for improved outcomes.

FUTURE INNOVATION

Evolution in PET is largely driven by advances in camera technology (hardware and software) and by the development of new tracers. Spatial resolution improvement is driven by size reduction of the crystal detectors and by novel reconstruction algorithms that take into account the point spread function of the camera. A resolution of approximately 2 mm probably will be the limit, because the two photons emitted during positron annihilation do not travel at exactly 180 degrees (“noncolinearity”). Time-of-flight (TOF) PET uses the time difference between two crystals that detect an incoming photon to reduce these photons’ origin from a line (as is classically done) to a short segment of this line. This reconstruction method results in improved signal-to-noise ratio, allowing faster acquisition times or tracer dose reduction.

Another feature that could improve the quality of the images, especially in respiratory medicine, is respiratory gating of PET acquisition. Because of respiratory motion, the volume of a lung lesion is “smeared out” and thus overestimated, while the FDG intensity is underestimated, especially in the lower lung fields. Synchronization of the acquisition of the PET emission images with respiratory motion is now available and being clinically evaluated, with exact quantification of tracer uptake and radiotherapy planning as the most promising fields. Reconstruction algorithms are being developed that incorporate anatomic information from either CT or MRI to obtain higher-resolution images with sharper edges, allowing better volume delineation in radiotherapy planning.

The other major driver of innovation in PET is new tracer development. Although FDG imaging allows highly accurate tumor detection and characterization, FDG uptake in inflammatory tissues remains a major limitation. Development of novel tracers offering a similar sensitivity with higher specificity is ongoing, but until now, no molecule has outperformed FDG in respiratory oncology. Molecular imaging of key molecules and cellular processes could, however, play an important role in noninvasive tumor characterization. Many crucial cellular processes can be studied, such as proliferation, angiogenesis, and expression of different receptor types. PET imaging with 3′-deoxy-3′-^{18}F-fluorothymidine (^{18}F-FLT) allows noninvasive assessment of proliferation and offers theoretical advantages in determination of response to cytostatic therapies. A whole range of PET tracers have been developed to image angiogenesis, the most intensively studied based on ligands for the dividing endothelial cell marker integrin $\alpha v\beta 3$. These tracers are being evaluated mainly in the context of prediction or assessment of response to antiangiogenic therapies. Tumor characterization based on receptor expression can be performed by PET imaging with binding of radiolabeled peptides to the somatostatin receptor (mainly types 2, 3, and 5), thereby allowing diagnosis and staging of carcinoid tumors. PET also is studied to assess the presence of pharmaceutical targets in tumor tissue. One example is 1-(2′-deoxy-2′-fluoroarabinofuranosyl) cytosine (FAC), a substrate for deoxycytidine kinase, the enzyme responsible for the conversion of gemcitabine from a prodrug to its active form. Selection of patients based on genetic mutations will become increasingly common, and novel PET tracers are being developed that allow detection of specific mutations, such as ^{18}F-PEG6-IPQA, a radiotracer with increased selectivity and irreversible binding to the active mutant L858R EGFR kinase (which is sensitive to gefitinib) but not to wild type or T790M-mutated EGFR kinase.

Many other tracers are being developed, and their clinical testing is eagerly awaited to help in the selection of patients for targeted therapies. The fact that PET imaging, with use of FDG or other, more specific molecular tracers, is being incorporated in some of the pivotal clinical trials establishing novel therapies will help to generate needed evidence for use of this modality in clinical decision making.

Section 2
DIAGNOSTIC TECHNIQUES

Chapter 9
Pulmonary Function Testing

Bruce H. Culver

Pulmonary function testing provides quantitative assessment of lung function and encompasses a variety of specific measurements, ranging those that can be obtained readily at the bedside or in the home to complex physiologic assessments made in a referral laboratory.

Spirometry in the office is used to screen for abnormalities of airflow or lung volume, to test bronchodilator responsiveness, and for interval assessments in patients who have asthma or chronic obstructive pulmonary disease (COPD). Screening spirometry has been recommended for middle-aged smokers and former smokers to identify airflow obstruction at an earlier stage than that typical for persons presenting with dyspnea. Although COPD often is suspected from smoking history and symptoms, the diagnosis rests on the demonstration of airflow obstruction from spirometry testing, and current measures of clinical quality require that such testing be done. COPD has now become the third leading cause of death (in U.S. statistics) yet frequently is diagnosed late in the course as it becomes disabling. Up to one half of the persons with this condition may remain undiagnosed, because the most common early symptoms, cough and exertional dyspnea, often are attributed to other causes.

Testing in the pulmonary function laboratory allows further classification and quantification of lung disease by adding data from the measurement of lung volumes and assessment of gas exchange through measurement of diffusing capacity and arterial blood gases, and from tests of gas distribution. Special testing is available for prethoracotomy evaluation, assessment of upper airway obstruction, bronchoprovocation challenge testing, and cardiopulmonary exercise response (discussed in Chapter 10). Although even comprehensive lung function testing may not provide a specific diagnosis, the pattern of physiologic derangements guides further assessment, and demonstration of the severity of impairment aids in prognosis.

Guidelines for pulmonary function equipment specifications, procedural techniques, and interpretation of results were most recently published in 2005 by a joint panel of the American Thoracic Society (ATS) and the European Respiratory Society (ERS). The multipart series of statements are included in the "Suggested Readings" listing, and the recommendations presented in this chapter are consistent with these guidelines.

SPIROMETRY

THE FORCED EXPIRATORY VOLUME MANEUVER

Assessments of vital capacity (VC), or forced vital capacity (FVC) and airflow are based on the forced expiratory volume maneuver, in which the subject inhales maximally to total lung capacity (TLC) and then exhales forcefully and completely to residual volume (RV). The expiratory flow rate at any point during this maneuver is determined by the driving pressure for airflow and the airway resistance. During a forceful exhalation, the intrathoracic pressure that surrounds the central airways exceeds the intraluminal pressure, causing dynamic compression of the airway (see Chapter 3, Figure 3-12). As a result, the effective driving pressure becomes the difference between alveolar pressure and the pleural pressure that compresses airways. This pressure difference ($P_A - Ppl$) is equivalent to the elastic recoil pressure of the lung tissue. Thus, even during a forceful effort, the intrinsic elastic properties of the lung are a major determinant of airflow. Airway resistance upstream from the point of compression is determined primarily by airway caliber, which varies directly with lung volume. Throughout exhalation from TLC, both recoil pressure and airway caliber progressively decrease, so that airflow rates, after an early peak, also progressively decrease. Although the peak expiratory flow rate varies with the rapidity and forcefulness of the expiratory effort, once dynamic compression begins, the flow rate during the middle to later portions of the maneuver is limited and independent of further effort beyond the threshold needed to begin compression. These flows also are independent of added resistance downstream from the point of flow limitation. This physiologic arrangement aids in making the basic measurements of spirometry quite reproducible on repeated efforts.

To obtain a satisfactory spirometric tracing, the preceding inspiration must be maximal and the forced expiratory volume maneuver must be continued to cessation of flow or, when emptying is slowed, for at least 6 to10 seconds. The resultant information commonly is displayed in one of two formats. The traditional *spirogram* (**Figure 9-1**) plots volume versus time, with flow rate indicated by the steepness of the plot. The orientation of the axes varies with equipment, with time moving to the right and exhaled volume plotted either up or down. In the *flow-volume display* (**Figure 9-2**), the instantaneous flow rate is measured continuously and directly plotted on the vertical axis with volume on the horizontal axis. Time is not shown on this plot but may be indicated by tick marks. With this display, the reproducibility of successive efforts and some patterns of abnormality may be more easily seen. It is important to recognize that both the traditional spirogram and the expiratory flow-volume display are obtained from the same maneuver but emphasize different aspects of the information thus obtained.

EXPIRATORY FLOW MEASUREMENTS

Basic measurements from the forced expiratory volume maneuver include FVC, the forced expiratory volume in 1 second

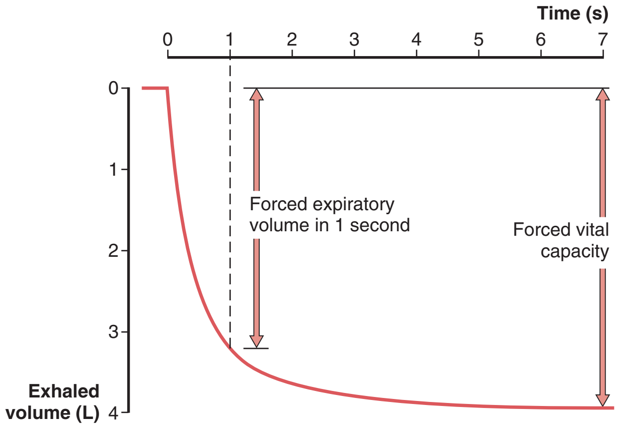

Figure 9-1 Normal forced expiratory spirogram plotted as exhaled volume versus time. The forced expiratory volume at 1 second (FEV_1) and forced vital capacity (FVC) are indicated by *arrows*. In this example, FEV_1 = 3.35 L, FVC = 4 L, and FEV_1/FVC = 0.84. *(Modified from Culver BH: Pulmonary function testing. In Kelly WN, editor:* Textbook of internal medicine, *Philadelphia, 1988, JB Lippincott.)*

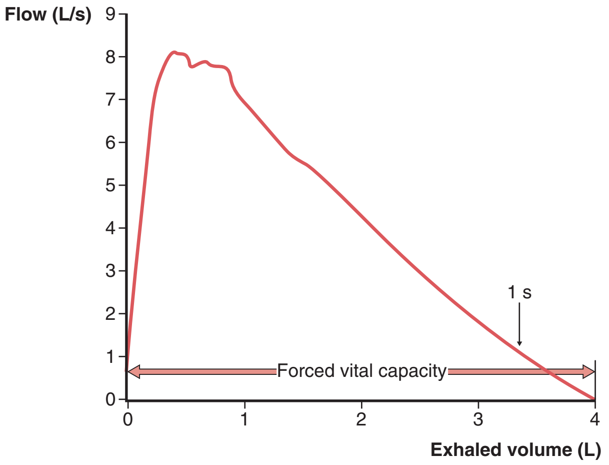

Figure 9-2 Normal expiratory flow-volume curve. The same forced expiratory volume maneuver shown in Figure 9-1 is plotted here as a flow-volume curve. The airflow rate reaches a peak early in the exhalation and then decreases progressively until flow ceases at residual volume. *(Modified from Culver BH: Pulmonary function testing. In Kelly WN, editor:* Textbook of internal medicine, *Philadelphia, 1988, JB Lippincott.)*

(FEV_1), and the ratio of FEV_1 to FVC. The FVC or total volume exhaled is equivalent in normal subjects to a so-called *slow VC*, obtained with a complete but not forceful exhalation. Patients who have advanced obstructive airway disease often manifest exaggerated dynamic compression (narrowing airways with forceful efforts), so that the FVC is smaller than the slow VC. A reduction in VC reflects either a reduction in TLC, an increase in RV, or a combination of both. The FEV_1 is readily obtained from the volume-time spirogram by observing the volume exhaled in the first 1 second of effort. This measurement cannot be seen on the flow-volume display but can be calculated by the microprocessors in the equipment that use this display. Determination of FEV_1/FVC is easily performed using simple equipment; this ratio provides the best index of airflow limitation. When the slow VC also is available, and if it is larger, this may be substituted for FVC, thereby increasing the sensitivity of the ratio for detection of obstruction. This ratio is commonly expressed as a percentage and sometimes is referred to as the "percent FEV_1"; however, this terminology may cause confusion, because the FEV_1 itself is commonly expressed as a percentage of its predicted value. Misunderstanding is lessened if the ratio is reported and discussed as a decimal (e.g., 0.82).

An additional flow measurement widely reported from the spirogram is the average forced expiratory flow rate between 25% and 75% of the exhaled VC ($FEF_{25–75}$), formerly referred to as the maximum midexpiratory flow rate. This measurement shows wider variability than that typical for FEV_1 or FEV_1/FVC, both within and between individual subjects. When this variability is appropriately accounted for, $FEF_{25–75}$ is not more sensitive than FEV_1/FVC for the detection of airflow limitation. Numerous other flow measurements can be obtained from the forced expiratory volume maneuver, but they are highly interdependent with those already described and add little new information. The $FEV_{0.5}$ may be used to assess the initiation of effort but adds little diagnostic information in adults. In young children, the $FEV_{0.5}$ or $FEV_{0.75}$ can be a useful index of flow, because children may fully empty their lungs within the first second.

Because it may be difficult for some subjects to consistently maintain the forced expiratory maneuver to full exhalation, which may take 10 to 15 seconds when airflow obstruction is present, the forced expiratory volume in 6 seconds (FEV_6) may be taken as a surrogate for FVC and used to calculate an FEV_1-to-FEV_6 ratio, which can be compared with appropriate reference values.

The peak expiratory flow rate achieved during the FVC maneuver cannot be accurately calculated from a spirogram display but is readily seen on the flow-volume display and can be calculated by microprocessors. It can show considerable effort-to-effort variability, even when FEV_1 and FVC measurements are nearly identical. A peak flow measurement also can be obtained with simple handheld devices, which are useful for interval follow-up evaluation and for home management of patients who have reactive airway disease but are less accurate and less sensitive than spirometry for screening. Whereas spirographic flow measurements are obtained over a time interval or volume interval, measurements from the flow-volume display or current microprocessors can be reported at specific lung volumes. Maximum flow rates at 50% and 75% of exhaled volume are commonly reported, but nomenclature varies, and the latter may be designated as the flow rate at 25% of remaining VC. Routine use of these measurements is not recommended.

The maximum voluntary ventilation (MVV) is measurable on some office spirometers but is primarily a laboratory measurement. The subject is instructed to breathe deeply and rapidly, typically at 60 to 70 breaths per minute, and the total volume of ventilation over a 12- to 15-second period is extrapolated to liters per minute. Historically, this was the initial dynamic test for obstructive disease; however, it has been supplanted by the forced expiratory maneuver for the diagnosis of airflow limitation. The MVV currently is used as a global assessment of ventilatory capacity in the evaluation of dyspnea, in the interpretation of exercise limitation, in disability assessment, in some preoperative testing, and to evaluate neuromuscular disease of the chest wall and diaphragm.

REVERSIBILITY

The usefulness of spirometry in the office or laboratory often is enhanced by the assessment of bronchodilator response. Spirometry is repeated after the administration of an inhaled bronchodilator, waiting 15 minutes after a beta agonist or 30 minutes after ipratropium bromide. An increase of more than 12% in the FEV_1 represents a significant response in a patient who has near-normal baseline spirometry results. With more severe obstructive disease, the magnitude of improvement also should be at least 200 mL to differentiate the pharmacologic response from test-to-test variability. FVC often improves in parallel with FEV_1. An improvement in FVC by more than 12% and 200 mL, in the absence of a significant change in FEV_1, may reflect either an improvement in flow rates after the first second or simply a longer duration of effort.

Although determination of the FEV_1/FVC ratio is the most useful test for the diagnosis of airflow limitation, the value may remain the same or even decrease after administration of a bronchodilator, depending on the relative change in its two components, so this ratio is not a useful index of reversibility. Because of its large intraindividual variability, FEF_{25-75} must show an increase of 30% to 40% to represent a significant bronchodilator effect. Occasionally, this parameter changes little or even decreases despite a clear improvement in FEV_1 or, particularly, FVC. This apparent paradox occurs because the bronchodilator has allowed exhalation to continue to a lower RV, so that the 25% to 75% increment is now measured at a lower lung volume, with consequent lower flow rates.

REFERENCE EQUATIONS AND LIMITS OF NORMALITY

Unlike many laboratory tests, lung function parameters vary greatly with body size and age, so the expected values must be determined on an individual basis. Numerous prediction equations have been derived from spirometric surveys of normal reference populations. Currently accepted studies exclude all smokers as well as persons who have any thoracic or cardiopulmonary disease. Most studies have found that lung function parameters can be predicted on the basis of gender, age, and height, and that the addition of other body size measurements does not improve the accuracy of the equations. The prediction equations give the midpoint of the normal range, which is unfortunately wide for most spirometry measurements.

The lower limit of normal (LLN) must be established from the variability among individual subjects who have the same prediction parameters. The limits of the normal range are chosen to exclude 5% of a normal population; that is, 5% will be misclassified as having disease. In screening a generally healthy population for a rare disease, a borderline-low result is more likely to reflect this misclassification than to represent true identification of disease. However, when spirometry is done for persons at risk for lung disease, or with suggestive symptoms, the probability that a borderline result reflects a true abnormality is much higher. For the spirometry measurements, only low values are considered of concern, so the LLN is set at the 5th percentile of the reference sample. Because the distribution of values in the reference population is adequately symmetric above and below the mean, the 5th percentile LLN often is taken as the predicted value minus 1.645 times the standard error of the estimate (SEE) of the regression equation. The predicted value and the LLN both are readily calculated from the reference data programmed into the spirometry equipment, and both should be reported for comparison against the actual measured value.

Spirometry reference data from a large, systematic survey of the U.S. population (the Third National Health and Nutrition Examination Survey [NHANES III]) are recommended for use in North America. Equations are provided for Caucasians, African Americans, and Mexican Americans ranging in age from 8 to 80 years. No single reference source currently is recommended for use in Europe, but an international effort is under way to merge the NHANES data with those for many reference populations from throughout Europe and elsewhere, to generate a new, widely applicable reference dataset.

The use of a percentage of the predicted value as a lower limit is convenient but less accurate than the 5th percentile, because it causes the normal range to vary with the magnitude of the predicted value, whereas the true variance is similar around small and large values. A lower limit value equal to 80% of the predicted value has been widely used in spirometric interpretation. Although this is a reasonable approximation of the LLN for FEV_1 and FVC at the midrange of age and height, it creates an overly broad normal range for younger, taller persons (in whom the true LLN is approximately 82% to 83%), and it is overly sensitive for older or smaller subjects (in whom the LLN may be as low as 73% to 75%). An 80% lower limit is quite inappropriate for FEF_{25-75}, because the normal range extends to 65% of the predicted value in the young and below 50% of predicted in older persons. The normal value for FEV_1/FVC varies little with height but does decline progressively with age (e.g., from 0.87 at age 20 to 0.77 at age 70 in females, and from 0.84 to 0.74 in males). The LNN is approximately 0.10 below the predicted ratio. Because the ratio often is expressed as a percentage, reporting this value as a percent of the predicted value is potentially confusing.

INTERPRETATION OF SPIROMETRIC ABNORMALITIES

Obstructive Impairment

A decrease in airflow is the hallmark of the obstructive diseases; this physiologic diagnosis rests primarily on the demonstration of an FEV_1/FVC (or FEV_1/VC) value below the age-appropriate LLN. When the FEV_1/FVC value is low, even persons with an FEV_1 itself as high as 100% of the predicted value (and, necessarily, with a high-normal FVC) are considered to have mild airflow obstruction, which has been shown to be associated with increased morbidity over time. Typically, FVC is normal early in the course of airflow obstruction but is reduced in more severe disease as the RV is increased because of trapped air. The severity of obstructive impairment is best quantified by the decrement in FEV_1 as a percent of predicted, because progressive loss of FVC with advanced severity and air trapping limits the reduction in FEV_1/FVC. Varying recommendations for categories of severity have been made by different groups, although an apparent consensus suggests that an FEV_1 below 50% of the predicted value reflects a “severe” impairment. A simple schema that represents a compromise between one included in the ATS-ERS guidelines and that used in the Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines is shown in Table 9-1.

Restrictive Impairment

A restrictive defect is defined by a reduction in TLC, but restriction in lung volume can be suspected from spirometry findings when the FVC is below the LLN and FEV_1 is similarly reduced, so that FEV_1/FVC is normal or high. In such cases, some persons will be found to have a normal TLC (see later under “Nonspecific Pattern”), but if the FVC is reduced below 60%, then the likelihood of true restriction is 80%. A decrement in FVC secondary to the increased RV of obstruction should not be classified as a restrictive defect, because TLC would then be normal to large. When both FVC and FEV_1/FVC are decreased, the presence and magnitude of any

Table 9-1 **Suggested Categories of Ventilatory Impairment** Based on FEV_1 expressed as a percent of the predicted value. Applicable to obstructive, restrictive, or mixed impairments after diagnosis of airflow obstruction by FEV_1/FVC and/or restriction by TLC.

Degree of Impairment	% Pred FEV_1
Mild	70-100%
Moderate	50-69%
Severe	30-49%
Very severe	<30%

concomitant restrictive impairment can be determined only by an assessment of TLC. Even when TLC is measured, the ATS-ERS guidelines recommend that the severity of a restrictive (or mixed) impairment be based on the reduction in FEV_1, because that correlates with exercise limitation and morbidity.

Mixed Impairment

The problem is clearly obstructive when the FEV_1/FVC ratio is low with a normal FVC, and restriction can be suspected when FEV_1/FVC is normal with a low FVC, with increased confidence when the FVC is more markedly reduced; however, other combinations leave uncertainty when only spirometry findings are available. A low ratio with a low FVC may reflect the air trapping of obstructive disease or a mixed pattern with both obstructive and restrictive components. When FEV_1/FVC is reduced to 0.55 (55%) or lower, a low FVC is most likely due to air trapping, because lung volume measurements show a normal TLC in more than 90% of cases. Conversely, when the ratio is only mildly reduced but the FVC is quite low, the likelihood of a mixed disorder is increased. When both FEV_1/FVC and FVC are low, and lung volume measurement is not available, it may be more helpful to note the overall "ventilatory impairment" indicated by the loss of FEV_1, than to try to separately assess the components.

LUNG VOLUMES

Spirometry can measure only those subdivisions of lung volume contained within the VC range (see Chapter 3, Figure 3-4). Measurement of TLC or FRC requires a method of measuring the gas that remains in the lungs at RV. Typically, the gas volume contained in the lungs at FRC is measured, with TLC and RV determined by adding or subtracting the appropriate increments from an accompanying spirogram. The methods used most widely to measure lung volumes include helium dilution, nitrogen washout, and body plethysmography. Also, TLC can be quite accurately determined from calculations based on planimetry of posteroanterior and lateral chest radiographs or from CT scans, using one of several geometric models.

MEASUREMENT BY HELIUM DILUTION

A spirometer is prepared that contains a known volume and concentration of an inert gas, typically 10% helium (Figure 9-3). While the subject breathes through a mouthpiece with nose clipped, a valve is turned at end-tidal exhalation to connect the airway to this closed system. As normal tidal breathing continues over the course of a few minutes, the gas in the subject's lung equilibrates with gas in the spirometer, and the helium concentration, which is continuously monitored, falls to a new, lower, steady-state level. Carbon dioxide is removed from the closed system by soda lime absorption, and a low flow of oxygen is added to compensate for the subject's ongoing oxygen consumption by keeping the mixing chamber or spirometer volume constant. The ratio of the initial to the final concentration of helium allows calculation of the unknown volume (FRC) added to the system. A continuous tracing of the spirogram, including a maximum inspiratory and expiratory effort, allows calculation of the subdivisions of lung volume, and correction for any offset from the relaxed FRC at the moment the valve was opened to start the test.

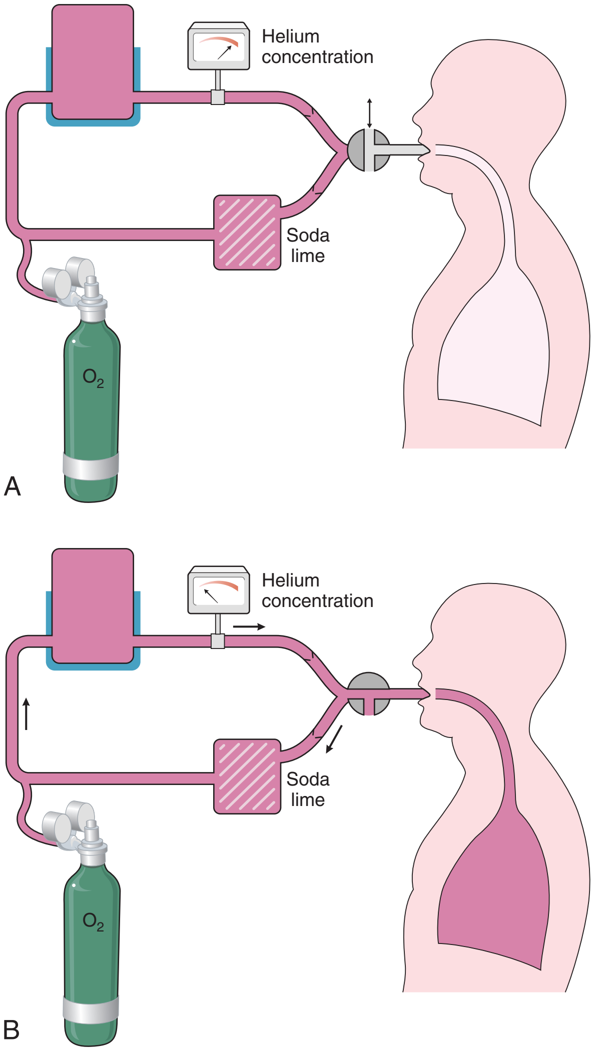

Figure 9-3 Lung volume measurement by helium dilution. **A,** The spirometer and circuit are prepared with a known gas volume and concentration of helium. **B,** The subject breathes the circuit, as CO_2 is absorbed and O_2 consumption is replaced, until a new, lower helium concentration is established. The unknown lung volume added to the circuit when the valve was turned is calculated from the dilution of the initial helium concentration: $[He]_{initial} \times Vol_1 = [He]_{final} \times (Vol_1 + FRC)$.

MEASUREMENT BY NITROGEN WASHOUT

The nitrogen washout technique also is based on the principle of conservation of mass of an inert gas—in this case, the nitrogen normally resident within the lungs. The subject breathes on a

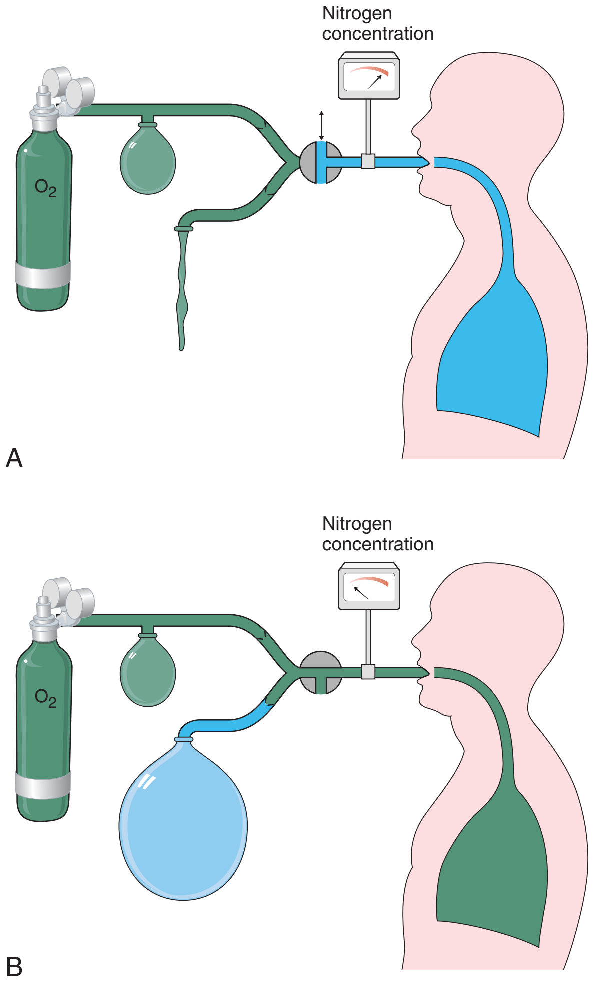

Figure 9-4 Lung volume measurement by nitrogen washout. **A,** Before the test, as the subject breathes air, the nitrogen concentration in the lungs is 80%, and the collection system is flushed free of nitrogen. **B,** The subject inhales 100% O_2 and exhales into the collection bag until the exhaled N_2 concentration approaches zero. The total volume of the bag and its final N_2 concentration are measured, and the unknown initial lung volume (including valve and mouthpiece dead space) is calculated: $[N_2]_{bag} \times Vol_{bag} = 0.80 \times FRC$.

mouthpiece that, at the end of a relaxed tidal exhalation, is connected to an inspiratory source of 100% oxygen (Figure 9-4), while the subsequent exhaled gas is directed by one-way valves into a collection bag, previously flushed with oxygen so that it contains no nitrogen. The resident nitrogen is washed out of the lungs progressively and monitored with continuous analysis at the mouthpiece. When the exhaled nitrogen concentration falls below 2%, the test is terminated, and the volume of nitrogen collected is measured. The FRC can be calculated on the basis that this nitrogen volume represents 80% of the lung gas contained at the beginning of the test. Instead of the collection bag, current microprocessors use a calculation based on instantaneous, breath-by-breath measurement of exhaled volume times nitrogen concentration. Washout can be completed in 3 to 4 minutes in normal subjects but may require longer than 15 minutes with severe obstructive airway disease, so that the gas volume in slowly exchanging spaces can be measured.

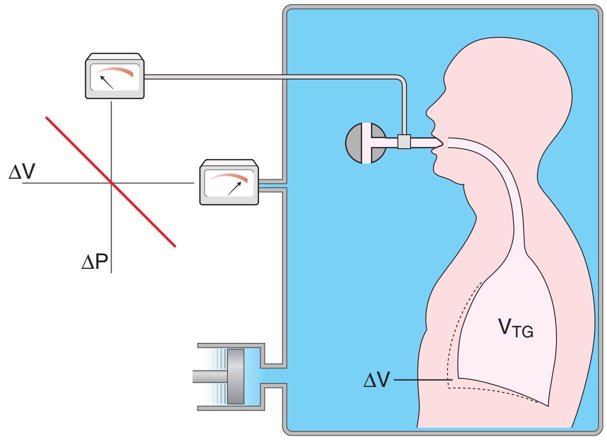

Figure 9-5 Lung volume measurement by body plethysmography. See text for description of the procedure. As the subject makes panting efforts against a closed airway shutter valve, the product of pressure and thoracic gas volume (V_{TG}) stays constant (Boyle's law). Thus, $P_B \times V_{TG} = (P_B - \Delta P) \times (V_{TG} + \Delta V)$. Solving for V_{TG} yields: $V_{TG} = P_B\,(\Delta V/\Delta P) - \Delta V$. Because ΔV is very small relative to V_{TG}, it is ignored, so $V_{TG} = P_B\,(\Delta V/\Delta P)$. ΔP is directly obtained from the airway pressure transducer, and ΔV is obtained from the pressure change in the plethysmograph, after calibration by cycling a known volume with a piston pump. V_{TG} is obtained from the slope of this relationship plotted during the panting maneuver.

MEASUREMENT BY BODY PLETHYSMOGRAPHY

The volume of gas within the thorax, whether in communication with airways or not, can be measured by the technique of body plethysmography, based on the physical principles of gas compression described by Boyle's law. The subject sits within a fully enclosed rigid box and breathes through a mouthpiece connected through a shutter to the internal volume of the box (Figure 9-5). Sensitive manometers monitor the pressure at the airway and inside the chamber. The apparatus is calibrated with the subject in place, so that the volume addition required within the chamber to raise the chamber pressure by 1 cm H_2O is known. At the end of a tidal exhalation, the airway shutter is closed, and the subject is asked to make panting efforts with the glottis open. An effort to expand the chest decompresses intrathoracic gas and reciprocally compresses that in the chamber; the opposite occurs during an expiratory effort.

Under conditions of constant temperature, which is well maintained by the high blood flow through the lungs, the product of airway pressure and lung gas volume is a constant. The slope of the relationship between the change in airway pressure and the change in thoracic volume, which can be calculated continuously or plotted on an oscilloscope, is inversely related to the intrathoracic volume. Because this technique is sensitive to gas volume not in free communication with the airways, such as that in bullae or even a pneumothorax, the measurement often is called "thoracic gas volume," which may exceed the FRC measured by gas dilution techniques. Advantages of this method, besides its inclusion of "trapped" gas, are that several measurements can be repeated rapidly, and that airway resistance can be measured with the same apparatus when panting is continued with the shutter open.

INTERPRETATION OF LUNG VOLUME ABNORMALITIES

Inspiration is limited at TLC when the maximum inspiratory force that can be applied by the chest muscles and diaphragm is opposed equally by the increasing recoil force of the lungs as they are distended to higher volumes. TLC is limited primarily by the elastic properties of the lungs, because variations in muscle strength have only a small effect on total chest expansion until weakness becomes quite marked. Parenchymal restrictive diseases reduce lung compliance, so greater distending pressure is required to achieve any volume change, and the maximum volume that can be achieved (TLC) is reduced. The displacement of intrathoracic gas volume by effusions, edema, intravascular volume, and inflammatory cells also can contribute to a reduction in measured lung gas volumes. Except for pleural effusions, these quantities are relatively small and outweighed by the frequently associated changes in lung elastic properties.

The minimum lung volume, or RV, is determined by a combination of two factors. The smallest volume to which the expiratory muscles can squeeze the chest wall and raise the diaphragm is the dominant factor in youth. By middle age, with the normal loss of tissue elastic recoil forces, the lung volume at which small airways close and trap remaining gas behind them increases and becomes the dominant factor in determining RV.

Restrictive Lung Diseases

Restrictive lung impairment is defined by a decrease in TLC below its lower limit of normal. In most parenchymal infiltrative processes, this is accompanied by parallel decrements in FRC, RV, and VC. The reduction in FRC reflects a shift in the balance of lung and chest wall recoil forces (see Chapter 3, Figure 3-7) and the reduction in RV occurs as increased tissue recoil delays airway closure. However, some patients with clear interstitial lung disease by radiologic evaluation or biopsy maintain lung volumes within the normal range. Obesity causes true restriction only when extreme but affects lung volumes in a pattern that differs from that of parenchymal lung diseases. The primary effect is on the relaxed end-expiratory volume or FRC, because the large abdomen and heavy chest wall reduce the outward recoil of the thoracic cage, which allows the inward recoil of the lung parenchyma to reduce FRC. RV is determined by airway closure, however, and is therefore less affected, and the TLC achievable using maximum inspiratory force is only minimally reduced until obesity becomes extreme (body mass index [BMI] greater than 40). Thus, the typical spirogram in even moderate obesity shows an end-expiratory volume (FRC) that approaches RV (i.e., the expiratory reserve volume is markedly reduced), but with a relatively large inspiratory capacity and a near-normal TLC and VC.

Obstructive Diseases

Airflow obstructive processes lead to airway closure that limits exhalation at higher lung volume because of the combined effects on luminal caliber of airway inflammation and loss of tissue recoil. These changes result in a progressive increase in RV (**Figure 9-6**), as increasing amounts of gas are trapped behind closed airways. Affected patients breathe at an increased FRC because of the combined effects of a decrease in lung recoil force from emphysema and the need to increase luminal caliber to minimize the resistive work of air flow. The TLC is normal to high, which again reflects the loss of lung recoil forces. Because RV increases to a greater extent than that seen in TLC, the VC decreases with severe airway obstruction.

Mixed Obstruction and Restriction

Obtaining lung volume measurement allows further characterization of the underlying problem in patients with both a low FEV$_1$/FVC and a low FVC. If the TLC is below the LLN, then they have restriction in addition to the obstructive abnormality, or a so-called mixed disorder. In such cases, the decrement in FEV$_1$ will reflect the contributions of both conditions, so it should not be attributed entirely to obstruction. For example, a patient with an FEV$_1$/FVC ratio of 0.65, a TLC of 60% predicted, and an FEV$_1$ of 45% predicted certainly has a "severe ventilatory impairment" but probably does not have severe airflow obstruction. It has been recently suggested that the severity of the obstructive component can be more appropriately attributed if the % predicted FEV$_1$ is divided by the % predicted TLC. Separate quantification of the components often is difficult, however, and clinical estimation of the overall severity of the combined impairment may be more important, because this is what affects the patient.

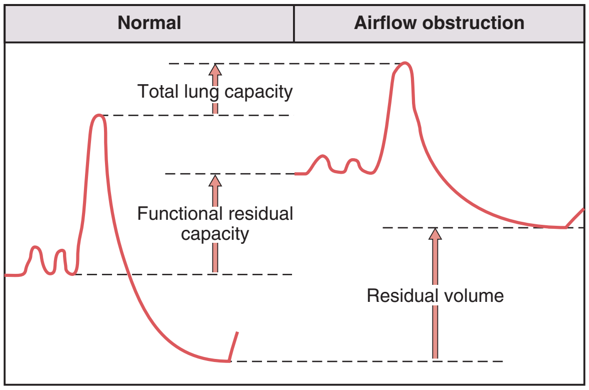

Figure 9-6 Severe airflow obstruction is associated with an increase in residual volume. Prolonged expiratory airflow may continue until the subsequent inhalation, and alveolar gas is trapped behind narrowed and closed airways. The functional residual capacity at which tidal breathing occurs also is increased, and total lung capacity may be high as well. *(Modified from Culver BH: Pulmonary function testing. In Kelly WN, editor:* Textbook of internal medicine, *Philadelphia, 1988, JB Lippincott.)*

Nonspecific Pattern

Some persons with reduction in both FVC and FEV$_1$ and with a normal ratio of FEV$_1$ to FVC will be found on lung volume testing to have a TLC within normal limits. Thus, they do not meet the definition for either obstruction or restriction, yet the low FEV$_1$ indicates some degree of impairment. The associated increase in RV may reflect early airway closure of uncertain cause. This so-called nonspecific pattern may be seen with obesity. Repeat studies over several years show that in most such cases, the same pattern is retained, with differentiation to either an obstructive or a restrictive pattern observed less frequently. The decrement in FEV$_1$ can be characterized as a mild ventilatory impairment of uncertain cause.

DIFFUSING CAPACITY

PRINCIPLES AND TECHNIQUE

The diffusing capacity (DL), also called transfer factor, is a measure of the capacity to transfer gas from alveolar spaces into the alveolar capillary blood. This process occurs by passive diffusion and is a function of the pressure difference that drives gas, the surface area over which exchange takes place, and the resistive properties to gas movement through the membrane and into chemical combination with the blood. The units are milliliters per minute per millimeter of mercury of driving pressure (mL/minute/mm Hg). (In SI units, 1 mole/minute/kPa = 2.896 mL/minute/mm Hg.) Carbon monoxide is used for the clinical test of diffusing capacity (DLCO), because its extreme avidity for hemoglobin allows the back pressure to diffusion to be considered negligible.

In the widely used single-breath method, the subject exhales to RV and then takes a VC inhalation of the test gas, which contains a low level of carbon monoxide (0.3%) and an inert gas not taken up in the blood (e.g., 10% helium). After breath-holding at full inspiration for 8 to 10 seconds, the subject exhales quickly. The initial portion of the expirate, which includes anatomic dead space, is discarded, and a sample of the subsequent alveolar gas is collected or measured by a rapidly responding sensor. The reduction in helium concentration in the alveolar sample allows calculation of the alveolar volume at TLC into which carbon monoxide was distributed, and of the initial carbon monoxide concentration after its dilution by the resident RV. The final concentration of carbon monoxide measured in the exhaled alveolar sample is applied in calculating the volume of carbon monoxide transferred out of alveoli and also allows a calculation, for which an exponential decline is assumed, of the mean carbon monoxide driving pressure during breath-holding. An effective residence time is calculated from the breath-hold period plus a portion of the time of inspiration and sample collection.

A significant problem with the diffusing capacity measurement is that numerous variations in the handling of small correction factors (for gas conditions, apparatus dead space, timing measurement, and so on) can cumulatively cause the calculated value to vary substantially among laboratories. Typically, two measurements are done and the results are averaged. Although reproducibility within a laboratory can be quite acceptable (±2.5 mL/minute/mm Hg), the accuracy of comparisons between laboratories or to reference data is much less consistent, as reflected by published predicted values that vary by 20% or more. It is essential that each laboratory choose prediction equations that are appropriate to the nuances of its equipment and technique.

INTERPRETATION OF DIFFUSION ABNORMALITIES

Although diffusion often is thought of as a function of alveolar membrane thickness, the dominant factor is usually the capillary blood volume, which influences both the surface area available for exchange and the volume of blood and hemoglobin available to accept carbon monoxide. The influence of hemoglobin concentration, [Hb], can be accounted for by theoretical or empirical correction factors. The velocity of blood flow is not important, because carbon monoxide is taken up even by stagnant blood (or extravasated blood in the case of pulmonary hemorrhage), but the recruitment of additional capillary segments during high flow conditions such as exercise or with congenital left-to-right shunt increases the measured diffusing capacity.

Many laboratories also report the diffusing capacity as a ratio of such capacity to the alveolar volume (DL/VA). This also is called the transfer coefficient (K_{CO}). The implication is that loss of lung volume secondary to mechanical abnormalities is accompanied by a parallel loss of diffusion capacity. This, however, is not the case with a voluntary limitation of inspiration, in which capillaries remain perfused and DL/VA rises, or with pneumonectomy, in which capillaries are recruited in the remaining lung and DL/VA is again high. Diffusing capacity is commonly reduced in parenchymal inflammatory diseases, primarily because of the loss of available capillaries. The most common pattern in diseases such as sarcoidosis and interstitial fibrosis is for DL to be reduced and DL/VA to be slightly low or "normal," because volume also is lost. Both DL and DL/VA are low with the loss of capillary surface area and blood volume in emphysema and in diseases that are primarily vascular, such as vasculitis, recurrent emboli, and pulmonary hypertension. Clinical interpretation of diffusion abnormality should be based primarily on the DL, not on the DL/VA, with small correction factors available for [Hb] and the lower oxygen levels of altitude.

TESTS OF GAS DISTRIBUTION

Abnormalities of spirometry and airflow rate reflect overall narrowing of airways, but most lung diseases affect airways heterogeneously, which leads to abnormalities of gas distribution that may be more sensitive indicators of early airway disease.

CLOSING VOLUME

As lung volume decreases, the smaller, intraparenchymal airways decrease in caliber until they close at low lung volume and ventilation to or from alveoli beyond them ceases. Because there is a vertical gradient in the pleural pressure that surrounds the lungs, the lung tissue is less distended in dependent regions than at higher levels in the thorax. In late exhalation, dependent airways close (i.e., these areas reach their regional RV), whereas air continues to flow from the upper portions of the lung until they too close, and overall RV is reached. The beginning of this wave of ascending airway closure can be detected by physiologic tests and is termed *closing volume.* Closing volume usually is expressed as a percentage of VC. That is, a closing volume of 20% means that airway closure can be detected during a slow exhalation when 20% of the VC remains before RV is attained (Figure 9-7). Alternatively, when RV is measured, this can be added to closing volume, and the sum, termed *closing capacity,* is expressed as a percentage of TLC.

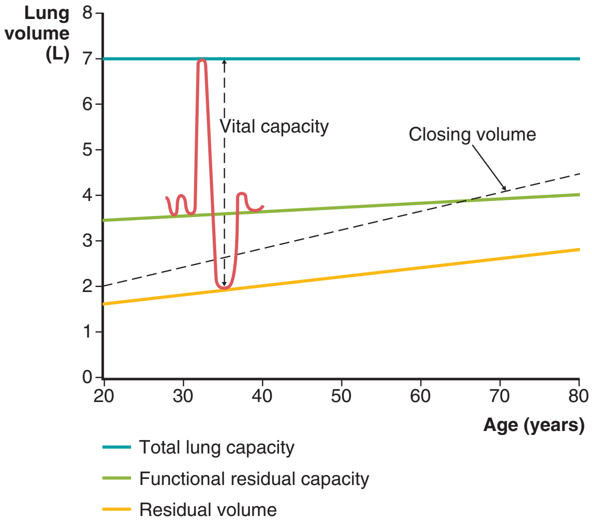

Figure 9-7 Effects of age on the normal spirogram. Residual volume progressively increases, with an associated small reduction in vital capacity. The functional residual capacity (FRC) increases slightly, but the closing volume, at which dependent airways cease to ventilate, increases more steeply and exceeds the normal FRC in older ages. *(Modified from Culver BH, Butler J: Alterations in pulmonary function. In Andres R, Bierman E, Hazzard W, editors:* Principles of geriatric medicine, *New York, 1985, McGraw-Hill.)*

Both of these measures have been used as tests of early airway dysfunction in the natural history of COPD. Abnormalities can be detected in a high percentage of smokers, but the prognostic usefulness is limited, because this group includes many who do not go on to develop progressive airflow limitation. On an individual patient basis, the closing volume is most helpful in its relationship to the lung volume at which tidal breathing occurs. When airway closure occurs at a volume below FRC, the airways are open throughout the lungs during tidal breathing, but when airway closure occurs above FRC, the affected alveoli are underventilated. Because the dependent regions are well perfused, premature airway closure creates a low ventilation-perfusion region, which contributes to hypoxemia. This abnormality occurs when the closing volume is increased by normal aging or COPD, and by the effect of peribronchial edema in left ventricular failure. Similar consequences are observed when FRC is reduced by recumbent posture or by obesity.

ARTERIAL BLOOD GAS MEASUREMENT

Measurement of pH, P_{CO_2}, and P_{O_2} in arterial blood is commonly included in the complete pulmonary function assessment of patients suspected to have significant lung disease. The pH and P_{CO_2} are directly measured, and the accompanying bicarbonate concentration is calculated from the Henderson-Hasselbalch equation. (The value of this “calculated” blood gas component must not be discounted; it is every bit as accurate as the pH and P_{CO_2} measurements from which it is derived.)

An increase in arterial P_{CO_2} means that alveolar ventilation is low relative to carbon dioxide production. This may be because total ventilation is low, the effective alveolar ventilation is reduced by excessive wasted ventilation, or the carbon dioxide production level has increased without a concomitant increase in ventilation. The matching of ventilation to metabolic need is a function of both mechanical capabilities and ventilatory drive. Most patients who suffer hypercapnia have severe mechanical impairments, but those who also have relatively low drive are more likely to retain carbon dioxide. Patients who have an FEV_1 greater than 1 L rarely retain carbon dioxide unless lack of drive is a major factor. Despite the airflow obstruction present during an acute asthmatic attack, multiple stimuli tend to increase drive and ventilation. However, when obstruction becomes extreme, again with an FEV_1 in the realm of 1 L or less for an adult, the development of acute hypercapnia is likely. Most parenchymal restrictive diseases tend to be associated with mild hyperventilation, presumably from mechanical stimuli to the respiratory centers, until the functional abnormalities become very severe.

The normal P_{CO_2} remains in a narrow range, around 40 mm Hg, throughout life, but the normal P_{O_2} diminishes progressively with age. This decline is more marked when P_{O_2} is measured with the subject in the supine position and in both cases reflects the progressive increase in closing volume with age (see Figure 9-7). Abnormal reductions in P_{O_2} are caused by hypoventilation, as reflected (but not caused) by an increase in P_{CO_2}, or result from the combined effects of pulmonary blood flow to poorly ventilated areas (low ventilation-perfusion ratio [$\dot{V}/\dot{Q}$]) and right-to-left shunting. Diffusion abnormalities, unless extremely severe, rarely contribute to a low P_{O_2} in patients at rest. The low P_{O_2} commonly seen in patients who have diffusion abnormalities reflects the concomitant presence of ventilation-perfusion abnormalities associated with their disease. Diffusion limitation may make a small contribution to a reduction in P_{O_2} observed during exercise, but again, the major component is a worsened effect of the ventilation-perfusion abnormalities.

SPECIAL TESTING

UPPER AIRWAY OBSTRUCTION

Obstruction in the central airways (e.g., tracheal tumor or stenosis) affects the expiratory flow-volume relationship in a different way than does the more common peripheral airway obstruction of COPD. The latter has its predominant effect late in expiration, with slowing of terminal flow rates, so that peak flow tends to be relatively maintained while the remaining flow-volume curve becomes progressively convex toward the horizontal axis (**Figure 9-8**). Central obstructions have their primary effect early, which results in a truncated, flat-topped flow-volume curve (**Figure 9-9**), reflecting a steady effort against a constant resistance. In the latter portion of the expiration, the decreasing lung volume and airway caliber shift the site of major resistance to the more peripheral airways, so that the latter portion of the flow-volume curve is normal.

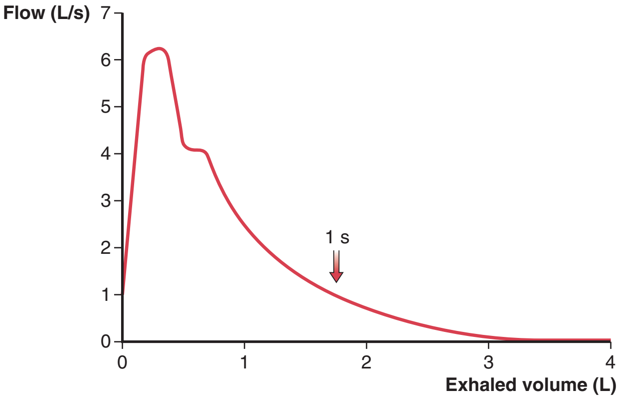

Figure 9-8 Expiratory flow-volume curve of chronic airflow obstruction. Airflow rates are markedly reduced at mid- to lower lung volumes, with a curve that is convex to the horizontal axis. In this example, just under 50% of the vital capacity has been exhaled in 1 second. *(Modified from Culver BH: Pulmonary function testing. In Kelly WN, editor:* Textbook of internal medicine, *Philadelphia, 1988, JB Lippincott.)*

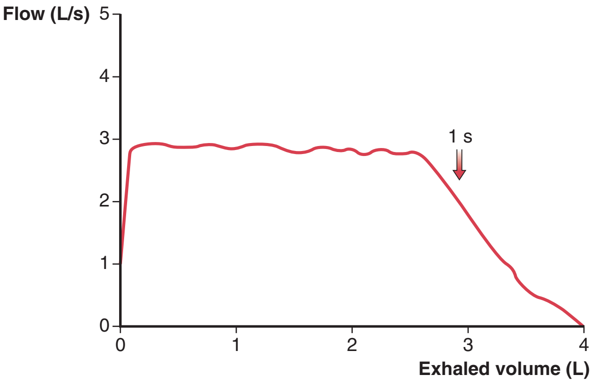

Figure 9-9 Expiratory flow-volume curve shows the pattern typical of central airway obstruction. Peak flow is markedly truncated, but the flow rates at low lung volume are unaffected. Despite the dramatic effect on the flow-volume curve, the ratio of FEV_1 to FVC is only modestly affected, with a value of 0.71 in this example. *(Modified from Culver BH: Pulmonary function testing. In Kelly WN, editor:* Textbook of internal medicine, *Philadelphia, 1988, JB Lippincott.)*

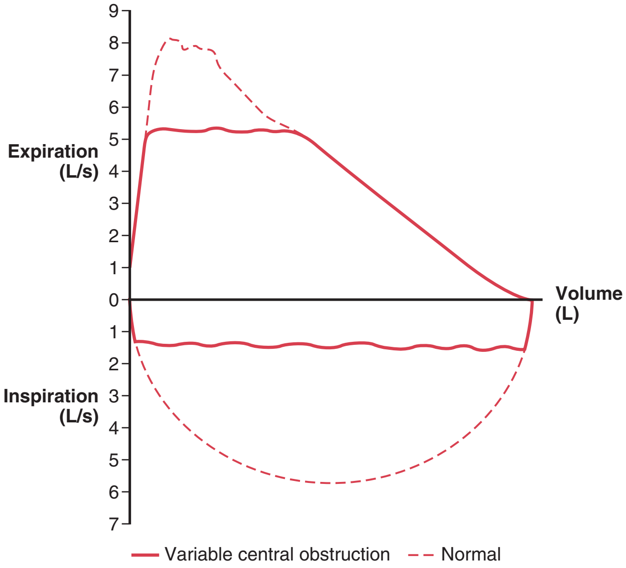

Figure 9-10 Flow-volume loop showing both forced expiratory and inspiratory airflows. The expiratory peak flow is somewhat truncated, consistent with a mild central obstruction during exhalation; inspiratory flow is markedly reduced from that for the normal curve. This pattern is typical of a flexible, extrathoracic obstruction, such as that secondary to paralysis of the vocal cords. *(Modified from Culver BH: Pulmonary function testing. In Kelly WN, editor:* Textbook of internal medicine, *Philadelphia, 1988, JB Lippincott.)*

When a central obstruction is in the extrathoracic airway and has some flexibility (e.g., vocal cord paralysis), its effect is much greater during inspiratory flow than expiratory flow. The negative intraluminal pressure generated during inspiration narrows the airway, which exacerbates the obstruction, whereas during expiration, the positive airway pressure below the site of obstruction tends to distend the airway, which reduces the abnormality. These lesions are assessed by recording on the flow-volume display the maximum effort inspiratory flow curve, as well as that during expiration, to complete a flow-volume "loop." The normal inspiratory flow pattern has a semicircular shape with peak inspiratory flow at midvolume that consistently exceeds midvolume expiratory flow (Figure 9-10).

BRONCHOPROVOCATION TESTING

Patients who have suspected reactive airway disease frequently demonstrate normal spirometry values when asymptomatic. When the diagnosis is unclear, provocation testing may be performed in an attempt to explain symptoms or predict future risks. A common clinical provocation of asthma is the airway mucosal cooling and drying effect of exercise hyperpnea or cold air inhalation. Provocation testing with *exercise* can utilize free running, treadmill running, or bicycle pedaling, with the relative yield of abnormal tests in that order. To provide a sufficient ventilatory stimulus, exercise level is increased over 2 to 3 minutes to 70% to 90% of maximal capability, as estimated from heart rate, and then sustained for an additional 4 to 6 minutes. Spirometric testing is done before exercise and repeated after exercise, with the most marked decrease in flow rates noted at 5 to 10 minutes after exercise. A reduction in FEV_1 of 10% is considered significant, because normal subjects typically show a small increase shortly after exercise. *Cold air challenge*, in which spirometric testing is done before and after isocapneic hyperventilation of air that has been dehumidified and cooled to 4° C, is less widely available as a provocation maneuver.

Methacholine responsiveness is a nonspecific indicator of airway reactivity. Starting with a single inhalation at a very low concentration, patients are tested after progressively increasing inhaled doses until either a predetermined maximum dose has been achieved or the FEV_1 has been observed to fall by 20%. Normal subjects do not respond to the maximum dose, whereas patients with asthma usually respond to very low to intermediate doses. A negative response at the maximum dose in a patient suspected to have asthma and recently symptomatic makes that diagnosis very unlikely, but positive responses are less specific. Persons who have a family history of asthma or hay fever symptoms may show intermediate responses, as may patients with COPD or cystic fibrosis, as well as some normal persons in the recovery period after viral respiratory infections.

Whereas methacholine directly stimulates smooth muscle contraction, indirect stimuli such as exercise or the recently developed mannitol challenge test act through changes in mucosal osmolarity and release of endogenous mediators. These stimuli are more specific for asthma and more responsive to variations in airway inflammation, but they tend to be less sensitive than methacholine challenge.

In selected circumstances, provocation testing may be carried out with suspected specific allergens or occupational exposures. Dose preparation needs to be very careful, to avoid an excessive and dangerous response. Studies may be designed to mimic the circumstances of the patient's clinical or occupational exposure. Testing may need to be continued for several hours to identify a late-phase reaction.

Section 2
DIAGNOSTIC TECHNIQUES

Chapter 10
Exercise Testing

Josep Roca • Felip Burgos

Clinical exercise testing is widely accepted as an important component of the clinical assessment of patients with chronic respiratory illness, because impaired exercise capacity in these patients shows significant associations with health-related quality of life and with relevant clinical outcomes such as hospitalization rates and survival.

Impaired exercise capacity can be defined by the inability of the subject to sustain a required work rate long enough for the successful completion of a given task that could be achieved by a healthy person. Limitation of oxygen transport from the atmosphere to the cell is the most common cause of exercise limitation in chronic respiratory disease, but altered oxygen utilization due to abnormally low mitochondrial oxidative potential also can be a contributing factor in patients with advanced disease (**Figure 10-1**).

Clinical manifestations of limited exercise capacity are breathlessness, perception of limb fatigue, or even, in some conditions, frank pain. Abnormally low exercise capacity is the hallmark of a range of cardiovascular, respiratory, and other systemic diseases, of which congestive heart failure and chronic obstructive pulmonary disease (COPD) are the most prominent. However, the causes of a reduced exercise capacity are many, ranging from physical unfitness and obesity to muscle and neurologic diseases, anemia, and locomotor disorders.

Several studies have shown that the functional reserve (i.e., aerobic capacity) of patients with COPD and interstitial lung disease is not accurately predicted from resting lung function indices. In this scenario, cardiopulmonary exercise testing (CPET) constitutes a proper tool to assess both magnitude and mechanisms of impaired exercise capacity. CPET also can provide indices of the functional reserve of the different systems (pulmonary, cardiovascular, skeletal muscle) involved in the exercise response, with implications for factors contributing to the limitation of oxygen uptake at peak exercise. Moreover, CPET also is useful for establishing the profiles and adequacy of the system responses at submaximal exercise.

The chapter describes the laboratory exercise protocols more commonly used for clinical purposes, but it also covers simple exercise tests of increasing clinical usefulness that are extensively used outside the laboratory with well-defined purposes.

CLINICAL INDICATIONS FOR EXERCISE TESTING

The various clinical indications for CPET can be divided into three principal groups: assessment of functional reserve (aerobic capacity), identification of predominant factors limiting exercise capacity, and, last but not least, diagnostic purposes. Of note, adequate identification of the clinical problem requiring exercise testing should be considered a necessary prelude to CPET, as should an appropriate preassessment of the patient by (1) medical history, (2) physical examination, (3) chest radiograph, (4) resting pulmonary function testing, and (5) electrocardiogram (ECG). The clinical problem that prompts CPET and the specific aims of such testing (e.g., assessment of aerobic capacity, analysis of pulmonary gas exchange during exercise) determine both the type of exercise protocol to be used and the variables to be considered in the interpretation of the findings.

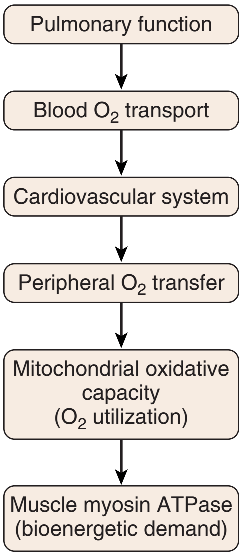
Assessment of aerobic capacity and identification of potential limiting factors constitute the most important indications for CPET. These goals are particularly important in evaluating dyspnea but also for assessing the degree of functional impairment in patients with chronic diseases. Appropriate use of CPET allows the investigator (1) to quantify the degree of functional limitation and to discriminate among causes of impairment of exercise capacity, (2) to differentiate between dyspnea of cardiac or pulmonary origin when respiratory and cardiac diseases coexist, and (3) to analyze unexplained dyspnea when initial pulmonary function testing does not provide conclusive results. CPET also is useful to assess the effects of pharmacologic interventions.

An important area for CPET is preoperative assessment in certain conditions—for example, for planned major abdominal surgery in elderly patients. Also, CPET is indicated before lung cancer resection and lung volume reduction surgery, either to confirm the patient's fitness to survive the procedure, if this is in question, or to ensure that postoperative respiratory function will be adequate. Information on predicted postoperative lung function can help to modulate the amount of lung parenchyma to be removed and determines the type of perioperative strategy needed to prevent complications. Pulmonary function tests performed in the resting state are considered adequate to evaluate low-risk patients (FEV_1 greater than 2 L and DLCO within the reference limits), but CPET plays a pivotal role in the evaluation of patients at high risk.

CPET should always play a central role in assessing candidates for a rehabilitation program and in the subsequent modulation of the exercise prescription.

Assessment of impairment-disability also constitutes a major indication for CPET. It is now well accepted that CPET provides different and relevant information, compared with resting cardiopulmonary measurements, in impairment-disability evaluation and therefore constitutes a key tool in this area.

Finally, CPET plays a role in the diagnosis of a range of disease conditions, namely: exercise-induced asthma, cardiac ischemia, foramen ovale patency with development of right-to-left shunt during exercise, and McArdle syndrome.



Pulmonary function
Blood O_2 transport
Cardiovascular system
Peripheral O_2 transfer
Mitochondrial oxidative capacity (O_2 utilization)
Muscle myosin ATPase (bioenergetic demand)

Figure 10-1 Major elements of the O_2 transport–O_2 utilization pathway. Integrated effects of all steps involved to move oxygen from air to mitochondria are essential to determine maximum capacity of the system. In disease, nonuniformity of ventilation-perfusion ratios in the lung, altered response of the cardiovascular system to exercise, and/or mismatching of metabolism-perfusion ratios in the peripheral tissues may be of considerable importance in determining cell oxygenation. Moreover, in patients with advanced chronic obstructive pulmonary disease (COPD), impaired oxygen utilization due to altered mitochondrial oxidative capacity has been demonstrated.

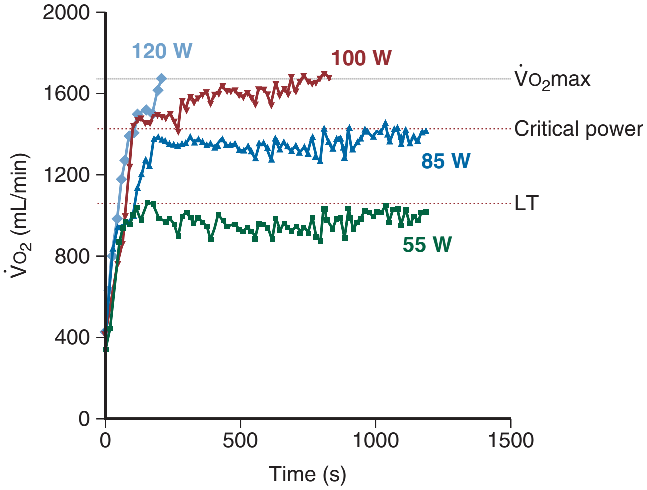


Figure 10-2 Response of oxygen uptake to four different constant-work-rate exercise tests carried out using a cycle ergometer in a healthy subject. From moderate to heavy exercise: *Green*, 55 watts, corresponding to a work rate moderately above the lactate threshold (LT), approximately 58% of $\dot{V}O_2$max, indicates the transition from moderate to intense exercise; *dark blue*, 85 watts, indicates the critical power (approximately 88% $\dot{V}O_2$max) corresponding to the highest level of sustainable exercise; *red*, 100 watts, indicates nonsustainable exercise above the critical power; and *light blue*, 120 watts, supramaximal nonsustainable exercise intensity. Of note, the two last exercise intensities, 100 and 120 watts, generate identical oxygen uptake that, by definition, corresponds to maximal O_2 uptake, $\dot{V}O_2$max.

EXERCISE INTENSITY AND ENERGY REQUIREMENTS

Availability of oxygen to all body tissues and cells is essential for survival. During steady-state conditions, oxygen consumption ($\dot{V}O_2$) matches the turnover of adenosine triphosphate (ATP), the high-energy phosphate needed to fulfill the bioenergetic requirements of the cells. ATP is efficiently generated by oxidative phosphorylation into the mitochondria. Within the inner mitochondrial matrix, pyruvate is converted to acetyl coenzyme A (CoA) and metabolized aerobically by way of the tricarboxylic acid cycle to yield water and carbon dioxide (CO_2) as residual products to be subsequently eliminated.

Alternative pathways of energy production not requiring oxygen constitute rapid but only transient solutions to fulfill the bioenergetic requirements. That is, anaerobic reduction of pyruvate to lactic acid in the cytosol is inefficient in terms of ATP production. Moreover, increased lactate levels provoke a marked fall in intracellular pH that may alter mitochondrial function. Likewise, skeletal muscle contains high levels of phosphocreatine (PCr) compared to other tissues, but the breakdown of muscle PCr stores can supply cellular needs of ATP for only a few seconds of strenuous contractions. Compared with glycolysis, aerobic metabolism requires longer to become activated. Energy utilization during exercise may require higher ATP turnover than the synthesis from aerobic pathways in the muscles allows. This phenomenon causes an “oxygen debt” that must be repaid after exercise. Aerobic metabolism, in turn, is more efficient in terms of ATP production and it enables the cell to utilize stored lipid as fuel via fatty acid metabolism. Consequently, the integrity of the different pathways governing cellular O_2 transport–O_2 utilization is a pivotal determinant of exercise capacity in both health and disease (see Figure 10-1).

In the progression from mild to high-intensity exercise, four conceptual steps that are important to a proper understanding of exercise testing can be identified:

Lactate threshold (LT), or anaerobic threshold, is the threshold $\dot{V}O_2$ for arterial lactate concentration increase. The LT should be considered to partition moderate from heavy-intensity exercise, and it corresponds to a transitional exercise intensity that triggers a series of physiologic responses associated with increased lactate production that stress ventilation, pulmonary gas exchange, and acid-base regulation. Of note, the LT is highly task-specific. It occurs at an appreciably lower $\dot{V}O_2$ for arm exercise than for leg exercise and typically is lower for cycle ergometry than for treadmill exercise, reflecting the magnitude of muscle mass over which the work is distributed. A wide range of techniques have been advocated for estimation of LT, including both direct measurements and indirect estimation, as described next.

Critical power is the highest sustainable level of $\dot{V}O_2$ and usually is at an intensity below the maximal $\dot{V}O_2$ for an individual subject and at an intensity of exercise that can still generate a plateau in $\dot{V}O_2$ (**Figure 10-2**). Heavier exercise intensities, well beyond LT, are not sustainable and may peak at $\dot{V}O_2$max (see Figure 10-2). During moderate intensity submaximal exercise, the components of the O_2 transport pathway can provide adequate O_2 flux between the air and the mitochondria. Mitochondrial oxidative capacity will not have been reached, symptoms usually are tolerable, and muscle fatigue has not occurred, or at least may be insufficient to impair performance appreciably. Although the concept of critical power is relevant for understanding the exercise response, it is not assessed in clinical exercise testing, because no normal ranges for submaximal exercise comparable between laboratories or diseases have been established.

Maximal exercise ($\dot{V}O_2max$) corresponds to maximal aerobic capacity, as displayed in Figure 10-2. At this point, maximal oxygen transport capacity and/or maximal mitochondrial oxidative potential have been reached. The subject cannot increase $\dot{V}O_2$ when work rate is increased or the highest tolerated work rate is sustained for a period of time. Often, $\dot{V}O_2max$ can only be clearly identified in fit subjects that can sustain high levels of exercise for a few minutes. Extreme motivation is needed to reach true $\dot{V}O_2max$, and it is, in general, an unsuitable and unsafe test for patient populations.

Peak exercise ($\dot{V}O_2peak$) occurs when maximal work rate has been limited by severe symptoms at a level that does not require maximal O_2 transport or maximal oxidative capacity. Under these conditions, a plateau in O_2 ($\dot{V}O_2max$) has not been reached, and the appropriate designation is *peak* rather than *maximal* $\dot{V}O_2$. Symptom-limited exercise testing is common in the clinical setting, and this approach does not preclude adequate interpretation of the test results.

Because the catabolic capacity of the myosin ATPase is such that it outstrips by far the capacity of the respiratory system to deliver energy aerobically, exercise tolerance ($\dot{V}O_2max$) is determined by the capacity of the O_2 transport–O_2 utilization system, rather than by the muscle's contractile machinery (see Figure 10-1).

Two physiologic muscle properties—muscle strength and muscle fatigability—may modulate functional performance of the patient in daily life activities as well as during clinical exercise testing. *Muscle strength* is defined as the force generated by a muscle. It is determined by the number and type of motor units recruited. *Muscle fatigue* has been defined as a loss of contractile functions (force, velocity, power, or work) that is caused by prolonged exercise and is reversible by rest. Factors involved in muscle fatigue are complex, consisting mainly of contractile machinery, muscle respiratory capacity, and redox status of the muscle.

RESPONSES TO EXERCISE IN HEALTH AND DISEASE

As the patient with lung disease exercises harder, O_2 consumption, CO_2 production, ventilation, and cardiac output all increase to fulfill increased muscle bioenergetic requirements, as they do in the normal subject, but submaximal exercise response is abnormal and peak levels attained are lower, and increasingly so with increasing severity of the disease.

PULMONARY RESPONSE TO EXERCISE IN HEALTHY HUMANS

Ventilation and cardiac output markedly increase during exercise to match O_2 transport with augmented cellular O_2 requirements. Because ventilation increases to a relatively higher extent than pulmonary blood flow, the ratio of total alveolar ventilation to blood flow (overall $\dot{V}A/\dot{Q}$ ratio) rises rather substantially. At moderate levels of exercise, the dispersion of the $\dot{V}A/\dot{Q}$ distributions does not change, but the $\dot{V}A/\dot{Q}$ ratios as the mean of both ventilation and perfusion distributions increase markedly owing to the higher overall $\dot{V}A/\dot{Q}$ ratio. Consequently, the efficiency of the lung as an O_2 and CO_2 exchanger improves at these exercise levels. Mixed venous PO_2 falls dramatically during exercise because the relative increase in $\dot{V}O_2$ is considerably greater than that of cardiac output, and mixed venous PCO_2 levels rise equally remarkably. Arterial PO_2 levels generally remain unchanged until extremely high levels of exercise are undertaken. Arterial PCO_2 levels also are relatively stable until the appearance of high blood lactate levels generates acidosis with even more ventilation and a corresponding fall in PCO_2 levels. The alveolar-arterial O_2 gradient, $PO_2(A–a)$, progressively increases with the level of exercise, reaching values of 20 mm Hg close to maximal exercise ($\dot{V}O_2$ peak) in average subjects and even greater—up to 40 mm Hg or more—in some elite athletes. Such an increase in $PO_2(A–a)$ indicates inefficiency of pulmonary gas exchange during heavy exercise that is even more apparent in other animal species. It has been shown that the increase in the $PO_2(A–a)$ during exercise is due in part to ventilation-perfusion mismatching, but it is mostly explained by alveolar–end-capillary O_2 diffusion limitation. Experimental studies suggest that development of subclinical pulmonary edema may explain the deterioration of pulmonary gas exchange during heavy exercise in elite athletes.

PULMONARY RESPONSE TO EXERCISE IN LUNG DISEASE

In patients with COPD, resting levels of minute ventilation ($\dot{V}E$) are abnormally high but, during exercise, the slope between $\dot{V}E$ and work rate is normal. For a given level of $\dot{V}E$ during exercise, tidal volume (VT) tends to be lower and respiratory rate (f) higher in patients than in healthy subjects. Moreover, the O_2 cost of breathing per unit ventilation is higher in persons with COPD than in healthy subjects. Impaired respiratory mechanics requires more effort to move a given volume of air. Peak exercise VT is strongly related to vital capacity in these patients, in whom two strategies are adopted during exercise to increase $\dot{V}E$: First, end-expiratory lung volume (EELV) increases, allowing higher maximum expiratory flow rates. This dynamic hyperinflation does not occur in normal persons, who show a fall in EELV during exercise (Figure 10-3).

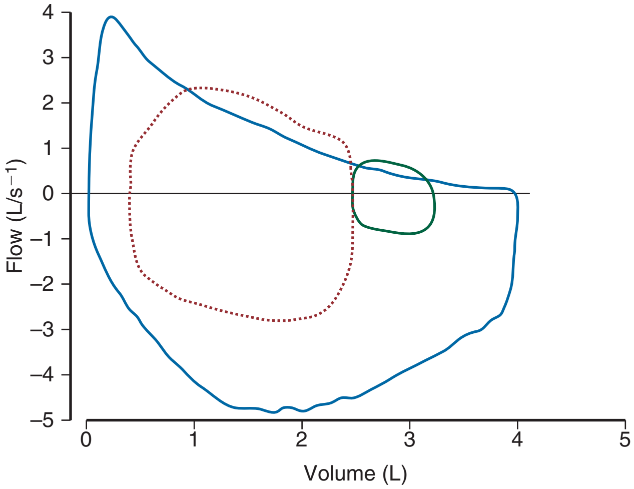

Figure 10-3 The resting maximal flow-volume curve from a patient with chronic obstructive pulmonary disease is represented by the *blue solid line*. The *solid smallest green loop* corresponds to tidal volume at rest, and the *dashed red curve* indicates tidal volume at maximal exercise. During exercise, end-inspiratory and end-expiratory lung volumes are increased (dynamic hyperinflation), and expiratory flow limitation is seen over most of expiration. *(From Roca J, Rabinovich R: Clinical exercise testing. In Gosselink R, Stam H, editors: Lung function testing,* Eur Resp Mon *31:146–165, 2005.)*

Second, inspiratory flow rate increases, so that inspiratory time decreases and more time is available for expiration.

Impaired respiratory mechanics (i.e., dynamic hyperinflation) seems to play a major role limiting exercise tolerance in these patients. During exercise in COPD, a balance is struck between the need for ventilation and the high cost of the work of breathing. The most common end result is a small rise in arterial P_{CO_2} and similar fall in Pa_{O_2}. However, unless pulmonary CO transfer capacity (D_{LCO}) is severely impaired (less than 50% predicted value), Pa_{O_2} does not fall during exercise, and may even increase in some subjects. Studies using the multiple inert gas elimination technique in COPD show that ventilation-perfusion mismatch usually is unchanged from that at rest, that shunts do not develop, and that diffusion limitation also does not occur. This is the case even when COPD is severe. In milder disease, there is evidence that small improvements in $\dot{V}_A/\dot{Q}$ relationships may occur on exercise, providing a partial reason for improvement in arterial P_{O_2}. It is not infrequently observed, however, that when the patient with COPD is encouraged to maximal effort, sudden hypoxemia and hypercapnia can develop just before the patient quits exercising.

In a variety of chronic respiratory disorders such as interstitial lung disease (ILD) and pulmonary vascular disease (PVD), abnormally high resting levels of $\dot{V}_E$ and normal slope between $\dot{V}_E$ and work rate during exercise are commonly observed but not dynamic hyperinflation, as seen in patients with COPD. In these patients, end-expiratory lung volume does not change significantly during exercise. Oxygen cost of breathing per unit ventilation is increased in patients with ILD because the increased elastic recoil requires more inspiratory muscle activity. They show a strong linear relationship between peak exercise V_T and vital capacity, suggesting that differences in peak V_T are due mainly to abnormal respiratory mechanics. During exercise, patients with ILD generally show typical and substantial blood gas changes, even at moderate effort. Although arterial P_{CO_2} generally is unaffected, Pa_{O_2} falls in almost all patients, sometimes severely, as does mixed venous P_{O_2}. It is this profound degree of arterial hypoxemia (and not respiratory mechanics) that mostly limits exercise tolerance in ILD. Worsening of ventilation-perfusion mismatching and shunt does not play a relevant role in exercise-induced hypoxemia seen in these patients. Therefore, the blood gas changes on exercise are mostly the consequence of (1) insufficient increase of alveolar ventilation relative to the rise in $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ and (2) secondary effects from the fall in mixed venous P_{O_2} causing a fall in arterial P_{O_2}. Also, O_2 diffusion limitation is seen in most patients with ILD during exercise, further adding to the hypoxemia. The presence of O_2 diffusion limitation in these patients, despite the relatively low cardiac output at peak exercise (less than 10 L/min) probably is related to the combination of (1) an abnormally low mixed venous P_{O_2}, (2) a short capillary transit time, and (3) some increased interstitial resistance for the diffusion of O_2 from the alveolar gas to the capillary blood caused by the large collagen deposits there.

Exercise-induced hypoxemia in patients with ILD is found to be due largely to the fall in venous P_{O_2}, because there is no systematic change in $\dot{V}_A/\dot{Q}$ relationships, nor does diffusion limitation develop.

HEMODYNAMIC RESPONSES TO EXERCISE IN HEALTH AND DISEASE

In healthy subjects, cardiac output ($\dot{Q}_T$) shows a linear increase in relation to O_2 uptake during exercise. Likewise, both stroke volume and heart rate also increase as $\dot{V}_{O_2}$ rises. In well-trained subjects, up to a five-fold increase (approximately 25 L/min) in $\dot{Q}_T$ at peak exercise can be seen. Systolic pulmonary pressure increases during exercise, but pulmonary vascular resistance falls because of vascular recruitment of underperfused areas of the pulmonary vascular bed. At systemic levels, systolic pressure increases, but not diastolic pressure. It is of note, however, that elite athletes at peak exercise show a potent sympathetic vasoconstriction at systemic level inducing massive redistribution of cardiac output, which ensures preferential perfusion to active skeletal muscle (due to local exercise-induced vasodilator effects) while preserving blood flow and O_2 delivery to essential organs such as the brain. During high-intensity exercise in COPD, restriction of intercostal muscle perfusion with preservation of quadriceps blood flow, along with attainment of a plateau in cardiac output, indicates the inability of the cardiovascular system to satisfy the energy demands of both the locomotor and respiratory muscles. In affected patients, the increase in thoracic and abdominal pressures due to dynamic hyperinflation and activity of abdominal expiratory muscles seems to preclude adequate increase in cardiac output during intense exercise.

In chronic respiratory diseases, pulmonary vascular abnormalities are present well before overt heart failure occurs. There is pulmonary hypertension often even evident at rest, and usually during exercise. The increase in pressure per unit increase in cardiac output is some three times greater in these patients than in the normal subjects.

In contrast with normal subjects, in whom pulmonary vascular resistance normally falls during exercise owing to a combination of vascular recruitment and distention in the lungs, in those with COPD, vascular resistance remains constant or may even rise. The vascular destruction or obstruction that occurs in these diseases, together with some vascular distortion and hypoxic vasoconstriction, are the reasons underlying these physiologic abnormalities. Eventually, as the diseases progress, the right heart will hypertrophy and ultimately fail, and clinically significant cor pulmonale will develop. Despite the two- to three-fold increase in vascular resistance and high pulmonary artery pressures, it is remarkable that even in advanced lung disease, the heart can pump essentially normally as a function of filling pressure.

At peak exercise, systemic O_2 delivery is clearly below normal predicted levels. Although the obvious culprit is impaired pulmonary function, it is not always through a reduction in Sa_{O_2} that systemic O_2 delivery is reduced, because despite $\dot{V}_A/\dot{Q}$ inequality and reduced effective alveolar ventilation, hypoxemia may not necessarily provoke a marked fall in arterial O_2 content. It is accepted that cardiac output at peak exercise is always well below normal levels. However, in COPD as in the absence of disease, cardiac output increases linearly in relation to oxygen uptake, because work rate increases during incremental exercise such that cardiac output at a given submaximal O_2 uptake is close to the expected normal value. Of note, however, the rise in cardiac output during exercise usually is achieved through a higher heart rate and lower stroke volume than in healthy subjects.

Because total ventilation, cardiac output, and exercise intensity remain closely coupled in COPD as in health, the inability to increase ventilation appears to be the principal governor of the O_2 transport process: A low ceiling on ventilation means a low ceiling on cardiac output and thus on systemic O_2 delivery. However, the mechanisms that couple ventilation to cardiac output during exercise are still not well understood. It has been proposed that the large pleural pressure swings observed during exercise can be paramount in constraint of left ventricular function, thus limiting both peak cardiac output and exercise tolerance in severe COPD. It also is accepted that abdominal expiratory muscles can play a role in limiting increases of cardiac output during exercise, as indicated previously. The coupling between whole-body O_2 uptake and cardiac output during exercise implies that the O_2 difference between arterial and mixed venous blood and the fractional O_2 extraction are normal or near normal. The cardiac response to exercise in patients with ILD is similar to the description for persons with COPD. By contrast, patients with PVD show a different cardiac response to exercise. Certainly, at peak exercise, cardiac output is lower. More important, however, the slope of the relationship between $\dot{V}O_2$ and cardiac output appears different. This observation suggests that for any given degree of exercise (i.e., $\dot{V}O_2$), cardiac output in patients with PVD does not increase as much as in control subjects or patients with COPD or ILD. This abnormal behavior is likely to be related to the increased afterload of the right ventricle. As expected, patients with PVD have, at rest, pulmonary artery hypertension and increased pulmonary vascular resistance. Compared with patients with COPD and ILD, patients with PVD show much worse hemodynamic responses. During exercise, pulmonary artery pressure increases in direct proportion to the increase in cardiac output and reaches extremely high values. This effect highlights the lack of pulmonary vascular reserve. In fact, the pathologically elevated pulmonary vascular resistance seen at rest does not change substantially during exercise.

MUSCLE O_2 UTILIZATION IN HEALTH AND DISEASE

It has been reported that well-trained men show O_2 supply dependency of maximum O_2 uptake, indicating that mitochondrial capacity does not constitute the rate-limiting factor for maximum exercise performance. By contrast, data from healthy sedentary subjects strongly suggest that muscle mitochondrial function is a limiting step for maximum O_2 uptake in sedentary persons. A recent study including direct measurements of cell PO_2 saturation during exercise with different levels of FIO_2 further indicates that sedentary subjects do not show O_2 supply dependency of $\dot{V}O_2max$. The plasticity of skeletal muscles during high-intensity physical training programs fully accounts for the differences alluded to between athletes and sedentary subjects. The scenario is far more complex in patients with COPD. Femoral blood flow ($\dot{Q}leg$) measurements in patients with moderate to severe airflow limitation have shown, as for cardiac output, a marked reduction in peak $\dot{Q}leg$. However, leg blood flow (and leg O_2 delivery) at a given submaximal whole-body O_2 uptake is above normal, which may indicate increased peripheral muscle O_2 demand. Moreover, poor muscle capillary networks in these patients seem to suggest that low peripheral O_2 diffusion capacity also may contribute to exercise-induced cell hypoxia, even in the absence of arterial hypoxemia. Increased lactate production is responsible for the fall in muscle pH, which in turn may play a role determining exercise intolerance in these patients. Premature lactic acidosis during exercise in COPD has been associated with reduced oxidative enzyme concentrations in the lower limb muscles that can be at least partly reversed by physical training.

Several studies exercising different muscle groups in heterogeneous groups of patients with COPD have consistently shown lower cellular bioenergetic status (^{31}P-nuclear magnetic resonance spectroscopy) and lower pH than in healthy sedentary control subjects at equivalent levels of exercise. Some evidence suggests that muscle deconditioning plays an underlying role in the disturbances of skeletal muscle bioenergetics in COPD. Recent evidence indicates that intrinsic skeletal muscle dysfunction may be present in COPD, as well as in other chronic disorders such as congestive heart failure. Abnormal redox status plays a central role in precipitating muscle mass wasting, particularly in susceptible subsets of patients with COPD.

It is accepted that the level of exercise tolerance is set by the integrity of each of the functions involved in the O_2 transport–O_2 utilization system, as well as by proper interactions among all of the aforementioned physiologic responses. Complex integrative pathways both at whole body level and at cellular level have been identified. Because not only intracellular pH but also cell PO_2 has been shown to modulate mitochondrial function, O_2 transport (cell PO_2) and O_2 utilization (mitochondrial capacity) cannot be analyzed as separate systems.

Also of major interest are the events surrounding peak or maximal $\dot{V}O_2$ and the physiologic basis of why peak or maximal $\dot{V}O_2$ is reduced, as it almost always is in disease. Of note in this regard, the amount of $\dot{V}O_2$ achieved by a given patient not only is set by the intrinsic characteristics of the system but also depends on several other factors that modulate the physiologic response of the whole body, such as (1) environmental conditions (e.g., altitude above sea level, FIO_2); (2) amount of exercising muscle mass (e.g., with cycling, walking, or localized quadriceps exercise); and (3) type of exercise protocol (e.g., incremental, endurance test, 6-minute walking test, shuttle test).

CLINICAL EXERCISE PROTOCOLS

The goal of CPET protocols is to stress the organ systems involved in the exercise response in a controlled manner. For this reason, the testing generally involves exercising large muscle groups, usually the lower extremity muscles. A key requirement is that the exercise stimulus must be quantifiable in terms of external work and power performed. Clinical exercise protocols are grouped into those carried out in the laboratory and simple exercise testing. As indicated earlier, the first step is proper identification of the clinical question to be answered through CPET, such that the appropriate protocol and corresponding measurements can be properly chosen.

INCREMENTAL EXERCISE IN THE LABORATORY

The appropriateness of the integrated systemic responses is best studied using incremental exercise testing either as a ramp function or as small work-rate increments of short duration. This approach provides a smooth incremental stress to the subjects, so that the entire range of exercise intensities can be spanned in a short period of time.

CPET has been classically built around the rapid ramp-incremental exercise test (performed on a cycle ergometer or motorized treadmill), breath-by-breath monitoring of cardiopulmonary variables (e.g., O_2 uptake, CO_2 output, ventilation, heart rate), and formulation of graphical clusters of response profiles that optimize estimation of key parameters such as $\dot{V}O_2$ peak and the lactate threshold and the characterization of pertinent response profiles (e.g., heart rate–$\dot{V}O_2$, oxygen pulse–$\dot{V}O_2$, $\dot{V}E$-$\dot{V}CO_2$). This approach provides a convenient way of (1) determining whether the magnitude and pattern of response of particular variables is normal with respect to other variables or to work rate, (2) establishing a subject's limiting or maximum attainable value for physiologic variables of interest, and (3) establishing exercise intensity domains, such as the transition between moderate and heavy-intensity exercise.

For incremental exercise testing, electronically braked cycle ergometry with constant pedaling frequency, of 60 revolutions per minute (rpm) is recommended. Equivalent results are obtained when work rate is increased either continuously (ramp test) or by a uniform amount each minute (1-minute incremental test) until the patient is limited by symptoms (i.e., the person cannot cycle faster than 40 rpm) or is not able to continue safely. The increment size should be set according to the clinical characteristics of the patient in order to obtain approximately 10 minutes of exercise. This may represent incremental rates of 10 to 20 watts per minute in a healthy sedentary subject or less in a patient with COPD. Data to be acquired in a test lasting less than 20 minutes from start to finish should include (1) measurements at rest, (2) 3 minutes of unloaded exercise, (3) incremental exercise (approximately 10 minutes), and (4) 2 minutes of recovery, at least. Standard noninvasive CPET carried out with the subject breathing room air ($F\text{IO}_2 = 0.21$) involves acquisition of breath-by-breath expired O_2 and CO_2 concentrations ($F\text{EO}_2$ and $F\text{ECO}_2$, respectively), work rate, expired airflow, heart rate, and systemic arterial pressure as primary variables. ECG and pulse oximetry tracings should be continuously monitored during the test. It is useful to establish a sense of the patient's exercise-related perceptions during the exercise test and at the point of discontinuation of exercise. Such perceptions should encompass exertion, dyspnea, chest pain, and skeletal muscle effort, with quantification achieved by means of standardized rating procedures (e.g., Borg visual analogue scale).

Proper evaluation of pulmonary gas exchange in patients with lung disease requires assessment of arterial blood gases (Figure 10-4). In such cases, arterial cannulation (preferably of the radial or brachial artery) is needed to obtain partial pressures of respiratory gases ($Pa\text{O}_2$ and $Pa\text{CO}_2$) and to determine $P\text{O}_2(\text{A–a})$. This also provides information on acid-base status (pH, $Pa\text{CO}_2$ and base excess) and allows continuous monitoring of systemic arterial blood pressure during the test. However, although "arterialized venous blood" (e.g., from the dorsum of the heated hand or vasodilated ear lobe) gives good values for $P\text{CO}_2$ and pH, it is not appropriate for $P\text{O}_2$. Furthermore, arterial respiratory blood gas values estimated using expired O_2 and CO_2 profiles or with "transcutaneous" electrodes and pulse oximetry should not be used as indices of arterial $P\text{O}_2$ and $P\text{CO}_2$ during exercise. It is important to recognize that arterial blood sampling immediately after exercise does not provide an adequate assessment of blood gas values at peak exercise. However, although pulse oximetry does not indicate arterial $P\text{O}_2$, it does provide valuable information on oxyhemoglobin saturation during exercise.

If the ergometer used in the CPET is a motor-driven treadmill, then the *Balke protocol* is considered the most appropriate for its simplicity. The speed of the treadmill is kept constant (3 to 3.5 mph) during the protocol while the slope is progressively increased (by 1% to 2% each minute). Of note, $\dot{V}\text{O}_2$peak assessed using treadmill usually is 10% to 15% higher than measurements obtained with a cycle ergometer, owing to a higher exercising muscle mass with the treadmill. Moreover, the assessment of the relationship between oxygen uptake and external work rate is more accurately done with use of a cycle ergometer than a treadmill.

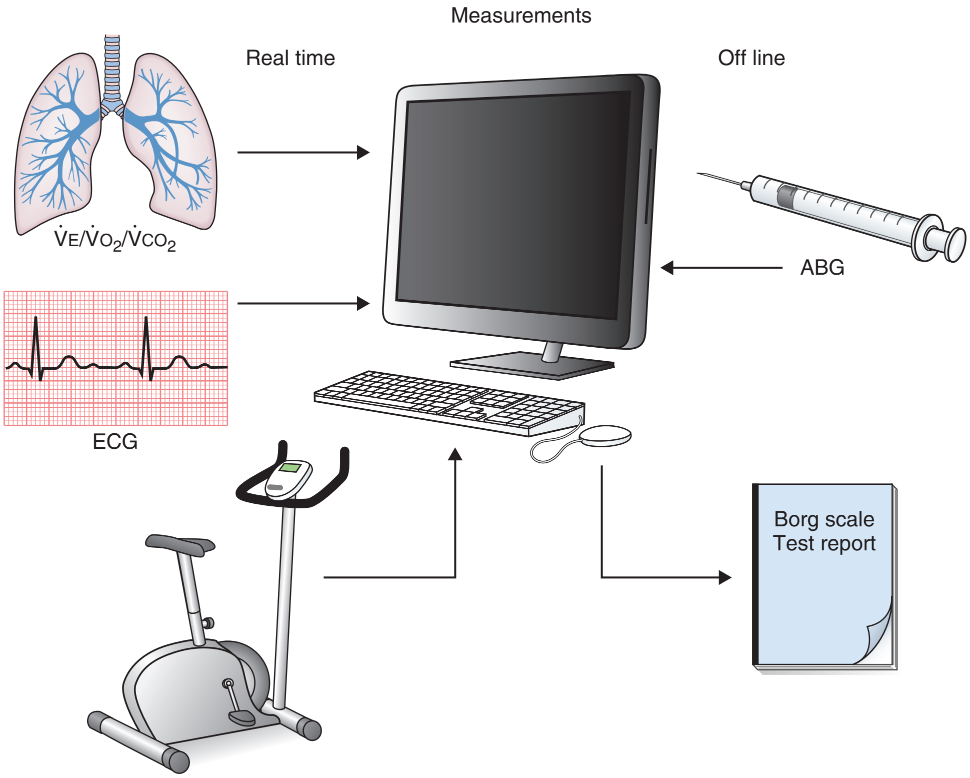

Figure 10-4 Measurements done during a standard incremental cardiopulmonary exercise protocol in the laboratory; see text for further explanation. *ABG*, arterial blood gas [analysis]; *ECG*, electrocardiogram; $\dot{V}\text{CO}_2$, carbon dioxide production; $\dot{V}\text{E}$, minute ventilation; $\dot{V}\text{O}_2$, oxygen uptake.

CONSTANT-WORK-RATE EXERCISE IN THE LABORATORY

Constant-work-rate protocols can result in steady-state responses when work rate is below the critical power (usually up to 60% of maximal). By contrast, a constant work rate of high intensity for the individual subject typically results in continually changing values in most variables of interest. Consequently, attainment of, or failure to attain, a steady-state $\dot{V}O_2$ during a constant-load test can be used to determine if a particular task is sustainable by the patient.

In the clinical setting, high-intensity constant-work-rate exercise (at approximately 75% of $\dot{V}O_2$peak) to exhaustion is a highly reproducible test to assess the effects of an intervention (e.g., bronchodilators, vasodilators, rehabilitation). Moreover, endurance time (time to exhaustion) properly reflects aerobic potential. Alternatively, the use of a high-intensity constant work rate to assess exercise-induced asthma has traditionally been used in the clinical setting, but it might be progressively substituted by a bronchial challenge with mannitol.

During a constant-work-rate protocol, the period of dynamic adjustment (time constant) to a constant-work-rate test provides information regarding the dynamic behavior of lung function, hemodynamics, and tissue O_2 utilization. To date, however, virtually no information is available on the confidence limits, reproducibility, and predictive value of the derived parameters in patient populations. In summary, incremental exercise testing with a cycle ergometer constitutes the standard exercise protocol in the laboratory to assess aerobic capacity and to explore limiting factors. In specific cases in which the effects of an intervention are to be explored, high-intensity, sustainable, constant-work-rate exercise using a cycle ergometer is the protocol of choice. Of note, simple exercise testing outside the laboratory is *not* an acceptable alternative choice to exercise testing in the laboratory; rather, it should be considered a complementary option that constitutes a useful expansion of the potential of clinical exercise testing.

SIMPLE EXERCISE TESTING OUTSIDE THE LABORATORY

Although incremental cycling protocols are designed to facilitate the assessment of the relationship between O_2 uptake and work rate throughout the test, timed-walking tests have important limitations in this regard. The three most important factors determining energy requirements during timed-walking tests are walking speed, ergonomics of the walking, and body weight. Because body weight remains unchanged, the other two factors modulate intrasubject variability of energy requirements during the test. Proportionality between $\dot{V}O_2$ and walking speed supports the contention that walking speed is a key determinant of work rate, together with body weight. The study displayed in Figure 10-5 demonstrates that physiologic responses during

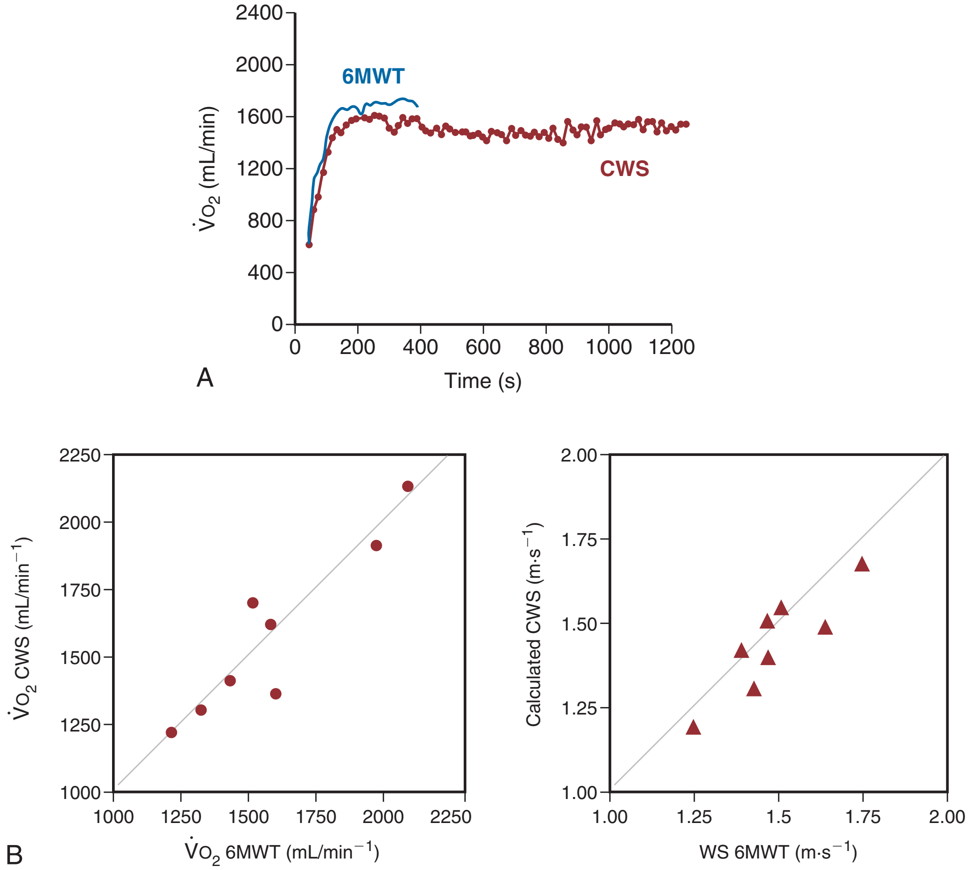

Figure 10-5 Equivalence of oxygen uptake responses for the 6-minute walking test (6MWT) and critical power in patients with chronic obstructive pulmonary disease (COPD). **A,** The upper graph indicates the $\dot{V}O_2$ response in a representative patient during 6MWT, in *blue*, and during timed-walking speed at the critical power (critical walking speed [CWS]), in *red*. **B,** Individual relationships between $\dot{V}O_2$ during CWS (y-axis) and $\dot{V}O_2$ during 6MWT (x-axis) ($r = .93$, $P < .001$) (*left*) and between CWS and walking speed (WS) during 6MWT ($r = .90$, $P < .01$) (*right*). Similar relationships were observed for heart rate and minute ventilation. $\dot{V}O_2$, oxygen uptake. *(From Casas A, Vilaro J, Rabinovich R, et al: Encouraged 6-min walking test indicates maximum sustainable exercise in COPD patients,* Chest *128:55–61, 2005.)*

the 6-minute walking test (6MWT) in patients with moderate to severe COPD are equivalent to those seen in persons walking at critical power (to achieve critical walking speed [CWS]), which corresponded to approximately 90% of maximum $\dot{V}O_2$ in the patients studied. The study seems to indicate that patients with moderate to severe COPD set their walking speed during the test to achieve critical O_2 uptake. The level of $\dot{V}O_2$ achieved at CWS may indicate the integrated response of the systems involved in O_2 transport–O_2 utilization that ultimately determine the highest sustainable level of exercise. These results may constitute the underlying explanation for the high prognostic value of the 6MWT, which, together with its simplicity, applicability, and acceptable reproducibility, prompts its recommendation as the most suitable choice for conventional clinical assessment in COPD, as part of the multidimensional evaluation of disease severity. At present, 6MWT is recognized to add prognostic information useful to the staging of patients with COPD, primary pulmonary hypertension, and congestive heart failure. Results of timed walking tests (e.g., 6MWT) are sensitive to changes after interventions such as inhaled bronchodilators, volume reduction surgery, and pulmonary rehabilitation.

Figure 10-6 and **Table 10-1** compare the physiologic responses with three simple exercise protocols (stair climbing test, incremental shuttle test, and 6MWT) and incremental cycling exercise using a cycle ergometer, all of them carried out by patients with moderate to severe COPD. It is clearly shown that approximately 80% of $\dot{V}O_2$peak was already achieved within the first minute of encouraged stair climbing.

Incremental cycling exercise and incremental shuttle test showed similar $\dot{V}O_2$ profiles (see Figure 10-6 and Table 10-1). At peak exercise, however, incremental cycling showed higher CO_2 output and higher respiratory exchange ratio than with the incremental shuttle test. Likewise, symptom scores also were higher during cycling exercise than for incremental shuttle test. The differences between these two tests could be explained by higher blood lactate levels, hence ventilatory requirements, during incremental cycling compared with timed-walking tests. In the study, $\dot{V}O_2$peak during incremental cycling was similar to $\dot{V}O_2$ at peak incremental shuttle (see Table 10-1), despite the fact that the amount of exercising muscle mass during cycling exercise is significantly smaller than in timed-walking tests and the characteristics of the exercise are different. As described earlier, patient's $\dot{V}O_2$max was observed at exhaustion in most of the exercise protocols carried out in Figure 10-5, irrespective of the amount of exercising muscle mass. A potential explanation for this finding is that the ceiling of whole-body $\dot{V}O_2$ in patients with COPD is defined mainly by the degree of pulmonary impairment and not by the amount of exercising muscle mass.

In summary, despite its well-recognized limitations, simple exercise testing (i.e., with the 6MWT) constitutes a complementary option to laboratory exercise testing in the clinical assessment of patients with chronic respiratory conditions.

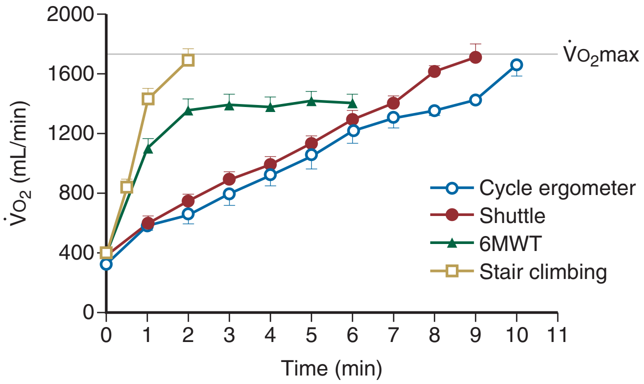

Figure 10-6 Comparison of mean O_2 uptake profiles for eight patients with moderate to severe chronic obstructive pulmonary disease (COPD) during four different clinical exercise protocols (mean ± SEM): incremental cycling (*open circles*), incremental shuttle (*solid circles*), 6MWT-90 (*solid triangles*), and stair climbing (*open squares*). See text for further explanation. *SEM*, standard error of the mean. *(From Casas A, Vilaro J, Rabinovich R, et al: Encouraged 6-min walking test indicates maximum sustainable exercise in COPD patients,* Chest *128:55–61, 2005.)*

Table 10-1 Comparison Among Clinical Exercise Protocols

Test Variable	Stair Climbing (peak)			Incremental Cycling (peak)			Incremental Shuttle (peak)			6MWT-90 (last 3 min)		
Time to exhaustion (s)	88	±	37	546	±	95	465	±	54		—	
$\dot{V}E$ (L/min)	57.7	±	14.1	56.0	±	8.3	48.2	±	10.0	44.2	±	$10.0^{*\dagger}$
$\dot{V}O_2$ (mL/min)	1693	±	256	1661	±	180	1651	±	243	1429	±	$227^{*\dagger}$
$\dot{V}CO_2$ (mL/min)	1749	±	359	1687	±	151	1473	±	$273^{\ddagger}$	1273	±	$220^{*\dagger}$
RER	1.03	±	0.12	1.02	±	0.06	0.89	±	$0.09^{\ddagger\S}$	0.89	±	$0.05^{*\dagger}$
Heart rate (beats/min)	131	±	18	133	±	15	130	±	14	128	±	13
SaO_2 (%)	91%	±	5%	91%	±	4%	91%	±	2%	90%	±	5%
Borg scale score—dyspnea	8 [3-10]			7 [3-9]			$5\ [1\text{-}9]^{\ddagger\S}$			$4\ [1\text{-}7]^{*\dagger}$		
Borg scale score—leg fatigue	5 [3-8]			6 [3-8]			$4\ [1\text{-}5]^{\ddagger}$			$4\ [1\text{-}7]^{*}$		

Results expressed as means ± SD except for Borg's scores that are expressed as mean and range.
*6MWT-90 vs incremental cycling: $\dot{V}O_2$ ($p < 0.01$); $\dot{V}CO_2$ ($p < 0.01$); $\dot{V}E$ ($p < 0.01$); Dyspnea ($p < 0.01$); Leg ($p < 0.05$)
†6MWT-90 vs stairs climbing: $\dot{V}O_2$ ($p < 0.005$); $\dot{V}CO_2$ ($p < 0.01$); $\dot{V}E$ ($p < 0.01$); Dyspnea ($p < 0.05$)

§Shuttle vs stair climbing: RER ($p < 0.05$); Dyspnea ($p < 0.05$)
6MWT-90, 6-minute walking test on a 90-meter course; *RER*, respiratory exchange ratio; *SaO_2*, blood oxygen saturation; *$\dot{V}CO_2$*, carbon dioxide production; *$\dot{V}E$*, minute ventilation; *$\dot{V}O_2$*, oxygen uptake.

TESTING PROCEDURES

Cardiopulmonary exercise testing should be conducted only by adequately trained personnel with a basic knowledge of exercise physiology. Technicians familiar with normal and abnormal responses during exercise and trained in cardiopulmonary resuscitation (CPR) should be present throughout the test. CPET should be performed under the supervision of a physician who is appropriately trained to conduct exercise tests and in advanced CPR. The degree of subject supervision needed during the test can be determined by the clinical status of the subject being tested and the type of exercise protocol. Although presence of the physician during the test is preferable, if this is not possible, a physician must be readily available to respond as needed. Additional roles for the physician are in the evaluation of the patient immediately before the test and in the interpretation of the results.

PATIENT PREPARATION

At the time of scheduling, the patient should be instructed to adhere to the usual medical regimen; he or she should not eat for at least 2 hours before the test, avoid cigarette smoking and caffeine, and dress appropriately for the exercise test. A brief history (with detailed inquiries about the medications) and physical examination should be done to rule out contraindications to testing. Results of recent resting-state pulmonary function tests—as a minimum, forced spirometry—should be available for patients in whom pulmonary disease is suspected.

On the patient's arrival at the CPET laboratory, a detailed explanation of the testing procedure and equipment should be provided, outlining risks and potential complications as described further on. The patient needs to become familiar with the equipment. If the treadmill is used, time is provided for several practice trials of starting and stopping until the patient feels confident. If the cycle ergometer is used, the seat height is adjusted so that the subject's legs are almost completely extended when the pedals are at the lowest point and the cycling rhythm is practiced.

Before the test, the ECG electrodes are carefully placed and secured after preparing the skin to ensure good recordings (if necessary, the area of the electrode placement can be shaved). A sphygmomanometer cuff is placed on the upper arm. The mouth piece and nose clip are then tried and the position adjusted until a comfortable position has been established. The patient is informed that it is acceptable to swallow with the mouth piece in place and that any unexpected difficulty should be signaled by a "thumb down" gesture. The patient is advised to point to the site of discomfort if chest or leg pain is experienced.

During the test, the patient is encouraged to carry on with a regular pedaling cadence (60 cycles/minute). Monitoring for symptoms and degree of discomfort is performed periodically (in accordance with the safety precautions described next). Good communication with the patient throughout the whole procedure increases the subject's confidence and promotes good effort. During recovery, the patient is told to continue to pedal, without external work load (or walk at a slow pace on the treadmill), for at least 2 minutes, to prevent fainting and to accelerate lactate removal. At the point of discontinuation of exercise, after the patient has removed the mouthpiece, the physician should ascertain the symptoms (type and intensity graded on the Borg scale) that prompted the patient to stop exercise. If the test does not provide adequate diagnostic information because of premature termination or inadequate cooperation of the patient, it should be repeated after a rest period of 30 to 45 minutes.

Although CPET may be considered to be a safe procedure, risks and complications have been reported. Good clinical judgment should be paramount in defining indications and contraindications for exercise testing. Cardiac (bradyarrhythmias, ventricular tachycardia, myocardial infarction, heart failure, hypotension, and shock) and noncardiac (musculoskeletal trauma, severe fatigue, dizziness, fainting, body aches) complications of CPET have been reported. Consequently, during the test, laboratory personnel should be alert to any abnormal event. The indications to stop the test must be clearly established and known by all persons involved in testing. These indications include symptoms and signs such as acute chest pain, sudden pallor, loss of coordination, mental confusion, extreme dyspnea, ECG changes including depression of the ST segment by more than 0.1 mV (values are less specific in female patients) and T wave inversion, sustained ventricular tachycardia, and fall in systolic blood pressure either below the resting value or about 20 mm Hg below its highest value during exercise testing. Relative indications to stop the test are occurrence of polymorphic and/or frequent premature ventricular beats and hypertension (blood pressure above 250 mm Hg systolic and above 130 mm Hg diastolic).

If the exercise test has been stopped for one of the aforementioned reasons, the patient should be monitored in the CPET laboratory until symptoms or ECG changes have completely cleared. Admission to the hospital for longer observation or more often for complementary investigation will be necessary in very rare cases. If necessary, intensive care can be administered on site. Full CPR equipment should be available in the CPET laboratory.

INTERPRETATION STRATEGIES

For the greatest diagnostic potential and impact on the clinical decision-making process, exercise testing should rely not on the utility of any one individual measurement, although some are obviously more important than others, but rather on their integrated use. Identification of a cluster of responses characteristic of different diseases often is useful. The major portion of the interpretation strategy is focused on CPET results generated during maximal, symptom-limited, incremental exercise testing. This is currently the most popular albeit not the exclusive protocol in use. Figure 10-7 displays data obtained in a normal subject performing cycle ergometry, for which the ergometer used an "assist" to provide an actual zero-watt work rate at "unloaded" pedaling. The four plots labeled *A* to *D* on this figure depict, in addition to the peak $\dot{V}O_2$, the variables commonly used to provide an indirect estimation of the lactate threshold. That is, they allow identification of the O_2 uptake at the transition between moderate to heavy-intensity exercise. Plot *E*—O_2 uptake versus work rate—reflects the exercise efficiency and the limits of exercise tolerance of the subject. Plot *F*—ventilation versus CO_2 output—and plot *H*—tidal volume versus ventilation—characterize aspects of the ventilatory response during submaximal and maximal exercise. Some investigators, however, find the relationship between $\dot{V}E$ and $\dot{V}O_2$ during such tests to be useful. Finally, plot *G*—heart rate (and O_2 pulse) versus O_2 uptake—is informative with respect to the characteristics of the hemodynamic response to exercise. The next step is to choose adequate reference values to establish patterns of normal or abnormal response.

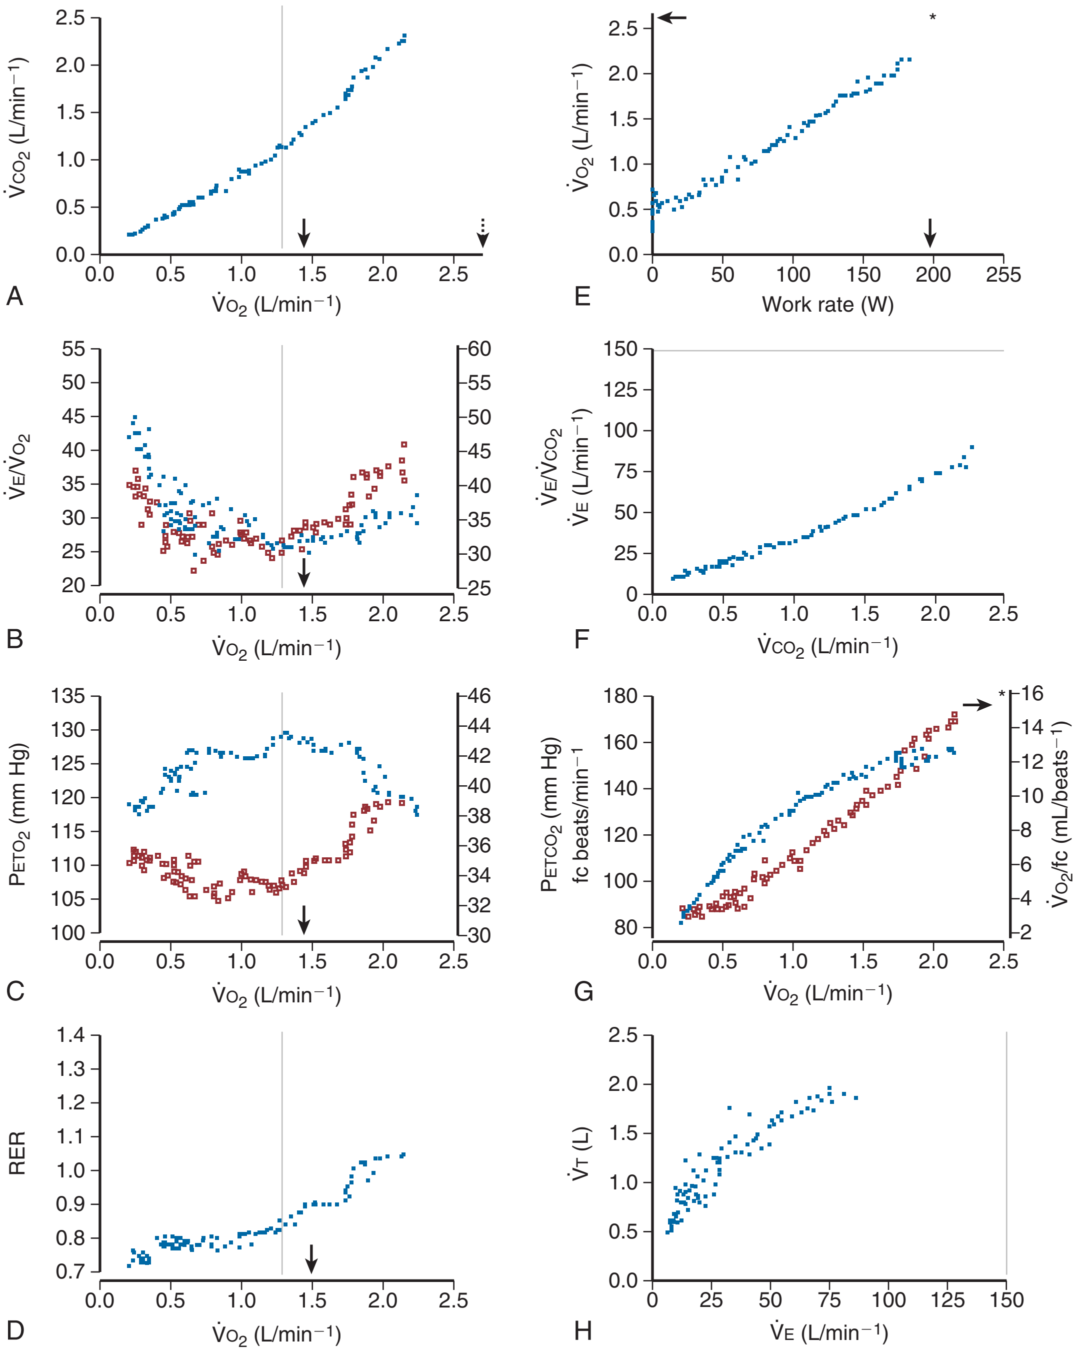

Figure 10-7 Exercise performance in a healthy sedentary male subject. The basic plots for interpretation of results of cardiopulmonary exercise testing are depicted. In **A** to **D**, in addition to peak oxygen uptake ($\dot{V}O_2$), the variables commonly used to indirectly estimate lactate threshold (LT) are given. That is, the $\dot{V}O_2$ at which the transition from moderate- to high-intensity exercise occurs is identified (*vertical dashed line*). The expected LT for a healthy subject (55% of predicted $\dot{V}O_2$peak) is indicated in **A** to **D** by a *small arrow with a solid shaft.* Predicted $\dot{V}O_2$peak is indicated in **A** by a *small arrow with a dashed shaft.* In **E,** $\dot{V}O_2$ versus work rate reflects the exercise efficiency and limits of exercise tolerance of the subject, with the expected peak exercise performance represented by the *asterisk.* **F** and **H** indicate minute ventilation ($\dot{V}E$) versus carbon dioxide uptake ($\dot{V}CO_2$) and tidal volume ($\dot{V}T$) versus $\dot{V}E$, respectively; these two plots describe the characteristics of the ventilatory response during submaximal and peak exercise. Finally, **G** presents characteristics of the hemodynamic response to exercise, with estimated peak heart rate represented by the *asterisk* and predicted peak O_2 pulse by the *arrow. P_{ETO_2}*, end-tidal pressure of oxygen; *P_{ETCO_2}*, end-tidal pressure of carbon dioxide; *RER*, respiratory exchange ratio. *(From Roca J, Rabinovich R: Clinical exercise testing. In Gosselink R, Stam H, editors: Lung function testing,* Eur Resp Mon *31:146–165, 2005.)*

SUMMARY

The chapter provides an overview of the clinical use of exercise testing in patients with chronic pulmonary disease. The roles and complementary benefits of both laboratory testing and simple exercise protocols are analyzed, with emphasis on the pivotal role of the O_2 transport–O_2 utilization system in determining maximum O_2 uptake in an integrative manner. Also described are the systemic responses to exercise in healthy subjects, both athletes and sedentary persons, and in patients with common pulmonary diseases. Finally, basic principles of exercise testing and interpretation of the results are reviewed.

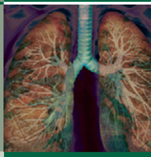
Section 2
DIAGNOSTIC TECHNIQUES



Chapter 11
Bronchoscopy

Anil Vachani • Andrew R. Haas • Daniel H. Sterman

The first bronchoscopy was performed by Gustav Killian in 1897. Technologic advances during the next century facilitated development of bronchoscopy as a pivotal diagnostic and therapeutic tool in pulmonary medicine. Although a number of bronchoesophagologists contributed to refinement of the technique based on the use of a rigid instrument, the advent of flexible fiberoptic bronchoscopy, pioneered by Shigeto Ikeda in 1967, opened new horizons to clinicians. At the end of the 1980s, the development of videobronchoscopy brought significant improvements in imaging quality and data storage. Subsequently, several other bronchoscopic applications have been developed for both diagnostic and therapeutic purposes.

This chapter presents an overview of bronchoscopy and related techniques. After a general discussion of bronchoscopy and associated instrumentation, applications of the technique and patient preparation are considered, and safety factors, contraindications, and complications of bronchoscopy are reviewed. Finally, specific indications for diagnostic and therapeutic bronchoscopy are discussed.

TYPES OF BRONCHOSCOPY AND GENERAL INSTRUMENTATION

RIGID BRONCHOSCOPY

The initial bronchoscope, developed by Killian and further optimized by Chevalier Jackson, was a rigid metal tube that permitted either spontaneous or mechanical ventilation. Over the decades, rigid bronchoscopes of various lengths and sizes that are adaptable for diverse applications in children and adults have become available. Although the flexible bronchoscope has to a large extent replaced the rigid scope for most diagnostic and some therapeutic indications, rigid bronchoscopy still has vital therapeutic applications.

Both rigid and flexible modern systems are equipped with optic capabilities for airway observation alone. With the rigid scope, various types of telescopic rods, equipped with circumferential illumination, permit direct and magnified visualization (Figure 11-1). Specially designed telescopes allow viewing not only directly forward but also at oblique and lateral angles. Various diagnostic and therapeutic instruments can be inserted through the rigid scope while the patient remains ventilated. Rigid bronchoscopy allows a number of therapies such as laser photoresection, endobronchial stents, balloon dilation, electrocautery, argon beam coagulation, and cryotherapy to be performed safely and effectively. Perhaps most important, a rigid scope can be used to “core out” large bulky airway tumors and to dilate central airway strictures and areas of stenosis very effectively and efficiently. In addition, the rigid bronchoscope also can be used for the passage of a flexible scope, which may be necessary for dealing with tortuous airways or distal lesions.

FLEXIBLE BRONCHOSCOPY

The flexible scope is used in most bronchoscopic procedures. Although initial flexible bronchoscopes used fiberoptic systems, most such instruments now use a charge-coupled device (CCD) camera at the tip that allows transmission of digital images to a monitor. The main advantages of flexible scopes include their ease of manipulation and greater flexibility, allowing a more complete tracheobronchial tree evaluation than with rigid bronchoscopy, and a less challenging path to expertise, permitting more rapid acquisition of skills (favorable learning curve), for use of these devices (Figure 11-2).

Flexible scopes vary in size, ranging from ultrathin devices allowing for endoscopy in infants and neonates to larger, adult-sized therapeutic scopes. The working channel of the bronchoscope can be used for aspiration of secretions and to accommodate various diagnostic or therapeutic accessories. Four main diagnostic tools have been developed for use during bronchoscopy in order to obtain diagnostic material: bronchoalveolar lavage (BAL), brushings, forceps biopsy, and needle aspiration (Figure 11-3). Since the inception of bronchoscopy more than 100 years ago, these diagnostic modalities have been hampered by limited ability to ensure direct localization of pulmonary nodules, masses, infiltrates, or lymph nodes. However, recent technologic developments in navigational technology and endoscopic ultrasound imaging have improved the ability to localize these lesions, to obtain diagnostic tissue, and to prevent unnecessary surgical intervention. The use of endobronchial ultrasound probes is discussed in Chapter 12.

Biopsy forceps are available in various sizes and may have smooth or serrated edges. In some models, a small central needle is present between the cups for anchoring and stabilization. Smooth cup edges also may reduce tissue trauma and the concomitant bleeding risk. Lesions not accessible to direct forceps biopsy can be approached with a bronchial brush. This device consists of a rigid central wire surrounded by bristles of various size and shape. Repeated brush movement against the adjacent tissue produces minor trauma but enables collection of cellular specimens for cytologic or microbiologic analysis. Uncontaminated specimens from the lower respiratory tract can be collected with a brush protected by an additional sheath and tip. Needles of various sizes can be used to obtain both cytologic and histologic material from transbronchial lesions (e.g., lymph nodes, mediastinal masses) or from endobronchial and submucosal lesions.

PATIENT PREPARATION AND MONITORING DURING BRONCHOSCOPY

All patients undergoing bronchoscopy should undergo a complete prebronchoscopy evaluation, including a medical history, physical examination, and chest imaging (Box 11-1). Although routine laboratory tests are not required, each evaluation should be individualized on the basis of patients' underlying conditions and the diagnostic and therapeutic procedures planned.

Most flexible bronchoscopy procedures are performed after patient sedation with any of a variety of pharmacologic agents. Most frequently, a combination of a short-acting benzodiazepine (e.g., midazolam) and a narcotic agent (e.g., fentanyl) are used for bronchoscopic sedation. Local anesthesia of the upper airway, larynx, and tracheobronchial tree is achieved with inhaled or bronchoscopically instilled lidocaine. Although rigid bronchoscopy initially was performed with use of minimal anesthesia and later with the patient under general anesthesia, the recent trend has been to perform the procedure with patients either breathing spontaneously or ventilated with a jet ventilator, often under total intravenous anesthesia (TIVA) with agents such as propofol and remifentanil. With appropriate monitoring, good oxygenation and adequate ventilation can be ensured.

Success of bronchoscopy, whether diagnostic or therapeutic, depends in large part on proper preparation of the patient, including relief of anxiety, muscle relaxation, cough suppression, and adequate anesthesia. Time spent in achieving these goals will be justified in reducing the complication risk and in increasing the ease of procedural performance.

TECHNIQUE

The flexible bronchoscope usually is inserted nasally, orally, or through an endotracheal tube or a tracheotomy stoma. When necessary, it also can be inserted through a rigid bronchoscope. The nasal route often is preferred because the nasal passage

Box 11-1 Prebronchoscopy Checklist

1. Is there an appropriate indication for bronchoscopy?
2. Has there been a previous bronchoscopy?
3. If the answer to the preceding question is yes, were there any problems or complications?
4. Does the patient (and close relative[s] if patient is unable to communicate) fully understand the goals, risks, and complications of bronchoscopy?
5. Does the patient's medical history (allergy to medications or topical anesthesia) and present clinical condition pose special problems or predispose to complications?
6. Are all the appropriate tests completed and the results available?
7. Are the premedications appropriate and the dosages correct?
8. Does the patient require special consideration before bronchoscopy (e.g., corticosteroids for asthma, insulin for diabetes mellitus, or prophylaxis against endocarditis) or during bronchoscopy (e.g., supplemental oxygen, extra sedation)?
9. Is the plan for postbronchoscopy care appropriate?
10. Are all the appropriate instruments and personnel available to assist during the procedure and to handle the potential complications?

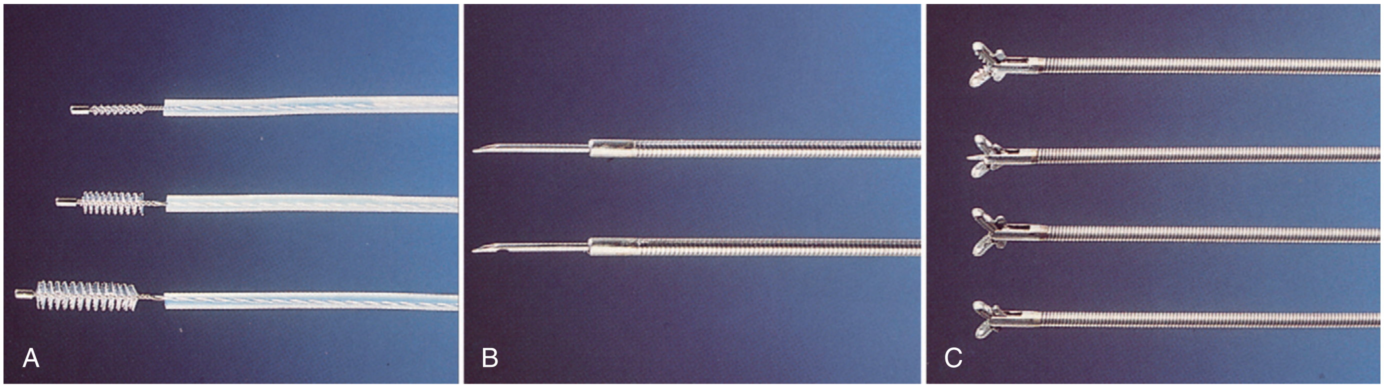

Figure 11-3 Bronchoscopy brushes (**A**), needles (**B**), and biopsy forceps (**C**) are available in various sizes and types. **B,** Biopsy needles shown are the standard 21 G aspiration needle *(top)*, and needle with side port *(bottom)*, allowing for cell collection from the side and tip of the needle. **C,** Biopsy forceps shown *(top to bottom)* are alligator-jaw, alligator-jaw with needle, elongated, and standard cup forceps. *(Courtesy Olympus Corporation of the Americas, Center Valley, Pennsylvania.)*

often provides some resistance against the scope and allows for somewhat better control during airway inspection. When the oral route is used, a "bite block" should be inserted to prevent the patient from biting and damaging the scope. Supplemental oxygen should be administered to prevent hypoxemia, which is fairly common during bronchoscopy, particularly in patients with underlying lung disease.

The bronchoscopic evaluation should begin with a thorough examination of the upper airway, as well as assessment of the integrity and function of the larynx. The vocal cords should be examined for any abnormalities, such as polyps or tumors, and evaluated for paralysis during phonation.

Once the upper airway inspection is completed, a systematic evaluation of the lower respiratory tract should be performed, beginning with an evaluation of the trachea and then all segmental bronchi. Airway integrity should be assessed including thorough evaluation of the mucosal and delineation of carinal size and shape for any abnormalities with special attention paid to changes in dynamic airway caliber during either relaxed breathing or forced expiration and coughing.

It is important to distinguish among normal anatomy, anatomic variations without clinical significance, and frankly pathologic conditions. These considerations have important implications regarding potential diagnostic and therapeutic approaches. For example, an abnormal branching of a bronchus may be of no clinical significance. On the other hand, such an abnormality could explain frequent infections caused by impaired ventilation and drainage of the affected area. Bronchoscopy is particularly useful in documenting posttraumatic or postsurgical changes in bronchial integrity, such as bronchial rupture, tracheoesophageal or bronchopleural fistulas, or anastomotic complications after reconstructive or lung transplantation surgery. Similarly, bronchoscopy can be used to document tracheal injuries occurring in critically ill patients after prolonged intubation or tracheostomy. Although tracheal injuries have decreased in incidence over the past decade, tracheal stenosis, tracheomalacia, and tracheoinnominate artery fistula are still clinically important complications that must be considered and identified. Complications specific to the use of percutaneous tracheotomy include protrusion of ruptured cartilage into the tracheal lumen and extraluminal tracheostomy tube placement.

A thorough evaluation of the mucosal surface is an important part of the bronchoscopic examination. The most common abnormality is a change in mucosal coloration, with prominent hypervascular areas seen in patients with chronic bronchitis. The presence of granulation tissue can be due to reaction to a foreign body. Inflammatory mucosal reactions, although not very characteristic, should raise the possibility of mycobacterial infection, nonspecific viral and nonviral infections, and other granulomatous diseases, such as sarcoidosis (Figure 11-4). Mucosal ulcerations are more characteristic of Wegener granulomatosis or malignancy. Loss of the usual mucosal luster and presence of a roughened surface may be early signs of an infiltrative or neoplastic process.

The trachea and bronchi are surrounded by mediastinal and parenchymal structures. Developmental or pathologic changes in these organs may be noted during bronchoscopic evaluation. An enlarged goiter or thymus can compress upper airways, resulting in airflow obstruction. Lymphadenopathy may produce structural changes, including widening of the main carina caused by subcarinal involvement, and compression of other bronchi—as, for example, in the right middle lobe syndrome. Peribronchial calcified lymph nodes may erode through the bronchial wall, resulting in broncholith formation. Such lesions are potential sources of obstruction, infection, or hemoptysis.

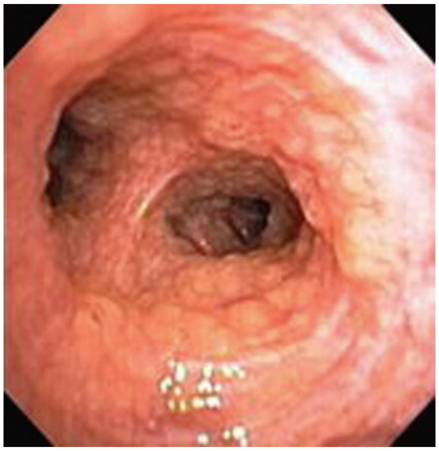

Figure 11-4 Endobronchial sarcoidosis. Bronchoscopy demonstrates edematous airways with a "cobblestone" appearance, often seen in endobronchial sarcoidosis. *(Courtesy Meeta Prasad, MD.)*

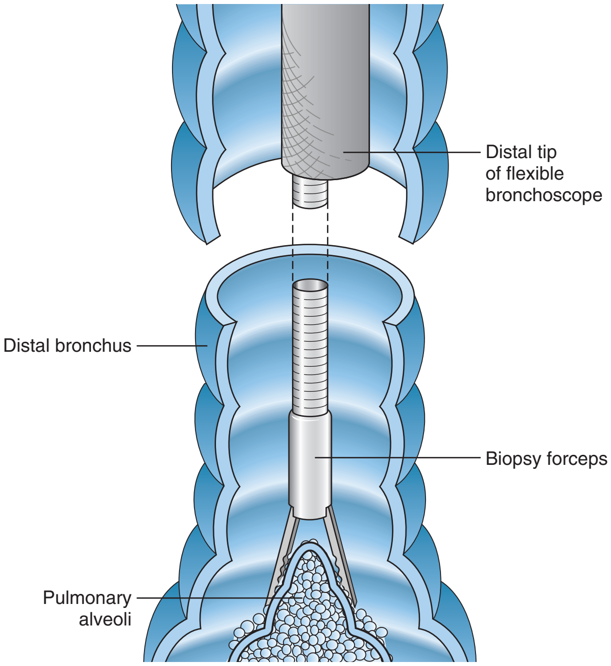

Figure 11-5 The mechanism by which bronchoscopic lung biopsy is obtained. The biopsy forceps pinches off the lung tissue located between two branches of terminal bronchi.

After the bronchoscopic inspection of the airways and surrounding structures has been performed, appropriate samplings should be obtained from the abnormalities identified. Aspirated secretions can be sent for microbiology cultures to determine the offending organism in cases of infection or suspected infection. Endobronchial lesions can be sampled with cytology brushes, biopsy forceps, or needles. Bronchoscopic lung biopsy can be performed for either focal abnormalities or diffuse lung diseases (Figure 11-5). For small or focal lesions, fluoroscopy helps guide peripheral forceps placement and improves the diagnostic yield of biopsies for focal lesions. The use of fluoroscopy also may obviate the need for routine chest radiography after transbronchoscopic lung biopsy. In the case of diffuse lung disease, such as sarcoidosis, use of

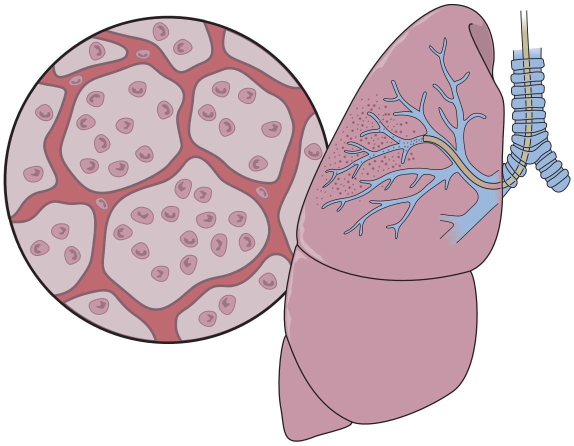

Figure 11-6 Bronchoalveolar lavage (BAL) is performed by wedging the tip of the flexible bronchoscope in the segmental bronchus leading to the parenchymal abnormalities detected by imaging techniques. Normal saline, 100 to 150 mL, in aliquots of 10 to 50 mL, is instilled through the bronchoscope channel and suctioned back into a container for analysis.

fluoroscopy has *not* been demonstrated to improve the diagnostic yield of transbronchial biopsies. Fluoroscopy is useful, however, in providing information regarding the proximity of the forceps to the pleura and in more rapidly establishing the diagnosis of complications (e.g., pneumothorax). Transbronchoscopic needle aspiration (TBNA) and biopsy (TBNB) permit sampling of peribronchial lymph nodes. These transbronchial approaches provide cost-effective diagnostic modalities with less risk and a lower complication rate than with mediastinoscopy (see Chapter 17).

Bronchoalveolar lavage (BAL) is a useful and generally well-tolerated bronchoscopic sampling technique (**Figure 11-6**). BAL is safe, even in critically ill patients, when biopsy or brushing methods are not recommended because of bleeding risk. Normal saline solution, devoid of any bacteriostatic material, is instilled into distal air spaces through the "wedged" flexible scope and then aspirated through the instrument's suction channel or from a sterile trap. The fluid collected can be analyzed for gross appearance to detect possible alveolar hemorrhage. The fluid also may be subjected to a variety of tests, depending on the clinical circumstances: microbiologic testing, specific cytologic analysis and cell count, immunologic parameters, presence of various biochemical mediators related to pathologic processes, tissue markers, polymerase chain reaction (PCR) assay, electron microscopy, flow cytometry, and DNA probes. The diagnostic yield of BAL very much depends on specific patient characteristics, the underlying pathologic process, and technical factors.

INDICATIONS FOR DIAGNOSTIC BRONCHOSCOPY

Many potential indications have been recognized for both diagnostic and therapeutic bronchoscopy, many of which are listed in Boxes 11-2 and 11-3. The most common reason for bronchoscopy remains the evaluation of a lung mass or nodule. Other major indications include investigation of pulmonary infiltrates, evaluation of opportunistic infections in immunocompromised persons, investigation of hemoptysis, assessment for suspected foreign body, and treatment of airway complications related to neoplasms in the tracheobronchial tree. Some of these indications are discussed next.

Box 11-2 Indications for Diagnostic Bronchoscopy

- Cough
- Hemoptysis
- Wheeze and stridor
- Abnormal chest radiograph
- Pulmonary infections
- Diffuse interstitial lung disease
- Intrathoracic lymphadenopathy or mass
- Bronchogenic carcinoma
- Metastatic carcinoma
- Esophageal and mediastinal tumors
- Foreign body in the tracheobronchial tree
- Tracheobronchial strictures and stenoses
- Airway burns
- Thoracic trauma
- Vocal cord paralysis
- Bronchopleural fistula
- Tracheoesophageal fistula
- Assessment of endotracheal tube placement or complications
- Assessment of airway anastomosis

Box 11-3 Indications for Therapeutic Bronchoscopy

- Hemoptysis
- Atelectasis
- Foreign body removal
- Neoplasms of the tracheobronchial tree
    - Bronchoscopic removal
    - Laser therapy
    - Argon plasma coagulation
    - Brachytherapy
    - Stent placement
- Strictures and stenoses
    - Bronchoscopic dilation
    - Laser therapy
    - Balloon dilation
    - Stent replacement
- Lung lavage (pulmonary alveolar proteinosis)
- Bronchoscopic drainage
    - Lung abscess
    - Mediastinal or bronchogenic cysts
- Thoracic trauma
- Endotracheal tube placement

CHRONIC COUGH

Chronic cough remains one of the most common reasons for patients to seek medical attention. Although flexible bronchoscopy frequently is used in the evaluation of chronic cough, its role has not been clearly defined, particularly in patients without other indications for the procedure. The routine use of bronchoscopy for investigation of chronic cough has a diagnostic yield of less than 5%. When chronic cough is associated with localizing signs and symptoms, such as hemoptysis, a focal wheeze, or abnormalities on an imaging study, a specific diagnosis by bronchoscopy is much more likely. In nonsmokers with normal findings on chest imaging, the most likely causes of cough are asthma, gastroesophageal reflux disease, and rhinitis. Bronchoscopy can be considered if these etiologic entities have been effectively ruled out by a combination of empirical treatment and diagnostic testing, including the use of spirometry, bronchoprovocation tests, sinus imaging, and esophageal pH probes.

HEMOPTYSIS

Hemoptysis is a common clinical sign and one of the most frequent indications for bronchoscopic evaluation. The most common causes of scant hemoptysis include chronic bronchitis, tuberculosis, and bronchiectasis, whereas massive hemoptysis, usually defined as bleeding greater than 200 mL in a 24-hour period, most often is due to tuberculous cavities, lung cancer, mycetomas, or lung abscess (see Chapter 24). Bronchoscopy can be of help in localizing the site and cause of bleeding. Although the timing of the procedure should be dictated by clinical circumstances, studies have shown that early bronchoscopy (within 48 hours) is more likely to demonstrate active bleeding and allow for the determination of the bleeding site. Chest imaging, with either chest radiograph or computed tomography (CT) scan, can assist in bleeding site localization and, in stable patients without massive hemoptysis, should precede bronchoscopy. In patients with a normal appearance on the chest film, the prevalence of malignancy is approximately 5%, which in most cases is visible by CT scan. The yield of bronchoscopy in patients with normal findings on CT scan is extremely low, and a conservative approach consisting of observation and serial imaging should be considered. Beyond its role as a diagnostic tool, bronchoscopy often can be used to perform various therapeutic procedures in patients experiencing hemoptysis (see further on).

PULMONARY INFECTIONS

Bronchoscopy is a useful technique in the diagnosis of pulmonary infections, allowing for the collection of respiratory samples for evaluation with special stains and culture. Respiratory samples can be collected by one or more techniques, including bronchial washing, BAL, protected specimen brushing (PSB), bronchoscopic lung biopsy, and TBNA (Table 11-1).

Bronchoscopy is not indicated for the diagnosis of community-acquired pneumonia, which is currently treated empirically with appropriate antibiotic therapy. Bronchoscopy is likely to be useful in cases of nonresolving pneumonia, ventilator-associated pneumonia (VAP), or new infiltrates in immunocompromised patients. Nonresolving pneumonia is defined as lack of improvement or worsening of symptoms despite a minimum of 10 days of antibiotic therapy or failure of radiographic abnormalities to resolve after 2 to 3 months. The causes of nonresolving pneumonia are myriad and include inadequate antibiotic therapy, resistant or highly virulent organisms, impaired host defenses, obstructing endobronchial lesions, or a noninfectious cause. Although controversial, bronchoscopy should be considered in these patients.

Ventilator-Associated Pneumonia

Ventilator-associated pneumonia is defined as a pneumonia occurring more than 48 hours after intubation and initiation of mechanical ventilation. Intubated patients are at increased risk for pneumonia because of the impairment in mucociliary clearance caused by the endotracheal tube. These patients also are often on broad-spectrum antibiotics and therefore are at greater risk for infections with resistant organisms. Recent guidelines support the use of either a quantitative or semiquantitative strategy (e.g., tracheal aspirates) in the diagnosis of VAP. Two quantitative bronchoscopic methods that are particularly useful are BAL and PSB. The threshold for VAP diagnosis with PSB is 10^3 colony-forming units (CFU) per milliliter. PSB seems to have higher specificity than sensitivity for the presence of VAP—a positive result greatly increases the likelihood that pneumonia is present. For quantitative BAL, a threshold of 10^4 or 10^5 CFU/mL is used for VAP diagnosis. The detection of VAP by quantitative BAL culture has a sensitivity of 40% to 90% and a specificity of 45% to 100%. Because a larger proportion of lung parenchyma is sampled with BAL, this may be a better method than PSB for VAP diagnosis. Techniques

Table 11-1 Bronchoscopic Techniques and Applications in Respiratory Infections

Technique	Clinical Applications
Bronchoscopy—visualization	Assessment of mucosal, intraluminal, and extraluminal pathology Evaluation of endobronchial tuberculosis, mycoses, viral vesicles (in AIDS) Evaluation of invasive tracheobronchial aspergillosis, candidiasis, and other conditions Follow-up evaluation of endobronchial disease (e.g., tuberculosis)
Bronchial washing	Culture for identification of mycobacteria, fungi, and viruses and *Pneumocystis* smears
Bronchoalveolar lavage	Culture for identification of all organisms, especially mycobacteria, fungi, cytomegalovirus and other viruses and *Pneumocystis* smears
Protected specimen brushing	Culture for aerobic and anaerobic bacteria
Nonprotected bronchial brushing	Stains and culture for identification of mycobacteria, fungi, *Pneumocystis*, and viruses
Endobronchial biopsy	Mucosal lesions caused by mycobacteria, fungi, protozoa Removal of obstructing lesions responsible for infection (e.g., tumor, foreign body) Drainage of lung abscess; piecemeal removal of mycetomas (aspergillomas, other fungus balls)
Bronchoscopic needle aspiration	Stains and culture of extrabronchial lymph node specimens for identification of mycobacteria and fungi Drainage of bronchogenic cyst and instillation of sclerosing agent
Bronchoscopic lung biopsy	Stains and culture for identification of all organisms, especially *Pneumocystis jiroveci*, mycobacteria, and fungi Detection of parasitic lung infections
Rigid or flexible bronchoscopy—therapeutic intervention	Insertion of tracheobronchial prosthesis (stent) to overcome airway obstruction caused by intrinsic stenosis (posttuberculosis or fungal) or extrinsic compression caused by mediastinal fibrosis due to histoplasmosis

incorporating molecular testing in addition to microbiologic cultures are currently being evaluated.

Mycobacterial Infections

In cases in which pulmonary tuberculosis is suspected, the initial diagnostic evaluation should consist of serial examination of sputum for the presence of acid-fast bacilli (AFB) in stained smears. Ideally, induced sputum samples should be obtained. If sputum study results are negative and tuberculosis is still suspected, bronchoscopy with BAL and biopsy should be performed. Both induced sputum collection and bronchoscopy should be performed with appropriate infection control precautions to minimize the risk of nosocomial transmission. A bronchoscopy may cause the patient to produce sputum for several days afterwards; these specimens also should be collected and analyzed, if possible. The utility of bronchoscopy varies widely in the literature, with reported diagnostic yields of 50% to 95%. The yield in patients with miliary tuberculosis, in whom sputum smears frequently are negative, is approximately 70%. Bronchoscopy also is useful in tuberculosis manifesting as an endobronchial lesion or with mediastinal and hilar adenopathy, in which case diagnostic tissue can be obtained with TBNA (**Figure 11-7**). The yield of diagnostic procedures, including bronchoscopy, can be expected to improve as newer interferon release assays and nucleic acid amplification techniques are incorporated into everyday practice (see Chapter 31).

Infections in Immunocompromised Patients

Pulmonary infection in immunocompromised patients is a frequent complication and represents an important contributor to mortality. Such infections are increasingly common, reflecting the expanding use of aggressive chemotherapeutic regimens and the ever-increasing number of solid organ and hematopoietic stem cell transplantations. The differential diagnosis of pulmonary infiltrates is broad in scope; however, most cases are caused by infectious agents, including bacterial, fungal, viral, and mycobacterial pathogens. Bronchoscopy is the most commonly used diagnostic procedure in these patients and should be performed as early as possible, because a delay in diagnosis of longer than 5 days has been shown to significantly increase mortality among these patients.

The sensitivity of bronchoscopy varies, depending on the immunocompromised population studied and the specific etiologic disorder. In non–human immunodeficiency virus (HIV)-infected patients, the yield of BAL for *Pneumocystis jiroveci* is approximately 80%, compared with a greater than 95% yield observed in HIV-seropositive patients. This difference is due to the much lower organism load present in non–HIV-seropositive subjects. Although empirical therapy often is initiated in patients suspected of having *P. jiroveci* infection, bronchoscopy should be performed in most cases to confirm the diagnosis. Bronchoscopic lung biopsy may increase the diagnostic yield of BAL for diagnosis of *P. jiroveci* infection, particularly in the non–HIV-infected population. Bronchoscopy also has a high diagnostic yield for cytomegalovirus (CMV); however, because CMV cultures from BAL are not specific, the diagnosis of CMV pneumonia should be limited to patients with pathologic evidence of CMV infection demonstrated by the presence of CMV inclusion bodies on BAL or biopsy. Although bronchoscopy also is useful for the diagnosis of aspergillosis—the sensitivity is approximately 50%—the disease often is peripheral and patchy and thus is not easily diagnosed by BAL or bronchoscopic biopsy. Overall, in immunocompromised patients with infiltrates, bronchoscopy is successful in establishing the diagnosis in as many as 80% of cases.

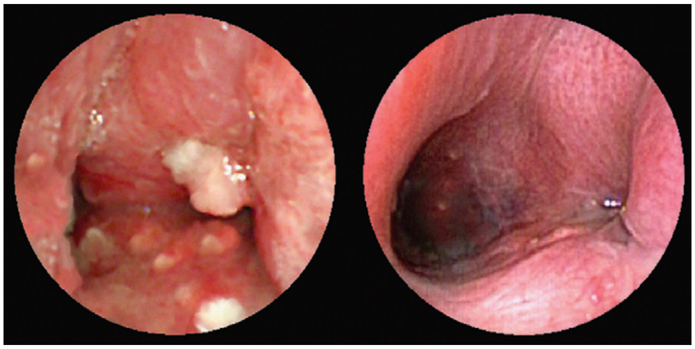

Figure 11-7 Endobronchial tuberculosis involving distal trachea and main bronchi. Image on the *left* was obtained before chemotherapy; the posttherapy appearance is shown in image on the *right*. Endobronchial tuberculosis is commonly mistaken for bronchogenic carcinoma.

Human Immunodeficiency Virus Syndrome

The introduction of highly active antiretroviral therapy (HAART) led to a sharp decline in the incidence of opportunistic infections in HIV-infected patients. Nevertheless, infectious complications remain one of the most common indications for bronchoscopy in this population. *Pneumocystis* pneumonia remains the most frequent serious opportunistic infection in HIV-seropositive patients. Bronchoscopy with BAL remains the preferred diagnostic procedure for this disease, although in select centers, the use of sputum induction has had a relatively high diagnostic yield and may avoid the need for bronchoscopy. As previously mentioned, bronchoscopic lung biopsy may increase the diagnostic yield of BAL. Empirical therapy often is initiated in patients with suspected *Pneumocystis* infection; such therapy can impair the diagnostic yield of BAL if the procedure is not performed within 24 hours. In patients receiving pentamidine prophylaxis, the diagnostic yield is decreased unless the upper lobes are sampled. Several PCR assays have been tested on BAL fluid, induced sputum, and oral wash specimens; these generally have been more sensitive but less specific than traditional microbiologic methods.

Bronchoscopy also plays an important diagnostic role in HIV-positive patients with infections caused by mycobacteria, including tuberculosis, atypical bacterial pneumonias, and various fungal infections. Kaposi sarcoma, caused by human herpesvirus type 8 (HHV8), can manifest with violaceous endobronchial plaques that typically occur at airway bifurcations; pulmonary parenchymal involvement is characterized by lymphangitic infiltration of tumor, leading to the development of nodules and masses.

BRONCHOGENIC CARCINOMA

Diagnosis

Bronchoscopy most commonly is performed in the evaluation of patients with suspected lung cancer. It remains the most commonly used modality for the diagnosis of bronchogenic carcinoma and plays an important role in staging of the disease as well. Centrally located lesions generally can be approached using flexible bronchoscopy with minimal risk. Bronchogenic carcinoma of the central airways can manifest as exophytic mass lesions with partial or total bronchial lumen occlusion, as peribronchial tumors with extrinsic compression of the airway, as submucosal tumor infiltration, or as some combination of these entities. The mucosal abnormalities seen with peribronchial tumors or with submucosal infiltration often are subtle—the airways should be examined closely for characteristic changes such as erythema, loss of bronchial markings, and nodularity of the mucosal surface.

Central lesions usually are sampled with a combination of bronchial washes, bronchial brushings, and endobronchial biopsies. The yield of endobronchial biopsy is highest for exophytic lesions, with a diagnostic yield of approximately 80%. Attempts should be made to obtain the biopsy specimens from areas of the lesion that seem viable. Endobronchial needle aspiration (EBNA) to obtain a "core" biopsy from centrally located tumors should be considered, particularly if the lesion appears necrotic. For submucosal lesions, EBNA can be performed by inserting the needle into the submucosal plane at an oblique angle, and in patients with peribronchial disease causing extrinsic compression, the needle should be passed through the bronchial wall into the lesion. For all of these indications, EBNA has been shown to increase the diagnostic yield of conventional sampling methods.

Peripheral lesions usually are sampled with a combination of bronchial wash, brushes, transbronchial biopsy, and TBNA. The diagnostic yield of bronchoscopy for peripheral lesions depends on a number of factors, including lesion size, the distance of the lesion from the central airways, and the relationship between the lesion and bronchus. The yield of bronchoscopy for lesions smaller than 3 cm varies, ranging from 14% to 50%, compared with a diagnostic yield of 46% to 80% when the lesion is larger than 3 cm. The presence of a bronchus sign on chest CT predicts a much higher yield of bronchoscopy for peripheral lung lesions. In these cases, fluoroscopic guidance should be used to ensure proper positioning of the diagnostic accessory (**Figure 11-8**).

Several newer methods have been developed for the evaluation of peripheral lung lesions, including endobronchial ultrasound (EBUS) imaging (see Chapter 12) and navigational bronchoscopy. The first U.S. Food and Drug Administration (FDA)-approved navigational system, the Electromagnetic Navigation Bronchoscopy (EMN) system (InReach System, SuperDimension, Inc., Minneapolis, Minnesota), uses an electromagnetic board to generate a magnetic field around the patient, a magnetic sensor probe, an extended working channel, and three-dimensional integration of CT scan reconstruction and flexible bronchoscope position (**Figure 11-9**). In essence, this navigational system works on the same triangulation principle as for a global positioning system and allows the bronchoscopist to direct the flexible scope through the airways to the target. Several studies have demonstrated EMN diagnostic sensitivity to range between 67% and 74%, independent of lesion size. Studies also show improved diagnostic yield with the combination of EMN with mini-ultrasound probes for sampling of small peripheral lesions. Beyond standard diagnostic utilization, novel navigational applications have been demonstrated in targeted therapeutic delivery, such as EMN-guided stereotactic radiosurgery fiducial placement or implantation of radiotherapy monitoring devices.

Several new navigational bronchoscopy systems have recently been introduced (LungPoint System, Broncus Technologies, Mountain View, California; SPiN Drive System, Veran Medical Technologies, St. Louis, Missouri; Bf-NAVI, Cybernet Systems, Tokyo, Japan). With LungPoint and Bf-NAVI, virtual bronchoscopic images are displayed adjacent to the actual procedural video, allowing an electronic pathway to be overlaid onto the endoscopic image. An image of the target lesion can be overlaid on the virtual bronchoscopy and actual video images for localization during biopsy.

Navigational bronchoscopy systems may be limited in general application by their high capital cost and training necessary for optimal utilization. These newer navigational technologies have not yet been rigorously evaluated but appear to offer improvements in diagnostic yield beyond that attainable with standard approaches. The lack of randomized, comparative studies with this technology raises concerns about its role relative to traditional or ultrasound-guided approaches.

Staging

Bronchoscopy is an important modality for establishing lung cancer stage. In patients with potentially resectable tumors, a thorough airway examination helps confirm the absence of a

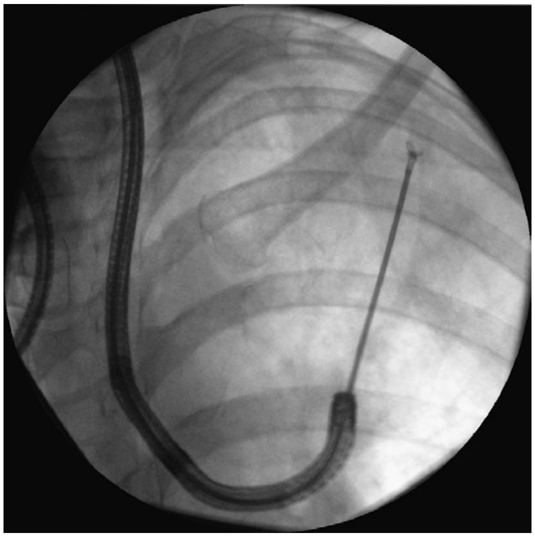

Figure 11-8 Bronchoscopic lung biopsy with fluoroscopic guidance. Fluoroscopy assists in the placement of the diagnostic accessory for investigation of small or focal lesions and improves the diagnostic yield.

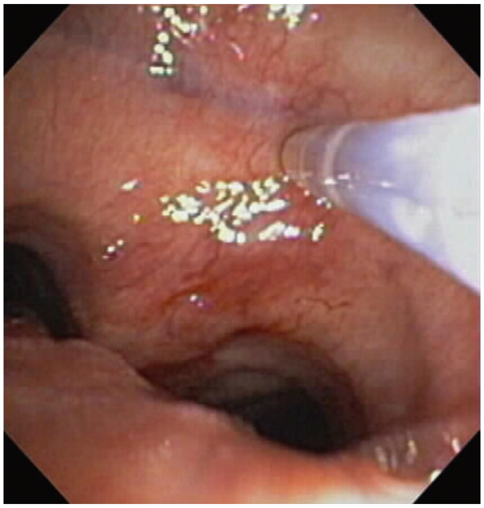

Figure 11-10 Transbronchial needle aspiration (TBNA) of a precarinal lymph node.

concomitant, radiographically occult lesion. For lesions that involve the central airways, it is important to document the extent of disease and the degree of involvement of "mainstem" bronchi and main carina.

TBNA has emerged as a valuable tool for the investigation of enlarged or metabolically active mediastinal lymph nodes (**Figure 11-10**). The procedure is particularly useful for evaluation of patients who are marginal or poor surgical candidates; in these patients, more invasive approaches, such as mediastinoscopy or mediastinotomy, may be obviated. TBNA has proved particularly useful with the use of *rapid onsite evaluation* (ROSE), whereby a cytopathologist working in or near the bronchoscopy suite can evaluate obtained specimens in real time (see Chapter 14).

Several precautions should be observed during the performance of TBNA to minimize the risk of false-positive results. The bronchoscope should be introduced into the bronchial tree without suction, and TBNA should be performed before distal airway inspection and before any other sampling procedures. N3 nodes should be sampled first, followed by N2 and N1 nodes.

Because of a relatively high false-negative rate (approximately 25%), a negative result with standard TBNA should prompt consideration of more invasive staging methods (i.e., mediastinoscopy). A positive result on TBNA is more likely with significant adenopathy on CT scanning, endoscopically visible tumors, subcarinal lymph nodes larger than 2 cm in diameter, or an abnormal-appearing carina. The use of image guidance with TBNA, such as ENB or EBUS, is promising and may provide higher diagnostic yields. This is particularly true of EBUS-TBNA.

Molecular and Immunohistochemical Assessment

In the past several years, the advent of targeted agents has improved survival rates in both recurrent and metastatic non–small cell lung cancer (NSCLC). It is increasingly apparent that both histologic analysis and molecular typing will be necessary to determine appropriate therapy for patients with NSCLC. For example, patients with activating mutations in the endothelial growth factor receptor (*EGFR*) gene are more likely to respond to EGFR inhibitors, whereas tumors with *EML4-ALK* translocations have recently been shown to improve with crizotinib therapy. Because a majority of patients with NSCLC are diagnosed by bronchoscopy with either transbronchial biopsy or cytology specimens, mutation testing often is limited by insufficient material. In addition to molecular typing, advanced histologic analysis is increasingly important, because the choice of specific cytotoxic agents now relies on distinguishing among the various NSCLC histologic subtypes. For example, pemetrexed appears to have preferential activity in adenocarcinoma over that in squamous cell or large cell carcinoma. These considerations require careful attention to sampling technique: adequate tissue must be obtained at diagnostic flexible bronchoscopy for subtype classification and molecular testing.

DIFFUSE LUNG DISEASES

A wide range of acute and chronic pulmonary disorders are capable of causing diffuse interstitial lung diseases with more than 150 distinct clinical entities. These processes include infection, neoplasm, pulmonary edema, alveolar hemorrhage, alveolar proteinosis, occupational lung diseases, drug-induced disease, and various types of interstitial lung disease. In general, patients with diffuse lung disease should undergo high-resolution CT (HRCT) scanning, which helps to narrow the differential diagnosis and in some cases is virtually diagnostic of certain disorders. In many cases, it is still necessary to obtain samples for cytologic and histologic evaluation to confirm a specific diagnosis and to help exclude other possible disorders.

The most common bronchoscopic procedures used to help establish the diagnosis in diffuse lung disease are BAL and bronchoscopic lung biopsy. The findings on HRCT can be used to determine the best location for BAL or lung biopsy. In truly diffuse disease, the right middle lobe and the lingula are the best locations for BAL; with these sites, ease of access and good fluid retrieval are typical. BAL should be performed using a total of 100 to 200 mL of saline instilled in multiple aliquots. It is important to obtain a reasonable sampling of the alveolar spaces for the necessary cellular analysis.

Certain findings on BAL can be suggestive or virtually diagnostic of a number of interstitial lung diseases (**Table 11-2**). It is important that the BAL findings be correlated with the clinical and HRCT findings. For example, specific characteristics of the freshly retrieved lavage fluid can support the diagnosis of alveolar hemorrhage, pulmonary alveolar proteinosis, microlithiasis, or lipid aspiration. In patients with suspected eosinophilic pneumonia, a high eosinophil count is diagnostic, and in cases of pulmonary Langerhans cell histiocytosis, BAL flow cytometry should be performed to evaluate for CD1at cells.

In a number of disorders, BAL findings may be suggestive, but additional diagnostic procedures probably will be required. Such diseases include sarcoidosis, hypersensitivity pneumonitis, and organizing pneumonia. Bronchoscopic lung biopsy should be considered in situations in which the diagnosis has not been established by HRCT and BAL. In many situations, bronchoscopic lung biopsy can establish the diagnosis and avoid the need for surgical lung biopsy (**Box 11-4**). For example, with pulmonary sarcoidosis, the diagnosis usually is established by a combination of BAL and biopsy findings. The BAL can be used to exclude the presence of tuberculosis and fungal infections and can demonstrate the characteristic high $CD4^+/CD8^+$ ratio seen in sarcoidosis, whereas bronchoscopic biopsy specimens may demonstrate the classic finding of noncaseating granulomas. In general, bronchoscopic biopsy should be performed in several affected areas, and at least five or six specimens should

Table 11-2 Bronchoalveolar Lavage (BAL) in Diffuse Interstitial Disease

Disorder	BAL Fluid Findings
Pulmonary hemorrhage	Progressive increase in RBCs with sequential aliquots; hemosiderin-laden macrophages
Pulmonary alveolar proteinosis (PAP)	Grossly cloudy, milky appearance; positive PAS stain
Eosinophilic pneumonia	Eosinophilia >25%
Sarcoidosis	$CD4^+/CD8^+$ ratio >3.5
Pulmonary Langerhans cell histiocytosis	CD1at cells >5%
Hypersensitivity pneumonitis	Lymphocytosis; decreased $CD4^+/CD8^+$ ratio
Lipid pneumonia	Oily material that layers above aqueous phase
RBILD/DIP	Brown macrophages

DIP, diffuse interstitial pneumonia; *PAS*, periodic acid–Schiff; *RBCs*, red blood cells; *RBILD*, respiratory bronchiolitis–associated interstitial lung disease.

Box 11-4 Pulmonary Disease in Which Bronchoscopic Lung Biopsy Provides High Diagnostic Yield

Diffuse alveolar cell carcinoma
Pneumocystis jiroveci infection
Mycobacterial infection
Mycoses
Cytomegalovirus infection
Pneumoconioses
Lung transplant rejection

be taken. The sensitivity for diagnosis of sarcoidosis is only approximately 60% to 70%, and many patients require further invasive testing, such as surgical lung biopsy. Recently, the use of EBUS-TBNA has been extended to the diagnosis of sarcoidosis, especially in patients with mediastinal and hilar adenopathy. The addition of TBNA to transbronchial biopsy can provide the diagnosis in more than 85% of sarcoidosis cases.

Bronchoscopy has a limited role in the diagnosis of idiopathic pulmonary fibrosis (IPF). A nonspecific increase in levels of neutrophils, eosinophils, and, less commonly, lymphocytes has been documented in BAL fluid. Bronchoscopic biopsy is limited by the small size of the specimen obtained and the lack of histologic preservation because of mechanical crushing of the tissue. In the cases in which the diagnosis of IPF is probable or definite on the basis of clinical and HRCT criteria, bronchoscopy (and surgical lung biopsy) is not required. In situations in which the HRCT findings are “nondiagnostic,” bronchoscopy should be considered to evaluate for the presence of other potential etiologic disorders. If the specific diagnosis cannot be established on the basis of BAL and bronchoscopic biopsy findings, surgical lung biopsy should be considered.

SAFETY FACTORS IN BRONCHOSCOPY

Bronchoscopy is a specialized procedure that requires extensive training. Familiarity with both the physiology and anatomy of the airways and other intrathoracic structures is essential. As with any other procedure, analysis of each patient’s risk-benefit ratio will help reduce the complication rate. Mild sedation, muscular relaxation, and anterograde amnesia increase patient cooperation and permit quicker and less traumatic procedures. During and shortly after the procedure, appropriate monitoring of hemodynamic parameters (heart rate, rhythm, and blood pressure), oxygenation, and ventilation all contribute to the safety of bronchoscopy. Last but not least, knowledge and proper application of safety standards and maintenance procedures will decrease bronchoscopy cost.

In general, bronchoscopy is a safe and well-tolerated procedure, with few absolute contraindications. Of note, bronchoscopy should not be performed in patients with severe refractory hypoxemia, unstable cardiac disease, or life-threatening arrhythmias. Bronchoscopic lung biopsy should be performed with caution in patients with moderate to severe pulmonary hypertension or refractory coagulopathy.

COMPLICATIONS OF BRONCHOSCOPY

Complications generally are due to inappropriate patient preparation before bronchoscopy, effects of local or general anesthesia, and manipulation of various instruments. Appropriate training and experience of the bronchoscopist and supporting team are crucial to limiting the complication rate.

ANESTHESIA AND RELATED BLOOD GAS ABNORMALITIES

The major complications of diagnostic bronchoscopy include respiratory depression, hypoventilation, hypotension, and syncope. Risk is significantly increased among elderly persons and in patients with serious concomitant illnesses, including cardiovascular disease, chronic pulmonary disease, renal and hepatic dysfunction, seizures, and altered mental status. In patients with underlying organ dysfunction, doses of sedative agents and topical anesthetics should be adjusted as appropriate. Conscious sedation techniques using short-acting benzodiazepines (e.g., midazolam) offer significant anterograde amnesia but less muscle relaxation and have reduced the incidence of potentially dangerous hypotension and respiratory depression.

Inadequate topical anesthesia potentiates coughing, gagging, and patient discomfort and increases the risk of injury during bronchoscopy. However, topical anesthetics such as lidocaine, the most frequently used agent, are absorbed systemically through the respiratory mucosa, increasing the risk of cardiac or central nervous system toxicity. These complications are more likely to occur in patients with underlying low cardiac output, hepatic dysfunction, and oropharyngeal candidiasis. Another, less frequent complication of excessive lidocaine use is methemoglobinemia and tissue hypoxia.

Introduction of the bronchoscope frequently results in a decrease in oxygenation and in hypoventilation with demonstrable increases in $Pa\text{CO}_2$. In patients with underlying chronic lung disease, severe hypoxemia may occur, triggering life-threatening cardiac arrhythmias. All patients should, therefore, be monitored continuously (electrocardiogram, blood pressure, O_2 saturation, and, if indicated, expiratory CO_2 concentration) from initiation of topical anesthesia through recovery from conscious sedation. Use of supplemental oxygen during the procedure should be routine.

FEVER AND INFECTION

A variety of pulmonary procedures, including bronchoscopy, have been reported to cause transient bacteremia. However, data demonstrating a link between bronchoscopy and increased risk of infective endocarditis are lacking. For patients at high risk for this condition (e.g., those with prosthetic valves, history of previous endocarditis, or congenital heart disease), the American Heart Association does not recommend the use of prophylactic antibiotics before bronchoscopy unless the procedure involves incision of the respiratory tract mucosa. Antibiotic prophylaxis should be considered, however, in high-risk patients who are undergoing a procedure to treat an active infection, such as drainage of an abscess.

Transient fever after bronchoscopy is fairly common and generally does not require any therapy. However, persistent fever in the setting of progressive radiographic infiltrates necessitates antibiotic therapy. The incidence of fever is increased in elderly persons, in patients with underlying chronic pulmonary disease or documented endobronchial obstruction, and in those undergoing bronchoscopic interventions for malignancy. The incidence of fever and extension of pulmonary infiltrates increase with the volume of BAL fluid and the total number of pulmonary segments lavaged. The incidence of postbronchoscopic infection is higher in immunocompromised persons and in patients with chronic suppurative lung disease, such as cystic fibrosis.

PNEUMOTHORAX

Pneumothorax after transbronchial biopsy occurs in approximately 4% of cases, even when the procedure is done under fluoroscopic guidance (Figure 11-11). The impact of fluoroscopy on the incidence of pneumothorax remains controversial. Uncontrolled studies have not found a difference in the incidence of pneumothorax after transbronchial biopsy when performed with and without fluoroscopy.

The incidence of pneumothorax is increased, however, in immunocompromised persons. This probably is due to the increased risk of pneumothorax associated with *Pneumocystis* infection. The risk also is elevated in mechanically ventilated patients, with peripheral lung biopsy, and in the presence of bullous lung disease. The risk of pneumothorax does not seem to be related to the size of the bronchoscopic biopsy forceps. In case of a significant pneumothorax, a chest tube should be inserted immediately to avoid oxygen desaturation and/or pathophysiologic changes in oxygen tension.

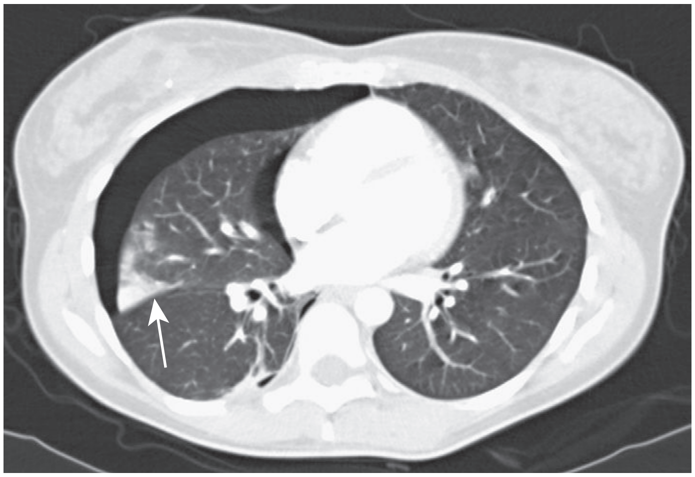

Figure 11-11 Computed tomography (CT) image demonstrating a pneumothorax of the right lung that developed after transbronchial lung biopsy. An area of focal hemorrhage in the lateral right upper lobe (*white arrow*) as a result of biopsy also can be seen.

HEMORRHAGE

One of the most frequently reported complications related to bronchoscopy is hemorrhage. Patients with uremia or with underlying bleeding disorders, especially those caused by platelet dysfunction or thrombocytopenia, have an increased risk of bleeding during bronchoscopy. Bronchoscopic lung biopsy should not be performed if the platelet count is less than 50,000/μL, and aggressive interventional procedures (laser therapy, bronchoplasty, or stent placement) probably are safe only with platelet counts greater than 75,000/μL. Manipulation of the bronchoscope, mechanical trauma, vigorous suctioning, endobronchial brushing and biopsy may result in bleeding during bronchoscopy. In one large series, the overall rate of bleeding after transbronchial biopsy was 4.7%, although the risk of severe bleeding (defined as the need for a bronchus blocker, application of fibrin, critical care admission, or blood transfusion) was less than 1%. Hemorrhage also can occur with inadvertent perforation of pulmonary vessels during transbronchial needle aspiration or biopsy.

SPECIAL BRONCHOSCOPIC TECHNIQUES

ULTRATHIN BRONCHOSCOPY

Bronchoscopes with small external diameters (less than 3 mm), otherwise known as ultrathin bronchoscopes, were developed to deal with specific clinical situations, such as performing bronchoscopy in pediatric patients, investigating peripheral lung lesions, and evaluating tracheobronchial stenoses. The external diameter of traditional bronchoscopes generally is 5 to 6 mm, and these devices cannot easily examine beyond fourth- to fifth-order bronchi in adults. The use of ultrathin bronchoscopes with small working channels allowing for BAL and the use of a cytology brush have demonstrated promise in the diagnosis of peripheral lung lesions. The newest generations of ultrathin scopes have larger channels that can accommodate forceps and larger cytology brushes.

VIRTUAL BRONCHOSCOPY

Virtual bronchoscopy (VBS) is a novel radiographic reconstruction technique that exploits the versatility of helical (spiral) CT by transforming axial CT data into simulated three-dimensional intraluminal views of the airways. This form of perspective rendering has benefited enormously from continued advances in computing technology and currently is capable of providing images that in many ways mimic those obtained during conventional bronchoscopy (Figure 11-12). Although VBS has yet to find its place in routine clinical practice, it has nonetheless proved useful in the evaluation and management of a wide range of pulmonary diseases and conditions involving the tracheobronchial tree, including bronchogenic carcinoma, benign airway stenoses, tracheobronchomalacia, lung transplantation, and bronchiectasis. With this technique, which provides the bronchoscopist with a "virtual camera" inside the patient's tracheobronchial tree, images and perspectives can be obtained and procedures can be planned before conventional bronchoscopy is undertaken. Specific advantages include examination of airways distal to a completely occluded bronchus, retroflexion of the bronchoscope, and en face views. Current limitations of VBS include its inability to adequately characterize mucosal abnormalities, identify subtle submucosal disease, or visualize small endobronchial lesions. Obviously, however, VBS can never completely replace conventional bronchoscopy because it does not allow biopsy or therapeutic intervention.

AUTOFLUORESCENCE AND NARROW BAND IMAGING

The development of *autofluorescence bronchoscopy* (AFB) has improved the detection of dysplasia, carcinoma in situ, and invasive carcinoma of the central airways. AFB systems rely on the principle that infiltrating tumors disturb the fluorescence characteristics of normal tissue. Fluorophores, substances responsible for fluorescence, are variously concentrated within organs and may change according to prevailing conditions. When the bronchial tree is illuminated with blue light (442 nm in wavelength), subepithelial fluorophores within normal tissues emit light with a higher fluorescence intensity than that observed for pre-neoplastic or neoplastic lesions, especially in the green light emission spectrum. Reasons for the weaker green fluorescence in dysplasia, carcinoma in situ, and microinvasive carcinoma include epithelial thickening, tumor hyperemia, and reduced fluorophore concentrations. Thus, the intensity of the emitted light is weaker, and observed light shifts to the red spectrum.

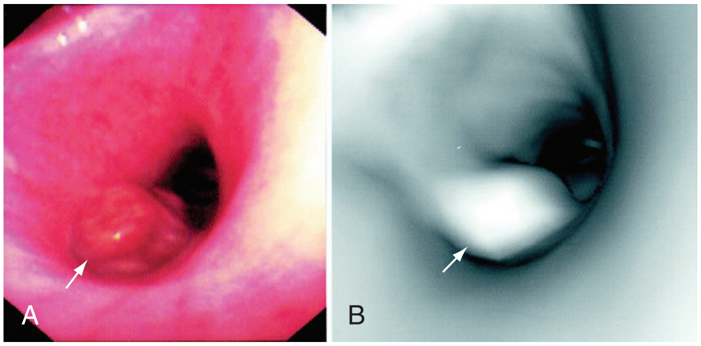

Figure 11-12 Endoluminal lesion obstructing the superior segment of the left lower lobe in a patient with metastatic melanoma. The images of this lesion (*arrow*) were obtained by flexible bronchoscopy (*top left*, **A**) and by virtual bronchoscopy (*top middle*, **B**). *(From Finkelstein SE, Schrump DS, Nguyen DM: Comparative evaluation of super high-resolution CT scan and virtual bronchoscopy for the detection of tracheobronchial malignancies,* Chest *124:1834–1840, 2003.)*

Several recent studies have evaluated the utility of AFB as a screening tool for dysplasia or carcinoma of the central airways in comparison with *white light bronchoscopy* (WLB). These studies have included patients at high risk for such pathology (e.g., those with a history of asbestos exposure, smokers), with known or suspected lung cancer, and after surgical resection for lung tumors. Although the sensitivity for detecting high-grade dysplasia or carcinoma in situ was increased two- to six-fold on average, AFB has limited specificity. Furthermore, no accepted algorithm has emerged for management of the lesions identified by AFB, and the question of whether screening bronchoscopy improves cancer survival remains unanswered. An additional important consideration is the significant interobserver variability documented among AFB endoscopists and histopathologists.

Narrow band imaging (NBI) uses a unique filter to select light wavelengths that preferentially are absorbed by hemoglobin, thereby permitting superior microvasculature detection. Because angiogenesis preferentially occurs in dysplastic and neoplastic lesions, NBI may identify early dysplastic lesions better than WLB or AFB. Studies suggest similar sensitivity between AFB and NBI, but improved NBI specificity for detecting abnormal lesions. Although current clinical applications for AFB and NBI in the general pulmonary population are limited, they may play an important role in future risk stratification, prognostication, and chemoprevention trials in high-risk patients.

OPTICAL COHERENCE TOMOGRAPHY

Optical coherence tomography (OCT) is the optical ultrasound analogue whereby near-infrared light transit time and reflection are used rather than sound waves and provides a macroscopic optical cross-sectional view of hollow organs. By using light instead of sound waves, OCT overcomes two major ultrasound limitations in the lung: (1) the inability to image through air and (2) poor spatial resolution. OCT resolution is between 4 and 20 nm, which is approximately 25 times higher than that of other modalities. In the airway, dysplastic, invasive cancer, or inflammatory changes appear to have unique OCT image patterns (Figure 11-13). The ability of OCT to provide

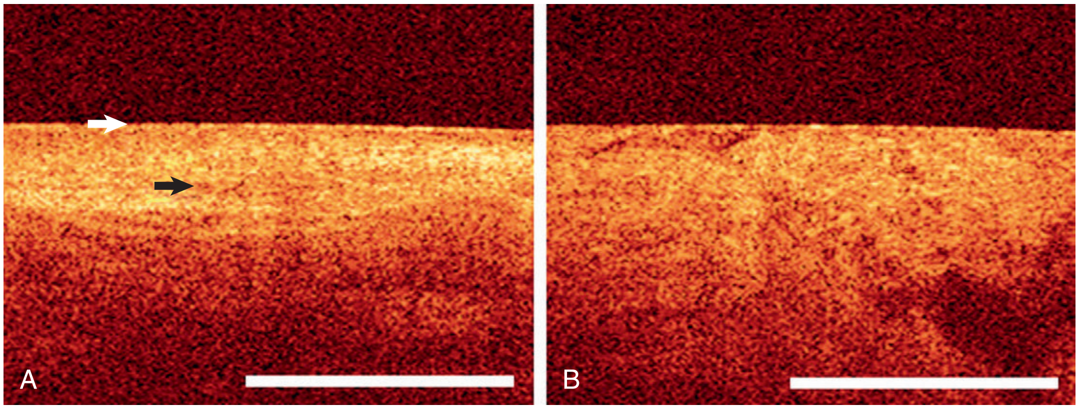

Figure 11-13 Optical coherence tomography images of bronchial mucosa in a patient with small cell carcinoma. **A,** Normal bronchial mucosa in uninvolved area of lung. Layers of epithelium (*white arrow*) and lamina propria (*black arrow*) can be seen. **B,** Within the tumor area, loss of identifiable microstructures is evident. The scale bars are 1 mm. *(From Ross RG, Kinawewitz GT, Fung KM, et al: Optical coherence tomography as an adjunct to flexible bronchoscopy in the diagnosis of lung cancer: a pilot study,* Chest *138:984–988, 2010.)*

an "optical biopsy" with information about microinvasive airway lesion evolution, airway wall remodeling in obstructive lung diseases, or interstitium alterations in idiopathic interstitial pneumonia (IIP) without the risk of tissue biopsy could provide a valuable bronchoscopic tool. Such data may provide diagnostic information, but more important, longitudinal evaluation in an individual patient may allow therapeutic tailoring in the future.

FIBERED CONFOCAL FLUORESCENCE MICROSCOPY

Fibered confocal fluorescence microscopy (FCFM) is a modification of confocal microscopy that allows imaging of thin-section biologic specimens by replacing the microscope's objective with a flexible fiberoptic miniprobe that can be introduced through a flexible bronchoscope. This technology does not rely on light reflectance, as in OCT, but rather is based on cellular and tissue autofluorescence on laser excitation. The predominant source of airway wall autofluorescence is the subepithelial elastin fibers, and alterations in this elastin network can be detected in microinvasive and invasive proximal airway lesions. FCFM can image alveolar and acinar elastin fiber alterations and alveolar macrophage accumulation in patients who smoke, compared with nonsmoking patients. Therefore, although available data are limited, this technology may have evolving applications in diagnosis and monitoring of therapeutic interventions in a variety of parenchymal lung diseases, including obstructive lung diseases, sarcoidosis, IIP, and microinvasive malignant lesions.

THERAPEUTIC BRONCHOSCOPY TECHNIQUES

Since the introduction of bronchoscopy, the technique has been used not only for observation and diagnostic purposes but also for treatment of airway disorders.

RIGID BRONCHOSCOPIC DEBULKING OR BALLOON DILATATION

The ideal tool for rapid reestablishment of airway patency in endoluminal obstruction is the rigid bronchoscope. Rigid bronchoscopes have beveled tips, which are ideal for "coring through" large airway tumors and for dilating strictures, and they have large internal diameters, which facilitates débridement of tumors, evacuation of clots, simultaneous insertion of multiple instruments, and concomitant ventilation. Despite advances in other adjunctive endoscopic techniques, rigid bronchoscopic recanalization remains the treatment of choice for life-threatening tracheobronchial obstruction.

Balloon dilation has become an attractive alternative to dissection with a blunt rigid bronchoscope in less urgent cases of obstruction caused by malignant tumors and benign strictures. High-pressure balloons of various lengths and diameters commonly were used in the past. There are now balloons designed specifically for tracheobronchial use that are expandable to specific diameters by application of defined positive pressure. These are inserted through the bronchoscope working channel under direct vision or fluoroscopic guidance. The balloon, filled with saline or radiopaque contrast media, is inflated at the site of interest until the desired diameter is attained. This technique often is used in combination with bronchoscopic thermal treatments (laser, argon plasma coagulation, electrocautery) and tracheobronchial stent placement for the treatment of airway stenosis (**Figure 11-14**).

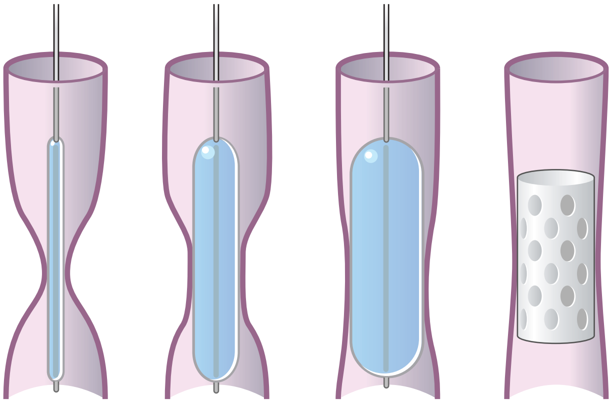

Figure 11-14 Diagrammatic representation of bronchoscopic balloon dilatation of tracheal stenosis. This procedure can be accomplished using a flexible or rigid bronchoscope with graduated dilating balloons. After optimal dilatation, a silicone stent (*far right*), placed using a rigid bronchoscope, relieves airway obstruction.

Balloon bronchoplasty also has been used successfully to treat other disorders, including endobronchial tuberculosis, fibrosing mediastinitis, and strictures associated with lung transplantation or prolonged intubation. It is less successful when used alone to treat stenosis accompanied by extrinsic airway compression and generally is not beneficial in patients with tracheobronchomalacia.

Complications of balloon dilation of airway lesions include bronchospasm, chest pain, mucosal laceration, airway perforation, bleeding, postprocedure airway edema, pneumothorax, and pneumomediastinum.

ENDOBRONCHIAL LASER THERAPY

Perhaps the most widely known technique in therapeutic bronchoscopy is laser photocoagulation or photoablation. Lasers produce a beam of monochromatic, coherent light that can induce tissue vaporization, coagulation, hemostasis, and necrosis. Although primarily useful in the ablation of endoluminal malignant tumors, bronchoscopic laser therapy also is beneficial for the treatment of other tracheobronchial disorders, including inflammatory strictures, obstructive granulation tissue, amyloidosis, and benign tumors such as hamartomas and lipomas.

Since the initial report of endobronchial laser ablation of an obstructive neoplasm by Laforet in 1976, several types of lasers have become available for the management of tracheobronchial obstruction. The carbon dioxide (CO_2) laser, used primarily by otolaryngologists, allows shallow penetration of tissue (to a depth of 0.1 to 0.5 mm) and highly precise cutting, but it has minimal hemostatic properties and traditionally was used through a rigid bronchoscope or with suspension laryngoscopy. More recently developed technology has facilitated the delivery of CO_2 laser energy by means of unique reflective fiberoptic probes allowing applications with flexible laryngoscopy and bronchoscopy. The CO_2 laser, with its fine control of tissue ablation, is ideal for the management of laryngeal lesions (e.g., webs, vocal cord nodules). For therapeutic bronchoscopy, neodymium:yttrium-aluminum-garnet (Nd:YAG) laser ablation is most commonly used and provides deeper tissue penetration (to a depth of 3 to 5 mm), superior coagulation, and improved hemostasis, but with less cutting precision. Nd:YAG laser procedures can be performed through a rigid or flexible bronchoscope. Success rates and complications directly related to laser therapy are not different when the procedure is performed through a rigid bronchoscope with the patient under general anesthesia or through a flexible bronchoscope with use of topical anesthesia and conscious sedation.

Nd:YAG laser photoablation therapy has demonstrated a single-modality recanalization rate greater than 90% for endobronchial obstruction of large central airways but is less successful for management of peripheral lesions or with associated extrinsic airway compression. Laser therapy may improve the chances of successful weaning from mechanical ventilation in patients with advanced endoluminal lung cancer presenting in respiratory failure. In addition, photocoagulation with an Nd:YAG laser is an invaluable treatment for patients with airway obstruction caused by benign endoluminal tumors.

Although endobronchial laser therapy generally is safe and well tolerated, it may be complicated by cardiac arrhythmias, airway perforation, pneumothorax, hemorrhage, hypoxemia, or endobronchial fire (ignition of the bronchoscope or endotracheal tube). The use of a laser in the tracheobronchial tree requires careful consideration of the anatomic location and configuration of the lesion. If the lesion is in close proximity to the esophagus or the pulmonary artery, endobronchial laser therapy carries a risk of fistula formation. Laser therapy in a patient with tracheobronchial narrowing caused by extrinsic compression may result in airway perforation. In rare cases, pulmonary edema or fatal pulmonary venous gas embolism has been reported. Patients with standard silicone endotracheal tubes or silicone tracheobronchial stents and those who require high concentrations of supplemental oxygen are at increased risk for endobronchial fire. Fortunately, the overall risk is less than 0.1%. The overall rate of mortality associated with endoscopic laser therapy is quite low, not exceeding 0.3% to 0.5% in several large series.

ENDOBRONCHIAL CRYOTHERAPY AND ELECTROCAUTERY

Cryotherapy and electrocautery are cost-effective alternatives to laser therapy for the management of tracheobronchial obstruction. The depth of penetration and resulting injury are, however, much more difficult to control. As with the Nd:YAG laser, both electrocautery and cryotherapy can be administered through a rigid or flexible bronchoscope. The effects of electrocautery on tissue are similar to those of Nd:YAG laser, with tissue destruction induced by coagulative necrosis. *Argon plasma coagulation* (APC) is similar to electrocautery except that it uses argon gas to conduct the electrical current, rather than a contact probe. APC has a depth of penetration of only 1 to 3 mm and is therefore more suitable for the treatment of superficial and spreading lesions. In contrast with cautery or APC, cryotherapy probes induce tissue necrosis through hypothermic cellular crystallization and microthrombosis. Specially designed cryoprobes are inserted through the bronchoscope until they contact the target tissue. Through the probe in the bronchoscopy working channel, liquid nitrous oxide or liquid nitrogen is introduced through a small orifice under pressure, resulting in rapid cooling with creation of an "ice ball" (approximate temperature of –20° C) at the probe tip. This freezing effect is maintained for approximately 20 seconds; the area is then allowed to thaw. Cryotherapy treatment of an endobronchial lesion requires several freeze-thaw cycles.

Cryotherapy and electrocautery have been used successfully to relieve airway obstruction caused by benign tracheobronchial tumors, polyps, and granulation tissue. These techniques—cryotherapy in particular—may be superior to lasers for distal lesions because of the lower risk of airway perforation. Similarly, carcinoma in situ and mucosal dysplasia may be adequately treated with cryotherapy or electrocautery alone, although multiple treatments may be required for optimal results. Cryotherapy is effective in the removal of certain foreign bodies that can be frozen to the probe and extracted. Of interest, cryotherapy can very effectively freeze endobronchial blood clots and mucous plugs to the probe, which can be easily extracted from the airway.

Endobronchial cryotherapy generally is not effective for management of paucicellular lesions that are relatively impervious to freezing, such as fibrotic stenoses, cartilaginous or bony lesions, and lipomas. Furthermore, endobronchial cryotherapy, unlike either laser therapy or electrocautery, is inefficient in achieving rapid relief of symptomatic airway obstruction. The most common serious complication of both electrocautery and cryotherapy is bleeding secondary to disruption of endobronchial tumor without full coagulation of distal tissue and tumor vessels. The estimated incidence of clinically significant bleeding in patients treated with electrocautery is 2.5%.

ENDOBRONCHIAL BRACHYTHERAPY

Brachytherapy is the local treatment of tumors with radiation delivered internally through implanted radioactive seeds or in a circumferential fashion with inserted wires. This technique ensures the delivery of a maximal therapeutic radiation dose to the tumor with a minimal effect on normal surrounding tissues. Endobronchial brachytherapy involves the bronchoscopic insertion of a thin, hollow "afterloading" catheter through or parallel to a malignant obstruction under fluoroscopic guidance. A radioactive implant is then inserted into the catheter and left in position for a predetermined period (2 to 40 hours, depending on the dose rate).

In 1922, Yankauer described the use of rigid bronchoscopic brachytherapy for the palliation of airway obstruction caused by malignant tumors. Modern techniques, including the use of flexible bronchoscopes, polyethylene afterloading catheters, and iridium 192 implants, were first described in 1983. Since the development of techniques involving high dose-rate delivery in the 1980s, endobronchial brachytherapy has become an option for outpatient treatment of peribronchial tumors.

Relief of airway obstruction is the primary goal of endobronchial brachytherapy, although curative treatment may be attempted in conjunction with external beam irradiation in selected patients. For rapid and sustained airway recanalization in malignant airway obstruction, brachytherapy generally is used as an adjunct to thermal tumor ablation, endobronchial stent placement, or conventional external beam irradiation. Brachytherapy is safest and most effective for management of central airway lesions, although in one study, small peripheral tumors proved to be more responsive than bulkier central tumors. Among patients with malignant airway obstruction, rates of recanalization range from 60% to 90%, with decreased dyspnea, cessation of hemoptysis, and relief of cough in most cases. Endobronchial brachytherapy may require multiple treatments to be effective.

Serious complications of brachytherapy include massive hemoptysis and fistula formation secondary to necrosis of the airway wall and adjacent vascular structures. Because of the risk of fatal hemorrhage, every effort should be made to rule out central vascular involvement of the tumor before brachytherapy administration. The reported incidence of serious complications varies widely, with rates as low as zero to 10% in some of the largest studies and as high as 30% to 40% in smaller studies.

PHOTODYNAMIC THERAPY

Photodynamic therapy (PDT) currently is approved by the FDA for malignant airway obstruction palliation and as an alternative to surgery in select patients with minimally invasive central lung cancer. PDT works on the principle that certain compounds, such as hematoporphyrin derivatives (Photofrin) or aminolevulinic acid (ALA), function as photosensitizing agents, rendering malignant cells susceptible to damage from monochromatic light. Tumor necrosis occurs as a result of cellular destruction through the generation of oxygen free radicals or by ischemic necrosis mediated by vascular occlusion resulting from thromboxane A_2 release. The selective effect of PDT on malignant cells is thought to be due to the greater uptake and retention of photosensitizing agents in neoplastic cells compared with normal cells—with the exception of cells of the reticuloendothelial system, particularly those in the skin. This relative tumor selectivity effect seems to be most pronounced within 24 to 48 hours after photosensitizing agent infusion. For this reason, bronchoscopic treatment of target lesions often is performed 1 or 2 days after agent administration. In view of the delayed onset of PDT action, it is not useful in patients with acute respiratory distress from malignant airway obstruction. Follow-up "toilet" bronchoscopies are required to debride necrotic tissue.

Ideal candidates for PDT include patients with airway obstruction caused by malignant endobronchial masses with minimal extrinsic airway compression, and patients with minimally invasive tumors of the central airways. Although surgical resection remains the treatment of choice for early lung cancer, some patients refuse surgery or have tumors that are deemed inoperable because of high surgical risk. In such cases, PDT may represent an appropriate alternative. Response rates are highest in patients with small tumors and minimal depth of penetration. In patients with bulky tumors, endobronchial PDT may substantially reduce the obstruction, with objective increases in spirometric measurements and subjective improvements in dyspnea and the quality of life. Metastatic tumors also have been treated successfully with PDT. Complications include increased skin photosensitivity and hemoptysis resulting from extensive tumor necrosis. Cutaneous photosensitivity, similar to that seen with sunburn, occurs in up to 20% of patients in various reported series and can be obviated by adequate sunlight precautions. Sensitivity to sunlight after photosensitizer administration can persist for 6 weeks or longer.

TRACHEOBRONCHIAL STENTING

The medical term *stent* refers to any device designed to maintain the integrity of hollow tubular structures, such as the coronary arteries and the esophagus. Anecdotal reports of attempts to implant stents in the tracheobronchial tree date back to 1915. The Montgomery T tube, designed in the 1960s, was the first reliable, dedicated airway stent. However, stent implantation in the lower trachea and bronchi did not become standard medical practice until Dumon's 1990 report on the safety and ease of placement of a dedicated airway stent made of silicone.

Two main types of endobronchial stents are in use today: tube stents made of silicone and self-expandable metallic stents (SEMSs). Silicone stents are placed by rigid bronchoscopy with the patient under general anesthesia. Silicone stents are relatively inexpensive (in the range of $400 to $500 USD) compared with SEMSs ($1800 to $2000 USD). Bifurcated silicone stents also are available for the palliation of distal tracheal and main carinal lesions. These stents have been effectively used in the management of carinal compression associated with malignant tumors, tracheoesophageal fistulas, and tracheobronchomalacia. Custom silicone stents can be designed by the treating bronchoscopist to deal with unique anatomic problems such as stump-related bronchopleural fistula after pneumonectomy. In one large single-center series, the complications of silicone stents included a 5% migration rate, a 10% incidence of granulation tissue formation, and a 27% incidence of partial stent occlusion by inspissated secretions.

Unlike silicone stents, SEMSs can be placed with flexible bronchoscopy, are less likely to migrate, and are more likely to preserve normal mucociliary clearance. However, if metal stents are misplaced in the airway, rigid bronchoscopy often is required for their removal. In addition, mucosal inflammation and the granulation tissue formation are common with uncovered SEMSs and at the proximal and distal ends of covered SEMSs, and repeated endoscopic intervention may be required to restore airway patency. For all these reasons, SEMSs have an FDA warning against their utilization in *benign* airway stenosis, unless all other treatment options, including silicone stenting, have been obviated. One exception to this rule is the development of dehiscence of the bronchial anastomosis in lung transplantation. In this setting, temporary uncovered SEMS insertion across the dehiscence has been used to induce focal granulation tissue formation, which promotes dehiscence closure.

Endobronchial stents have a critical role in multimodality endoscopic approaches to both benign and malignant airway obstruction. Airway obstruction caused by locally advanced bronchogenic carcinoma can be treated with a combination of thermal tumor ablation and stent implantation to regain and to preserve airway lumen diameter by preventing tumor ingrowth (Figure 11-15). Stent placement also can be used to maintain airway patency after endobronchial brachytherapy or can be combined with laser therapy and balloon dilation in the endoscopic management of benign fibrotic strictures. Most large studies of endobronchial stent placement have demonstrated impressive efficacy. Dumon and colleagues reported excellent clinical outcomes and few complications with silicone stent use in patients with malignant airway obstruction but a lower success rate among patients with tracheal stenosis caused by other disorders. Success rates, with "success" broadly defined as symptomatic relief, have ranged in limited studies between 78% and 98%, although none of the early trials used objective measures such as the Lung Cancer Symptom Score (LCSS) to determine efficacy. In two small studies in patients who were intubated because of respiratory failure secondary to unresectable tracheobronchial and mediastinal disease, stent placement facilitated extubation in most patients.

The benefits of stent placement seem to persist in patients who survive for a period of several months or years after stent implantation. Long-term follow-up data, however, are derived from patients with benign disease, because the mean follow-up period in patients with malignant airway obstruction does not usually exceed 3 to 4 months, because of limited underlying disease survival. Some investigators have reported poor long-term results with the use of metal stents in patients with fibroinflammatory stenosis caused by nonmalignant disorders. In addition, there have been case reports of massive hemorrhage associated with the use of stents in patients with extrinsic

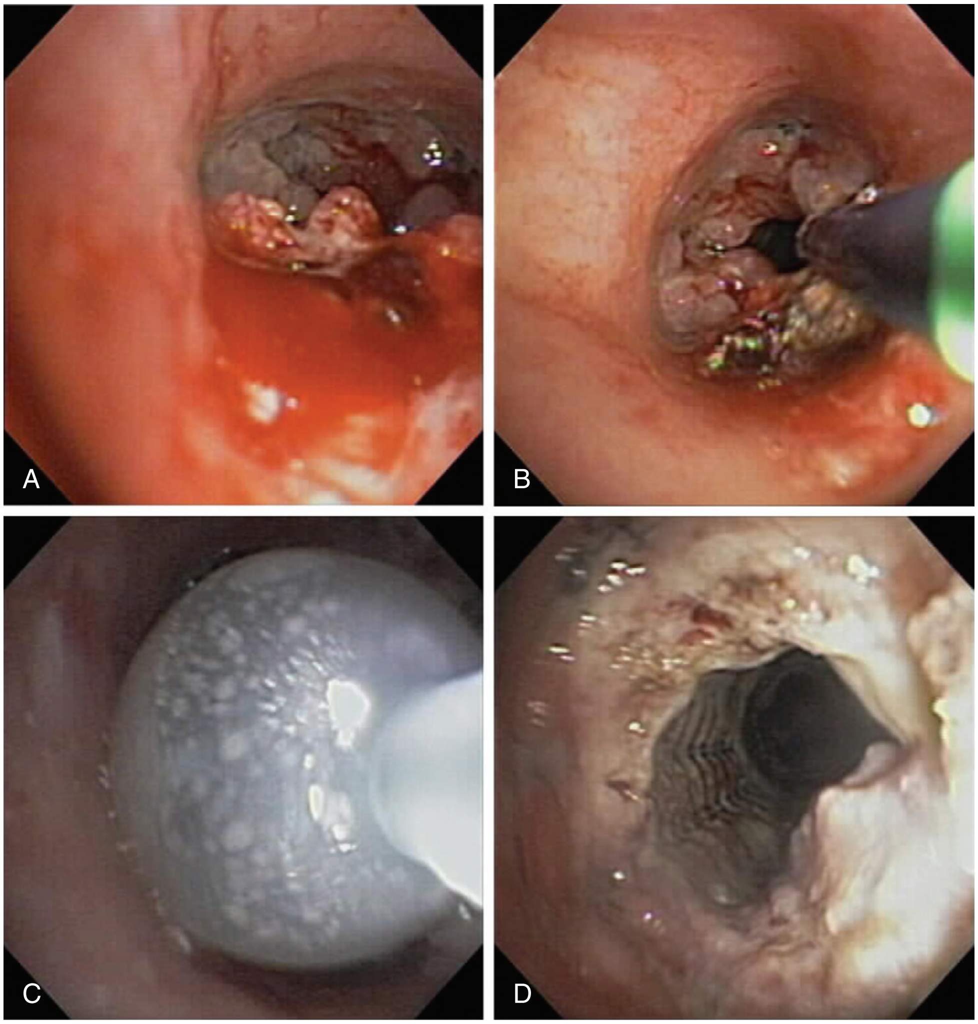

Figure 11-15 **A,** Endoluminal tumor with extrinsic compression treated with a combination of modalities: bronchoscopic laser therapy (**B**), balloon bronchoplasty (**C**), and stent placement (**D**).

compression attributable to aneurysmal dilatation or congenital aortic malformations.

INDICATIONS FOR THERAPEUTIC BRONCHOSCOPY

Therapeutic bronchoscopy most commonly is performed for aspiration of retained secretions and mucous plugs and for the treatment of airway obstruction. The indications for therapeutic bronchoscopy are listed in Box 11-3; many of these are discussed next.

ENDOLUMINAL AIRWAY OBSTRUCTION

Endoluminal obstruction of the tracheobronchial tree may result from various benign and malignant processes. The most common cause of endobronchial obstruction is advanced bronchogenic carcinoma. In patients with inoperable central airway tumors, restoration of airway patency may provide palliation and may even prolong life, particularly in the case of impending respiratory failure or postobstructive pneumonia.

Signs and symptoms of central malignant airway obstruction vary but often include progressive dyspnea and functional limitation, wheezing, cough, stridor, hoarseness, hemoptysis, and chest pain. A careful pretreatment evaluation should be performed to distinguish symptoms attributable to focal tracheobronchial lesions from those related to underlying obstructive lung disease or parenchymal lung disease, or both. A mild obstruction, for example, may contribute only marginally to the dyspnea experienced by a patient with concomitant severe chronic obstructive pulmonary disease (COPD). Although pulmonary function testing and thoracic imaging techniques such as chest CT may be useful in the evaluation of a patient with suspected malignant airway obstruction, bronchoscopy, either rigid or flexible, remains the diagnostic and therapeutic “gold standard.” Increasingly, however, three-dimensional reconstruction CT imaging—so-called virtual bronchoscopy—is being applied as a reliable noninvasive method of assessing the nature and extent of malignant airway obstruction to allow preprocedural intervention planning.

The bronchoscopic approach to management of malignant airway obstruction depends on the lesion location, the presence or absence of associated extrinsic compression, and the degree of clinical urgency (Table 11-3). Rigid bronchoscopic debulking with adjunctive thermal ablation is recommended when airway recanalization must be performed on an emergency basis. If endobronchial obstruction is accompanied by marked extrinsic compression, stent placement may be beneficial (Figure 11-16).

The complexity of a lesion is equally important in determining the best approach to resection. Benign tracheal webs often are managed by laser or electrocautery-mediated resection

Table 11-3 **Bronchoscopic Therapies**

Therapy	Type of Lesion Therapy	Type of Bronchoscope	Rapidity of Positive Result	Repeatability
Mechanical débridement	Endoluminal or submucosal	Rigid or flexible (rigid preferable)	++++	+
Laser	Endoluminal	Rigid or flexible (rigid preferable)	++++	++++
Argon plasma	Endoluminal	Rigid or flexible	++++	++++
Brachytherapy	Endoluminal or submucosal	Flexible	+	+
Cryotherapy	Endoluminal	Rigid or flexible	++	+++
Balloon dilation	Endoluminal or submucosal with extraluminal compression	Rigid or flexible (rigid preferable)	++++	++++
Photodynamic therapy	Endoluminal	Flexible	++	+++
Electrocautery	Endoluminal	Rigid or flexible	+++	++++
Stent	Endoluminal with extraluminal compression	Rigid or flexible (Dumon stent requires rigid bronchoscope; Wall stents and Gianturco stents require fluoroscopy)	++++	+++

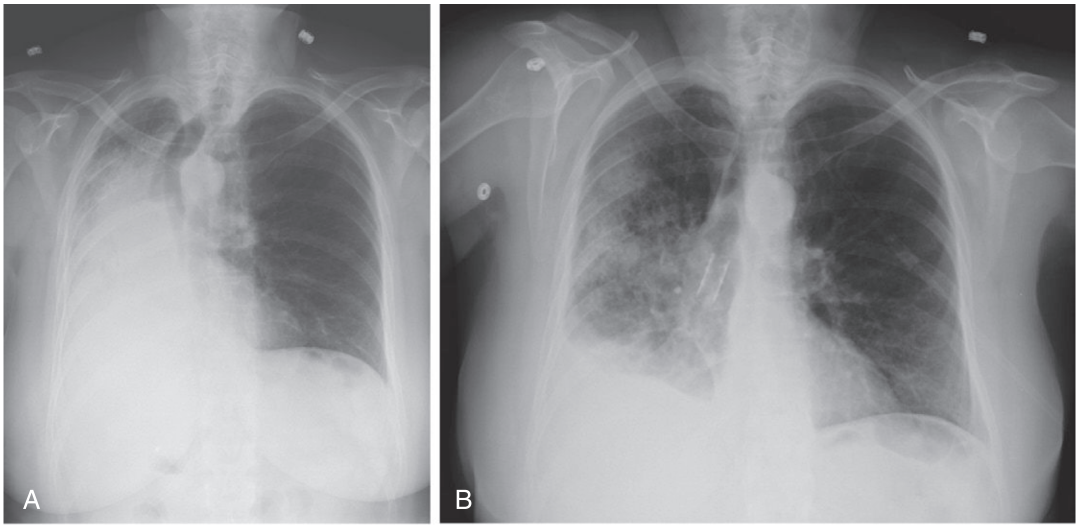

Figure 11-16 **A,** Chest radiograph of an obstructing small cell carcinoma in right main bronchus, causing right lung atelectasis and mediastinal shift. **B,** Radiographic appearance after rigid bronchoscopic debulking of the lesion and placement of a Dumon silicone stent. *(**A** and **B**, Courtesy Colin Gillespie, MD.)*

alone, whereas complex fibrotic strictures may warrant the combination of rigid bronchoscopic or balloon dilation, thermal incision, and stent placement. For focal tracheal stenosis in patients at low risk for complications, surgical resection with primary reanastomosis should remain the treatment of choice.

EXTRINSIC AIRWAY COMPRESSION

Extrinsic airway compression usually results from malignant involvement of structures adjacent to the central airways, such as mediastinal lymph nodes or the esophagus, but it may be associated with a benign process, such as fibrosing mediastinitis, tuberculosis, aneurysmal dilatation of the aorta, or sarcoidosis. The clinical signs and symptoms of extrinsic airway compression often mimic those of endobronchial obstruction. The diagnosis is established on the basis of bronchoscopic detection of marked airway narrowing in the absence of an endoluminal mass.

Therapeutic options in the management of extrinsic airway compression are limited. Ablative endoscopic approaches such as laser therapy, cryotherapy, PDT, and electrocautery are contraindicated because of the lack of demonstrable benefit and risk of airway perforation. Although some patients with malignant disease may benefit from endobronchial brachytherapy, tracheobronchial stent placement is the palliative treatment of choice for patients with symptomatic extrinsic airway compression.

TRACHEOBRONCHOMALACIA

Diffuse or focal tracheobronchomalacia is perhaps the most challenging disorder encountered by the therapeutic bronchoscopist. *Cartilaginous* tracheobronchomalacia, as seen in patients with relapsing polychondritis, reflects a loss of the structural integrity of the trachea and/or main bronchi secondary to airway cartilaginous ring destruction. *Membranous*, or *crescentic*, tracheobronchomalacia, also known as excessive dynamic airway collapse (EDAC), is manifested by displacement of the posterior membrane toward the anterior tracheal wall during exhalation as a result of trachea and main bronchus posterior membrane laxity and usually is seen in patients with

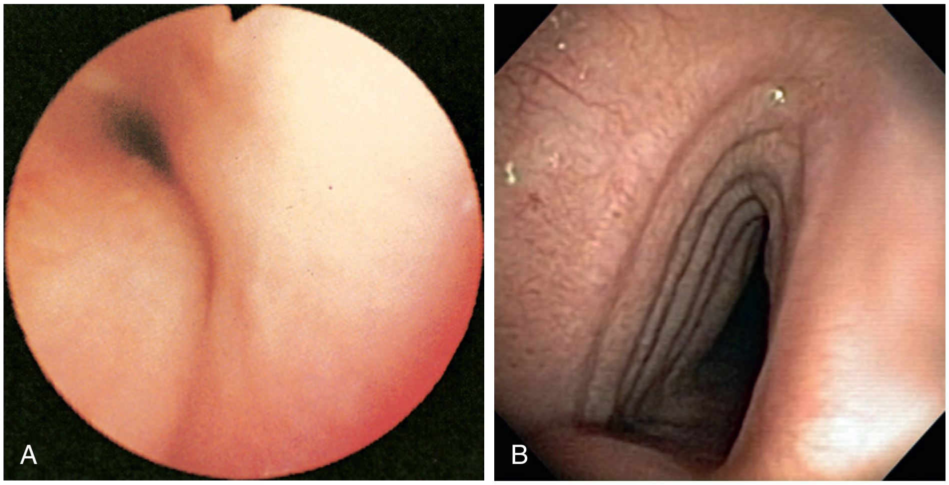

Figure 11-17 **A,** Tracheal buckling. In a patient presenting with dyspnea, cough, and stridor, bronchoscopic examination revealed localized upper tracheal buckling on hyperflexion of the neck. Symptoms cleared after three tracheal rings were resected. Histopathologic analysis showed localized tracheomalacia. **B,** "Saber sheath trachea." Fixed reduction in coronal diameter with concomitant increase in sagittal diameter of the trachea results in the classic bronchoscopic appearance of this lesion.

long-standing COPD. Focal tracheobronchomalacia may be a complication of long-standing intubation or an anastomotic complication after lung transplantation.

Tracheobronchomalacia is best diagnosed on the basis of findings on flexible bronchoscopy, performed with the patient breathing spontaneously (**Figure 11-17,** ***A***), although dynamic CT scanning, with images obtained on inspiration and expiration, often is helpful. Tracheobronchomalacia should be distinguished from a *saber sheath trachea,* which is characterized by a fixed reduction of the transverse diameter of the intrathoracic portion of the trachea, in the presence of accentuation of the sagittal diameter (see Figure 11-17, *B*).

The endoscopic treatment of choice for patients with diffuse tracheobronchomalacia is the insertion of a standard or bifurcated silicone tracheobronchial stent. This intervention is more likely to be successful in patients with the cartilaginous type of tracheobronchomalacia than in those with the membranous type. Patients with membranous tracheobronchomalacia may benefit from a trial of silicone stent placement. For those who benefit in terms of decreased respiratory symptoms and improved pulmonary function, surgical plication or buttressing of the posterior membrane, or both, can be performed, often with good results and with facilitation of stent removal. For many patients with focal tracheomalacia, particularly from postintubation injury, surgical resection with primary reanastomosis is the best therapeutic option. An alternative treatment for selected patients with diffuse tracheobronchomalacia is the "pneumatic stent" provided by noninvasive ventilatory techniques such as continuous positive airway pressure.

CONTROL OF HEMOPTYSIS

In cases of hemoptysis, bronchoscopy may be of value not only for diagnosis but frequently for emergency management of endobronchial bleeding (**Box 11-5**). Because of difficulties with visualization, instruments with large and maximally effective suction channels should be used. Rigid bronchoscopy generally is preferred with massive bleeding and when the need to remove large clots is anticipated.

When continuous suctioning of blood fails to clear the airways, other means can be used. An iced saline solution can be instilled along with vasoactive drugs, such as epinephrine, to induce vasoconstriction. The bronchoscope itself can occlude the lumen of the bronchus from which the bleeding originates. The same effect, perhaps with better local control, can be achieved with bronchoscopic balloon catheters (**Figure 11-18**). Specially designed catheters have been developed for introduction through the working channel of the flexible bronchoscope, several permitting subsequent removal of the scope while the tamponading balloon remains in place, as well as the potential for suctioning beyond the balloon for clearance of blood from distal airways. Another effective method for control of visible sources of bleeding, particularly from endobronchial neoplasms, is Nd:YAG laser photocoagulation.

Recent reports have demonstrated the benefit of endobronchial packing, accomplished using either flexible or rigid bronchoscopy, with oxidized regenerated cellulose (Surgicel), which functions in multiple capacities, including local tamponade and isolation at the segmental or subsegmental bleeding site, absorption of blood, and promotion of endobronchial clot formation by induction of fibrin polymerization. This procedure may obviate the need for bronchial artery embolization or other, more invasive procedures.

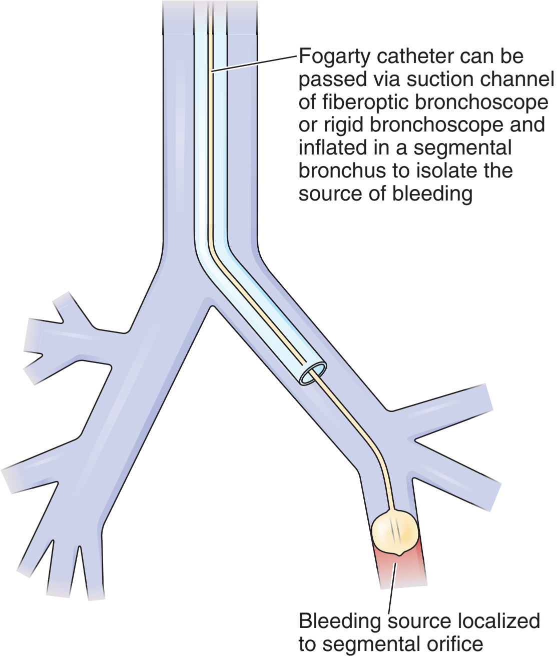
Box 11-5 **Measures and Agents for Bronchoscopic Control of Hemoptysis**

- Repeated suctioning (to keep open the airways)
- Iced saline irrigation
- Vasoactive drugs (epinephrine, vasopressin analogues)
- Bronchoscopic tamponade
- Balloon tamponade
- Tamponade with gauze or surgical gel (Gelfoam)
- Thrombin or fibrinogen instillation
- Laser coagulation
- Argon plasma coagulator
- Electrocautery
- Cryotherapy*
- Bronchoscopic brachytherapy†
- Isolation of bronchial tree (e.g., double-lumen endotracheal tube)

*Not suitable for management of massive hemoptysis.
†Not suitable for management of massive hemoptysis or for acute control of hemoptysis.

REMOVAL OF FOREIGN BODIES

Foreign body aspiration is more likely to occur in children than in adults, with most occurring in children younger than 3 years. In children the obstruction most often involves a mainstem



Fogarty catheter can be passed via suction channel of fiberoptic bronchoscope or rigid bronchoscope and inflated in a segmental bronchus to isolate the source of bleeding
Bleeding source localized to segmental orifice

Figure 11-18 Placement of a Fogarty balloon catheter under bronchoscopic guidance to control massive hemorrhage from a segmental or lobar bronchus. *(From Lordan JL, Gascoigne A, Corris PA: The pulmonary physician in critical care: illustrative case 7: assessment and management of massive hemoptysis,* Thorax *58:814-819, 2003.)*

bronchus, whereas in adults most foreign bodies are wedged distally, most commonly in the right lower lobe. Before the development of bronchoscopy, most foreign body aspirations resulted in high morbidity and mortality, commonly from postobstructive pneumonia. Until the introduction of the flexible bronchoscope, all foreign body removals were accomplished with rigid bronchoscopy. Even at present, the rigid bronchoscope remains the tool of choice for the removal of foreign bodies, especially in children. The advantage of the rigid instrument resides in its larger access channel, permitting use of larger and more adaptable retrieval tools and ability to simultaneously provide and maintain ventilation. In adults, flexible bronchoscopy is the most common initial diagnostic tool for foreign body aspiration and allows for successful foreign body removal in most cases.

Various types of instruments have been developed for use with bronchoscopy for the removal of foreign bodies, including grasping forceps, balloon catheters, retrieval baskets, snares, and magnetic extractors. The instrument choice depends on the specifics of the type of foreign body and its location in the tracheobronchial tree. Grasping forceps may be helpful in the retrieval of hard objects with an irregular surface. Smooth objects or organic material (e.g., nuts, food particles) may require the use of expandable baskets or a combination of balloon catheters, suction devices, and grasping forceps. Fogarty balloon catheters frequently are used to dislodge a foreign body and bring it proximally into the trachea before its removal with other instruments.

Special attention should be paid to the period after removal of the foreign body, because serious complications can occur. Patients should be observed closely for any signs of hemoptysis, subcutaneous emphysema, or subglottic edema. Trauma inflicted during the extraction or forceful manipulation of instruments greatly accentuates the risk of postoperative complications, particularly if oversized instruments are used or if the bronchoscopy procedure is prolonged.

ASPIRATION OF SECRETIONS

According to a survey of bronchoscopists in the United States, removal of retained secretions is cited as a leading indication for therapeutic bronchoscopy. Bronchoscopic secretion aspiration may be indicated in patients presenting with respiratory muscle weakness (e.g., because of underlying neuromuscular disease or the postoperative state) or disorders leading to recurrent aspiration of food or excessive upper airway secretions. In critically ill or mechanically ventilated patients, removal of secretions and mucous plugs usually can be rapidly achieved through the flexible bronchoscope. A flexible scope with a large-diameter suction channel should be chosen for this procedure. The nature of the retained material—its consistency and viscosity—may dictate frequent bronchoscopy procedures to relieve segmental or lobar atelectasis because of inspissated mucous plugs. Underlying pulmonary diseases, such as bronchiectasis, may aggravate the airway secretion retention. Bronchoscopic secretion aspiration should not be considered “routine” in the postoperative period or in other conditions in which good chest physiotherapy and maintenance of adequate pulmonary toilet could be more effective.

Two specific disorders are worth highlighting in the context of therapeutic bronchoscopy: pulmonary alveolar proteinosis (PAP) and allergic bronchopulmonary aspergillosis (ABPA). In PAP, BAL has been used for therapeutic clearance of alveolar material, although the standard approach is whole-lung lavage that uses double-lumen endotracheal tube intubation. In ABPA, lavage with saline solution may be insufficient to remove tenacious impactions (described as “plastic bronchitis”). In these circumstances, use of bronchoscopic forceps or snare may prove helpful.

CLOSURE OF BRONCHIAL FISTULAS

Prolonged air leaks are a common problem associated with primary or secondary pneumothorax and are the most frequent complication after pulmonary resection, with the highest rate after lung volume reduction surgery (LVRS). The current management for prolonged air leaks usually includes prolonged chest tube drainage with Heimlich valve, attempts at surgical repair, and/or blood patch and pleurodesis.

Either flexible or rigid bronchoscopy can be a useful intervention in confirming suspected bronchopleural fistulas or alveolopleural fistulas and in specifying their precise location. The most common approach is to perform selective airway occlusion with a balloon catheter while observing the chest tube air leak rate or volume. Depending on the fistula location and the size, bronchoscopic procedures can be attempted with the goal of occlusion and sealing the bronchopleural fistulas. Small bronchial openings in an otherwise normal bronchus after thoracic surgery respond much better, with a higher rate of success of bronchoscopic sealing. It is much more difficult to achieve good obliteration of a fistula if it is infected or is due to an underlying malignancy. Many different techniques for permanent closure have been used, including introduction of bronchial mucosal irritants (e.g., silver nitrate), with the object of stimulating reactive granulation tissue formation. Several potentially useful agents have been described, including surgical gel (Gelfoam), autologous blood patch, cryoprecipitate, and thrombin injection to create fibrin clot. In addition, laser photocoagulation surrounding small, proximal bronchopleural fistulas has been reported to be beneficial. Recent case series suggest that the placement of one-way endobronchial valves leads to complete or partial resolution in the large majority of patients with prolonged air leaks from diverse causes.

BRONCHOSCOPIC TREATMENTS FOR COMMON "BENIGN" LUNG DISEASES

One of the major advances in therapeutic bronchoscopic use over the past decade has been the development of experimental bronchoscopic interventions for highly prevalent lung diseases such as asthma and emphysema.

BRONCHOSCOPIC TREATMENTS FOR EMPHYSEMA

The risks associated with LVRS, in which diseased portions of emphysematous lung are resected through median sternotomy or with use of videothoracoscopy, including a perioperative mortality of 5% or greater, as well as substantial perioperative morbidity, have spurred the development of minimally invasive approaches for dyspnea palliation in patients with emphysema. The bronchoscopic lung volume reduction (BLVR) approaches evaluated have used a range of different techniques, including airway occlusion with silicone plugs (i.e., Endobronchial Watanabe Spigot [EWS]); insertion of one-way bronchial valves; and creation of artificial noncompressible communications ("bypass tracts") between cartilaginous airways and emphysematous parenchyma. Endobronchial valves are designed to limit ventilation to the most severely emphysematous regions of lung and reduce dynamic hyperinflation. When placed correctly, the valves allow one-way flow of secretions and air out of the occluded pulmonary segment. The major advantage of the bronchial valve approach for emphysema palliation is the potential for reversibility—the valves generally are removable with minimal risk to the patient. The bane of the pulmonologist attempting to use bronchial valves in the treatment of emphysema is collateral ventilation, which inhibits induction of atelectasis, thereby preventing successful lung volume reduction. Results from the first randomized study of endobronchial valves, a double-blinded sham-controlled multicenter trial of the Zephyr endobronchial valve, demonstrated modest increases in forced expiratory ventilation in 1 second (FEV_1) and 6-minute walk distance at 6 months, but unfortunately with an increased rate of complications, including COPD exacerbations and hemoptysis.

The results from the randomized study of Airway Bypass also did not demonstrate statistically significant improvements in the primary end points of forced vital capacity (FVC) and dyspnea score. Studies evaluating the use of other novel endobronchial approaches are ongoing. These include the placement of airway implants (e.g., Nitinol coils); intrabronchial injection of steam to induce tissue necrosis resulting in loss of lung tissue, volume, and ventilation; and biologic restructuring of emphysematous lung parenchyma to induce tissue fibrosis, atelectasis, and contraction, with consequent lung volume reduction. The latter approach was inspired by numerous case reports of "medical" lung volume reduction, in which patients with heterogeneous emphysema achieved significant clinical and physiologic improvements in lung function after receiving external beam radiation therapy for an upper lobe non–small cell carcinoma or after developing infection or inflammation in an upper lobe bulla resulting in fibrosis and contraction of the bullous lung tissue after resolution of the infectious or inflammatory process. One of the major downsides of the biologic approach to lung volume reduction is the permanent destruction of lung tissue, with no option for reversibility in the event of worsening lung function.

BRONCHIAL THERMOPLASTY

Chronic asthma is a major cause of morbidity and death and also a major contributor to rapidly rising health care costs. Bronchial thermoplasty (BT) is a new bronchoscopic procedure that delivers controlled thermal energy to the bronchial wall of conducting airways, with the intent to inhibit airway smooth muscle contractile function. This offers the potential to attenuate bronchoconstriction occurring during asthma exacerbations. BT is performed by use of a single-use radiofrequency device that delivers thermal energy to the bronchial wall during an outpatient bronchoscopic procedure. Three separate procedures are performed in order to treat all accessible upper and lower lobe airways, ranging from 3 to 10 mm in diameter. The initial randomized, multicenter Airway Intervention with Radiofrequency (AIR) trial in patients with moderate to severe disease demonstrated decreased asthma exacerbations in the group undergoing BT compared with those patients treated with standard medical treatment alone. This was followed by a randomized, sham-controlled multicenter trial (AIR2) demonstrating significant improvement in the primary end point, asthma-related quality of life. Although an increase was noted in early posttreatment asthma exacerbations requiring emergency department visits and hospitalizations, the long-term follow-up data showed decreased asthma-related health care utilization for patients undergoing BT as opposed to the sham procedure. On the basis of these data, BT should be considered for patients with severe asthma that is not well controlled by medication therapy. Studies are ongoing to collect additional safety data and to assess the durability of the BT treatment effect.

COMPLICATIONS OF THERAPEUTIC BRONCHOSCOPIC TECHNIQUES

The advent of interventional bronchoscopy has resulted in complications not ordinarily seen with diagnostic bronchoscopy. Inappropriate use of lasers has resulted in endobronchial burns and bronchial perforations associated with catastrophic bleeding, pneumomediastinum, or pneumothorax. Endobronchial edema and mucosal sloughing also may occur as a result of laser thermal effects.

As noted previously, the use of airway stents is associated with several complications. Stents may not be properly adapted to the diameter of the airway, resulting in either incomplete stent deployment or stent migration, possibly engendering life-threatening airway obstruction. The presence of an endoprosthesis in the airway may predispose the patient to difficulties with secretion clearance and accumulation of inspissated mucus. Placement of SEMSs may be followed by severe local airway reactions, with consequent formation of granulation tissue, hemorrhage, or bronchial perforation.

SUMMARY

Technologic advances in bronchoscopy continue to improve the pulmonologist's ability to perform minimally invasive, accurate evaluations of the tracheobronchial tree and to implement an ever-increasing array of diagnostic, therapeutic, and palliative interventions. The role of both diagnostic and therapeutic bronchoscopy will continue to evolve as further improvements are made in bronchoscopes, accessory equipment, and imaging technologies. Therapeutic bronchoscopy may soon be used to provide treatment for conditions that traditionally have been treated with surgery. The major challenge in the adoption of the many new bronchoscopic techniques into routine clinical practice is the need for well-designed studies to delineate the appropriate use of these interventions and to better define their limitations.

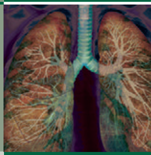
Section 2

DIAGNOSTIC TECHNIQUES



Chapter 12

Endobronchial and Endoesophageal Ultrasound Techniques

Felix J.F. Herth

Lung cancer is still the leading cause of cancer deaths worldwide, with an overall 5-year survival rate of 10% to 15%. Mediastinal lymph node sampling in lung cancer is important for adequate staging to determine appropriate treatment, as well as for predicting outcome. Adequate staging of lung cancer also is important in order to improve research into lung cancer, both for accurate comparison of data and for quality control.

Mediastinal lymph node staging can be performed preoperatively by radiologic imaging, endoscopically, or surgically. CT scanning, magnetic resonance imaging (MRI), positron emission tomography (PET), and integrated PET-CT are useful noninvasive imaging techniques for staging of lung cancer; however, they are not sufficiently sensitive or specific to determine mediastinal lymph node involvement. CT scanning usually is the initial method for staging of mediastinal nodes. Only lymph nodes with a short-axis diameter greater than 1 cm (with or without positive findings on PET-CT or other PET study) usually are considered to be suspicious for malignant involvement by radiologic criteria set forth in national and international guidelines. Nevertheless, in view of the high false-positive rate for CT and PET-CT, neither of which provides a tissue diagnosis, it is important to obtain lymph node tissue to determine operability.

Mediastinoscopy with nodal biopsy has been the “gold standard” for mediastinal staging for many years and has a sensitivity of 90% to 95% for detection of metastases in this region. Only certain lymph node stations—2, 4, and anterior 7—are accessible by this approach, in which access to the posterior and inferior mediastinum is limited, typically necessitating extending the procedure to cervical mediastinoscopy or thoracoscopy. However, it is essentially a surgical approach requiring general anesthesia and occasionally hospitalization. Endoscopic techniques provide a minimally invasive alternative to surgical staging. Accordingly, the past few years have seen the development of a number of less invasive staging modalities, including endobronchial ultrasound (EBUS) and endoesophageal ultrasound (EUS) techniques.

TRANSBRONCHIAL NEEDLE ASPIRATION

Merely a curiosity at its inception, flexible bronchoscopy has emerged as an essential diagnostic and therapeutic modality in the management of a variety of lung diseases. The addition of transbronchial needle aspiration (TBNA) not only improved bronchoscopy’s diagnostic yield but further extended the role of this modality in the evaluation of mediastinal disease, and in the diagnosis and staging of bronchogenic carcinoma. The first description of sampling mediastinal lymph nodes through the tracheal carina using a rigid bronchoscope was by Schieppati. In 1978, Wang and associates demonstrated that it was feasible to sample paratracheal nodes using TBNA. Subsequent publications highlighted the use of the technique in the diagnosis of endobronchial (Figure 12-1) and peripheral lesions and the ability of TBNA to provide a diagnosis even in the absence of endobronchial disease.

The diagnostic yield of TBNA in the assessment of hilar-mediastinal lymph node involvement in lung cancer varies greatly in published series, with reported rates ranging from 15% to 85%. Recently, a metaanalysis assessing TBNA for mediastinal staging in non–small cell lung cancer demonstrated that TBNA is highly specific for the identification of mediastinal metastases, with sensitivity depending heavily on the study population under investigation. In studies that included patient populations with a prevalence of mediastinal metastases of 34%, sensitivity was only 39%, whereas in a population with a prevalence of 81%, sensitivity for detection of metastases was 78%.

Nevertheless, even after more than 50 years since the advent of TBNA, the technique is still underused. The main reasons for the limited use of TBNA have been lack of needle monitoring, difficulties in performing the procedure, and a belief, despite good evidence to the contrary, that TBNA is not useful.

ENDOBRONCHIAL ULTRASOUND TECHNIQUE

The integration of ultrasound technology and flexible fiberoptic bronchoscopy enables imaging of lymph nodes, lesions, and vessels located beyond the tracheobronchial mucosa. Developed in 2002, the EBUS bronchoscope looks similar to a normal bronchovideoscope (Figure 12-2) but is 6.9 mm wide and has a 2-mm instrument channel and a 30-degree side viewing optic. Furthermore, a curved linear array ultrasound transducer sits on the distal end and can be used either with direct contact to the mucosal surface or with an inflatable balloon that can be attached at the tip. This setup produces a conventional endoscopic picture side by side with the ultrasound view. Ultrasound scanning is performed at a frequency of 7.5 to 12 MHz, with tissue penetration of 20 to 50 mm. An ultrasound processor generates the ultrasound image.

EBUS allows the bronchoscopist to visualize airway structures as well as surrounding processes. It is useful for staging advanced cancer, especially as it relates to intramural or nodal

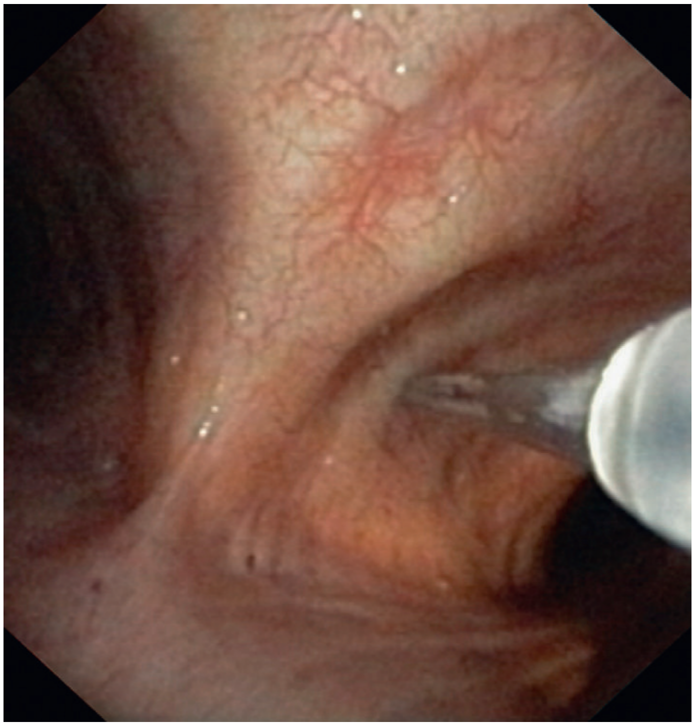


Figure 12-1 Classical transbronchial needle aspiration (TBNA) biopsy of the lymph node.

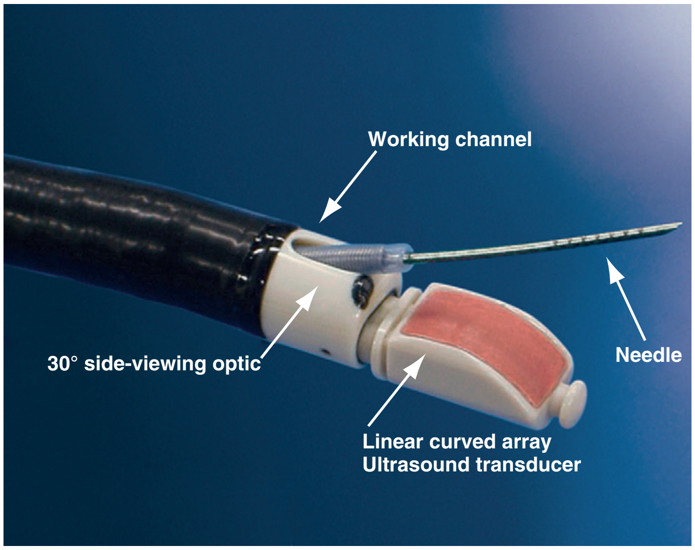

Figure 12-2 The tip of the endobronchial ultrasound (EBUS) scope. The transbronchial needle aspiration (TBNA) needle is already inserted.

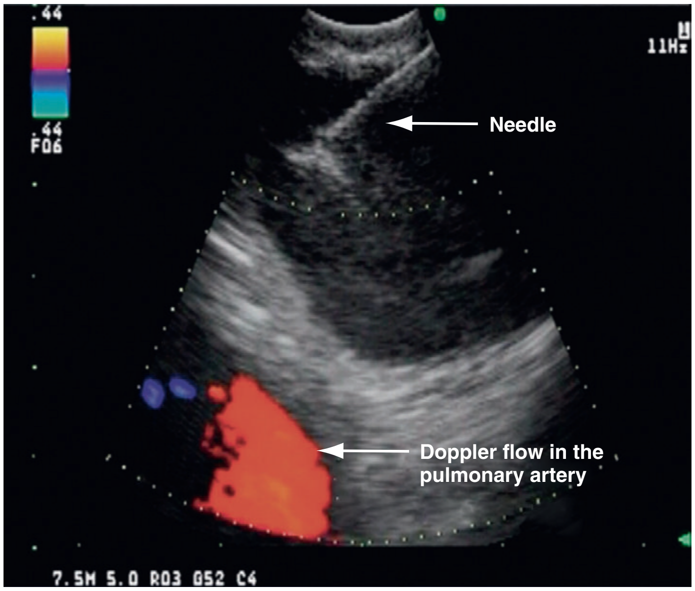

Figure 12-3 Endobronchial ultrasound–transbronchial needle aspiration (EBUS-TBNA) of a lymph node in position 4R.

spread. EBUS can identify N1, N2, and N3 nodes without the need for surgical intervention and can hence decrease the need for expensive surgery.

Procedure

The actual TBNA is performed using direct transducer contact with the wall of the trachea or bronchus. When a lesion is outlined, a 21 or 22 gauge needle can be advanced through the working channel, and lymph nodes can be punctured under real-time ultrasound visualization. The needle is encased in an internal sheath in order to avoid contamination during biopsy. At the same time, color Doppler can be used to identify surrounding vascular structures. Once the target lymph node or mass has been clearly identified with EBUS, the needle is inserted under real-time ultrasound guidance and then placed within the lesion (Figures 12-3 and 12-4). Suction is applied with a syringe, and the needle is moved back and forth to achieve multiple punctures. The stylet of the needle is left in place on the first puncture to minimize bronchial cell contamination; once the needle tip is inside the target tissue, the stylet is removed. We stab the target 10 to 15 times without suction and apply suction only for the last two or three stabbing motions. Before retraction of the needle into the needle sheath, suction must be removed to minimize sample loss into the syringe. The specimen is then air-flushed onto a slide, and the needle is flushed with heparin-saline solution to avoid clotting; the same procedure is repeated three times at every lymph node station.

Lymph node stations that can be reached using EBUS are the highest mediastinal (station 1), the upper paratracheal (2L and 2R), the lower paratracheal (4R and 4L), the subcarinal (station 7), the hilar (station 10) nodes, as well as the interlobar (station 11) and lobar (station 12) nodes. The highest-staging node (e.g., an N3 contralateral mediastinal lymph node before an N2, an ipsilateral mediastinal lymph node before an N1 hilar lymph node) should be biopsied first; otherwise, the needle needs to be changed each time.

Lymph nodes at a size of 5 mm and upwards can be successfully sampled and have to date shown excellent diagnostic yield. The number of mediastinal lymph node stations to sample depends on the purpose of the examination.

Every attempt should be made to sample nodes at these sites, even if size and ultrasonographic features are normal. At our institution, we routinely sample mediastinal lymph nodes that are 5 mm or larger in short-axis diameter.

The learning curve for EBUS-TBNA has been evaluated: performance of at least 10 procedures is necessary in order to achieve excellent sensitivity and diagnostic accuracy, although that number may be higher, depending on operator skill level.

Results

In recently published metaanalysis, EBUS-TBNA has been shown to have a high pooled sensitivity of 93% and specificity of 100%. Multiple publications have shown that even in

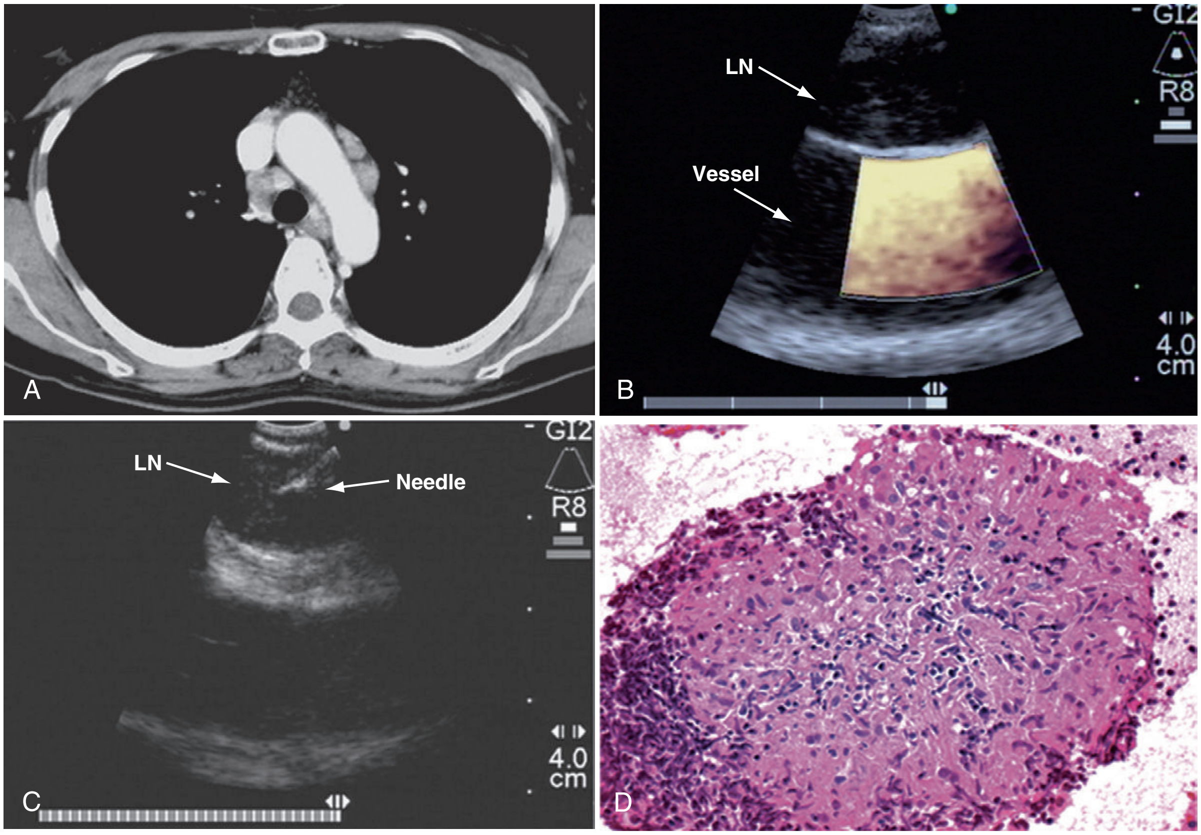

Figure 12-4 **A,** Enlarged lymph node in the upper mediastinum in position 4r. **B,** The vessels are readily seen on the power Doppler image. **C,** Real-time ultrasound image of the aspiration biopsy procedure. **D,** The histopathologic pattern was consistent with a diagnosis of sarcoidosis. *LN*, lymph node.

patients with lymph nodes less than 1 cm in diameter (which had been termed N0 by CT criteria), with the use of EBUS-TBNA, a large percentage could still be shown to have N2 or N3 disease (in some cases, despite a negative result on PET-CT).

Numerous studies have looked at the use of EBUS-TBNA for biomarkers and tumor genetics in lung cancer. In a recent published trial, endothelial growth factor receptor (EGFR) gene analysis of the EBUS-TBNA sample was feasible in 26 of 36 patients (72.2%) with lymph node metastasis. Somatic mutations of the *EGFR* gene were detected in tissue obtained through EBUS-TBNA in 2 of 20 patients (10%) with metastatic lung adenocarcinoma. Complications such as bleeding or infection are very rare and have been reported only as case reports.

EBUS-TBNA also has been shown to have utility in diagnosis of other pulmonary diseases besides lung cancer. In patients with clinically suspected lymphoma, the reported diagnostic sensitivity is 70% to 80%. If more tissue specimens are needed for histologic analysis, it is even possible to insert a 1.15-mm mini-forceps through the EBUS scope and past the airway wall via a needle puncture, to obtain forceps biopsy specimens of mediastinal lymph nodes under real-time ultrasound guidance.

Different prospective studies have assessed the usefulness of EBUS-TBNA in evaluation of patients with suspected sarcoidosis. EBUS-TBNA has been reported to have a diagnostic yield of 85% to 93%, which increases with the number of passes performed. In one study in which a cytopathologist performed on-site evaluations, the diagnostic yield was greater than 80% at five passes and did not increase further after seven passes. In a recently published randomized controlled trial, EBUS-TBNA provided a diagnostic yield superior to that with conventional TBNA (83% versus 54%). In patients with suspected sarcoidosis, EUS-FNA has a similar diagnostic yield of 82% to 86%. The choice between the two diagnostic methods is therefore based on the location and accessibility of the enlarged lymph nodes and on the expertise of the operator.

ENDOESOPHAGEAL ULTRASOUND TECHNIQUE

Gastroenterologists have been using the endoesophageal ultrasound (EUS) technique for many years in the investigation of esophageal and pancreatic malignancies. Mediastinal EUS-guided fine needle aspiration (FNA) was first used in the early 1990s and subsequently has become a popular method to diagnose a variety of intraabdominal and intrathoracic masses, including mediastinal lesions. EUS-FNA has been shown to be useful in biopsying mediastinal lesions, even in patients in whom a previous conventional technique was nondiagnostic, and may be more cost-effective as an initial staging procedure in patients with non–small cell lung cancer (NSCLC) than classical techniques.

Procedure

The linear EUS bronchoscope has the same basic architecture as that of the EBUS scope and uses a scanner frequency of between 5 and 10 MHz. The penetrating ultrasound depth can be up to 8 cm. Needles used for biopsy are 19 or 21 gauge, again equipped with a stylet. The procedure usually is performed on an outpatient basis and takes approximately 30 minutes. As with EBUS, the puncture of lymph nodes is performed under real-time ultrasound guidance (Figure 12-5).

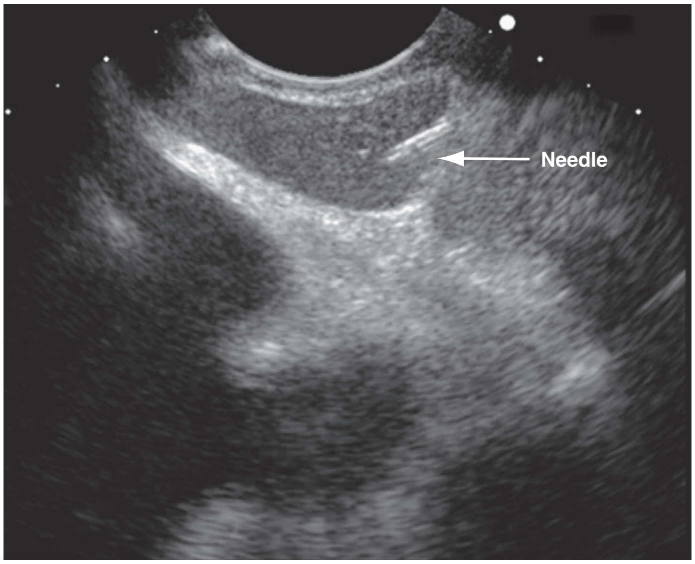

Figure 12-5 Endoesophageal ultrasound–guided fine needle aspiration (EUS-FNA) of an enlarged node in station 7.

However, EUS-FNA has limited access, because only lymph node stations 2L, 4L, 7, 8, and 9 are accessible through a transesophageal approach. Lymph node station 5 is not routinely accessible by EUS, and transvascular FNA may be required to sample this tissue.

Results

EUS is especially useful in staging of the posterior mediastinum. The left adrenal can be reached and identified in 97% of cases. It has a characteristic "seagull" shape on ultrasound images and is particularly well visualized in cases of metastatic enlargement. Furthermore, the left lobe of the liver also can be reached. The hilar and precarinal lymph nodes cannot be reached.

The procedure carries only a very small risk of mediastinitis or bleeding. Unless cysts are punctured antibiotics do not need to be administered routinely.

EUS is more accurate and has a higher predictive value than either PET scan or CT for assessment of posterior mediastinal lymph nodes.

Multiple publications and a metaanalysis of data on EUS-FNA have shown high sensitivity and specificity. Even in cases in which mediastinal lymph node enlargement is not seen on CT, EUS-FNA has been able to demonstrate metastases in 25% of patients with lung cancer.

For both techniques, however, it is important to recognize that the negative predictive value (NPV) is limited. Therefore, if samples do not contain tumor cells, follow-up evaluation with a more definitive procedure such as mediastinoscopy with biopsy or video-assisted thoracoscopic surgery (VATS) is indicated.

COMBINING ENDOBRONCHIAL AND ENDOESOPHAGEAL ULTRASOUND TECHNIQUES

For tissue sampling of mediastinal lymph nodes after conventional TBNA, our own preference is for minimally invasive methods such as EBUS-TBNA and EUS-FNA over more invasive procedures such as mediastinoscopy and VATS. EUS-FNA and EBUS-TBNA have been shown to avoid the need for mediastinoscopy to a large extent (Figure 12-6). EBUS-TBNA and EUS-FNA have a complementary reach in analyzing mediastinal nodes: EBUS has access to the paratracheal, subcarinal, and hilar regions, and EUS, to the lower mediastinum and aortopulmonary window.

Increasingly, EUS-FNA and EBUS-TBNA are thought of as complementary rather than competitive procedures. In principle, the combined access to mediastinal, hilar, and periesophageal disease affords the most complete staging possible.

As shown above, EUS and EBUS provide access to different areas of the mediastinum. In combining techniques, most lymph node stations as well as the left adrenal gland can be reached (apart from stations 5 and 6). In six recent series, the accuracy of EUS-FNA and EBUS-TBNA used in combination for the diagnosis of mediastinal cancer was 95%. With use of the EBUS scope for concurrent endobronchial and endoesophageal sampling in the same patient, the sensitivity for cancer detection combining the results with both modes of access can be as high as 96% (sensitivity of 89% for EUS and 91% for EBUS); specificity, 100%; and NPV value, 96% (NPV for EUS alone of 82% and for EBUS alone, 92%).

In a recently published trial, the hypothesis of the current guidelines recommending minimally invasive endosonography followed by surgical staging (if no nodal metastases are found by endosonography) as an alternative to immediate surgical staging was proved in a randomized design. Patients were randomly assigned to undergo either surgical staging alone (the surgical staging group, representing the current standard of care) or endosonography (combined EUS-FNA and EBUS-TBNA) followed by surgical staging if no nodal metastases were found at endosonography (the endosonography group, representing a novel alternative staging strategy). A total of 241 patients were enrolled in the trial. Nodal metastases were found in 41 patients by surgical staging and in 56 patients by endosonography, and in 62 patients by endosonography followed by surgical staging. These findings corresponded to sensitivity of 79% (versus 85%) and 94%. Thoracotomy was unnecessary in 21 patients in the mediastinoscopy group, versus 9 in the endosonography group (P = .02). The complication rates were similar in both groups, although a majority of complications in the endosonography group were due to the addition of surgery. The investigators concluded that among patients with NSCLC, a staging strategy combining endosonography and surgical staging versus surgical staging alone resulted in greater sensitivity for detection of mediastinal nodal metastases without unnecessary thoracotomies.

A reasonable approach, therefore, is to begin the staging evaluation with EBUS or EUS. If the result is positive, the staging process is complete. If it is negative, a strategy of surgical staging followed by immediate surgery is recommended.

RESTAGING PATIENTS WITH LUNG CANCER AFTER CHEMOTHERAPY

Patients with N2 disease (stage IIIA) considered unresectable at diagnosis may nevertheless become candidates for surgical resection if chemotherapy or chemoradiation therapy can lead to successful downstaging. Documentation of downstaging (complete histopathologic response in N2 lymph nodes) is essential for such potentially curative resection. Imaging procedures (CT and PET-CT) are helpful in this regard but show unacceptably high rates of false-positive and false-negative results, and a tissue diagnosis is required to guide management. EUS-FNA or EBUS-TBNA, or both, can be performed depending on the location of the lymph nodes initially involved. Usually the mediastinal N2 lymph node that initially was proved to be positive should be rebiopsied using the same techniques. Mediastinoscopy, which is technically difficult as a consequence of fibrosis, especially after radiation therapy, usually is reserved for cases in which analysis of samples obtained by endoscopic needling techniques fails to show malignancy. Compared with initial mediastinoscopy, repeat mediastinoscopy is associated with lower sensitivity and diagnostic accuracy. With all other diagnostic techniques, restaging sensitivity and accuracy are lower than for the initial procedure as a result of the effects of chemotherapy and irradiation on tissues with ensuing fibrosis, as well as tumor shrinkage, necrosis, and cystic degeneration. In a study of 124 patients with NSCLC who had undergone induction chemotherapy, restaging by EBUS-TBNA found persistent nodal metastases in 89 patients (72%); however, 28 of the 35 patients with negative results on EBUS were found to have residual N2 disease at surgery. Therefore, the NPV of EBUS-TBNA in restaging was only 20%.

In a recent published trial, a total of 61 patients underwent restaging EBUS-TBNA. EBUS-TBNA revealed metastatic lymph node involvement in 30% of patients. In 43 patients with negative or uncertain results on EBUS-TBNA, metastatic disease remaining in nodes was diagnosed in nine patients, in seven in stations accessible for EBUS-TBNA, and in two stations not accessible for EBUS-TBNA. The false-negative results of biopsies were found only in small nodes. Moreover, all positive N2 nodes diagnosed by surgery contained only small metastatic deposits. Reported values for diagnostic sensitivity, specificity, accuracy, positive predictive value (PPV), and NPV of the restaging EBUS-TBNA were 67%, 86%, 80%, 91%, and 78%, respectively.

The value of EUS-FNA in restaging of the mediastinum also was evaluated in other trials. The numbers of patients included in these trials are limited in comparison with the EBUS trials, but all series showed an NPV above 90%.

As mentioned before, the adequate restaging technique remains a matter of debate, because comparison of the different techniques is still problematic. Endoscopic techniques are safe and minimally invasive and produce accurate results in comparison with surgical data from repeat mediastinoscopy. However, if results on needle aspiration are negative, surgical restaging is required for adequate assessment of the mediastinum.

CONCLUSIONS AND OUTLOOK

Overall, EBUS and EUS are safe and effective techniques for staging of mediastinal disease. The novel diagnostic modalities of EBUS-guided TBNA and transesophageal ultrasound–guided FNA allow ultrasound-controlled mediastinal tissue sampling. These techniques are minimally invasive, avoiding many of the risks associated with invasive staging procedures.

At present, the main limitation with TBNA is the current restriction of its use to EBUS and EUS, which are performed predominantly at major clinical centers and hence only in selected patients. Training of physicians and surgeons remains the issue, and performance of an adequate numbers of procedures per year is required in order to maintain competency. Reimbursement remains an issue in some countries, as well as actual implementation and incorporation into cancer guidelines within hospitals. Increasingly, both techniques are being used in hospitals across the world, with consequent improvement in diagnostic yield. Use of combined EBUS and EUS, as the first ultrasound techniques for detection of metastases to the mediastinum, has been termed "complete endo-echo staging."

Beyond doubt, implementation of these techniques can be expected to drastically alter lung cancer staging algorithms in the near future. Thanks to its minimally invasive approach, safety record, accuracy, and diagnostic reach, complete ambulatory endoscopic staging of lung cancer may be the way of the future.

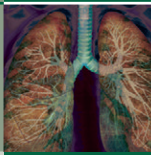
DIAGNOSTIC TECHNIQUES



Chapter 13

Percutaneous Biopsy Procedures: Techniques and Indications

Asia A. Ahmed • Magali N. Taylor • Penny J. Shaw

This chapter describes the techniques and equipment available to obtain diagnostic samples from intrathoracic and selected extrathoracic lesions by the percutaneous route. The common lesions sampled and their locations are listed in Figure 13-1. The most frequent methods of sampling intrathoracic lesions, depending on their site, are summarized in Figure 13-2. The techniques and indications are different from those required to diagnose more diffuse intrapulmonary disease. The latter, which includes conditions such as idiopathic pulmonary fibrosis, requires a transbronchial lung biopsy or an open lung biopsy through a mini-thoracotomy or video-assisted thoracoscopy (VATS) procedure.

Imaging plays an important role in detecting and confirming the site of lesions and in evaluating their size and the quality of the surrounding tissues. Imaging is also used to assess the extent of pathology and the presence of other diseases. The radiologist determines whether lesions are amenable to percutaneous sampling, selects the optimum target for biopsy (often with the aid of positron emission tomography [PET] imaging), and decides which imaging modality is best suited to guide intervention. The choice and size of needle depend on the site, size, and solidity of the lesion, as well as the operator's personal preference. Cores of tissue are invariably obtained, in keeping with requirements for immunohistochemistry analysis, and, increasingly, to assess for the presence of mutations to assist targeted therapy in lung cancer.

METHODS OF TISSUE SAMPLING

Imaging Techniques

Several factors are considered in selecting the most appropriate imaging modality to guide percutaneous tissue sampling. These include the site, size, and depth of the lesion; its proximity to the pleura and neurovascular structures; and performance status of the patient.

Ultrasound

Ultrasound techniques are ideal for imaging superficial lesions including lymph nodes, the pleura, chest wall lesions, and the liver. Certain characteristics, such as the normal fatty hila of lymph nodes, are better depicted on ultrasound examination. Other advantages include easy access, real-time needle visibility leading to reduced time of procedure, and absence of radiation exposure. High-resolution transducers allow access to technically difficult areas, such as the supraclavicular fossae, and patients can be placed in different positions to optimize access. Mobile lesions can be secured by applying gentle pressure with the probe, and if the lesion is close to major vessels, local anesthetic can be introduced to create space around the lesion. Color Doppler imaging is useful to assess lesion vascularity as well as the surrounding structures.

The use of ultrasound imaging becomes limited when lesions lie deep to the skin surface, because resolution decreases and visibility becomes poor. Imaging through air (e.g., the lungs) and bone is inadequate.

Computed Tomography

Computed tomography (CT) offers better contrast resolution between tissues of differing density. Pulmonary and mediastinal lesions, which are often partly surrounded by air, are better depicted. Deeper structures are clearly visualized, and detailed vascular anatomy is obtained with or without contrast enhancement. CT with multiplanar reconstruction provides a panoramic view of any lesion—in particular, its relationship to key structures, including the heart and great vessels. In the lung, CT allows accurate targeting of small lesions and tracking of mobile lesions located close to the diaphragm.

Unlike ultrasonography, CT does involve radiation exposure to the patient. It is of limited use in sampling central parenchymal and nodal disease, because biopsy in this region is associated with greater risks and complications; however, it remains useful for biopsy of mediastinal masses and pulmonary lesions.

Integrated Positron Emission Tomography–Computed Tomography

Positron emission tomography (PET) has an established role in the detection and staging of neoplastic diseases. In lung cancer it provides information on the primary lesion, early nodal involvement, and distant metastases. The positron-emitting agent most frequently used is ^{18}F-fluorodeoxyglucose (FDG). This tracer accumulates at sites of increased glycolysis (e.g., tumor cells), and this activity is then detected by the PET camera. The intensity of activity is displayed on a color scale, and a quantitative assessment is made by measuring the *standardized uptake value* (SUV).

CT combined with PET allows accurate anatomic localization of FDG-avid foci. This technique is particularly useful in isolating active foci surrounded by benign changes, such as within thickened pleura, or in separating tumor from collapse, allowing greater precision in positioning the biopsy needle (Figure 13-3).

The sensitivity of PET is limited by the size of the lesion. Small lesions (usually less than 1 cm) may not accumulate sufficient FDG to be detected on PET imaging, leading to false-negative results. The latter can also occur in tumors with relatively low metabolic activity such as carcinoids and alveolar cell cancers.

Inflammatory conditions such as bacterial pneumonias, abscesses, tuberculosis, and active sarcoidosis are associated with increased granulocytic activity. Such activity promotes increased uptake of FDG, potentially giving rise to false-positive results.

Needles

The two main modes of sampling are fine needle aspiration (FNA) for cytologic study and core biopsy for histopathologic examination. Both methods retrieve samples that are suitable for culture. Although the sensitivity of FNA is improved by having a cytologist present to ensure that an adequate sample is obtained, the diagnostic yield in benign disease remains low (20% to 50%) compared with that for core biopsy (70%) (Greif et al., 1999). In malignant disease, the techniques are analogous, with a sensitivity of 90% to 95% (Klein et al., 1996). The clinical requirement for cores of tissue for immunohistochemical analysis has led to a reduction in the use of FNA, and when feasible, cores are always obtained.

Figure 13-1 Common sites for biopsy.

FNA involves inserting a fine needle into a lesion and carefully moving the tip to and fro within the tissue, to obtain an aspirate. Gentle suction can be applied by attaching a 5-mL syringe to the needle hub. A variety of fine needles are available, including the Westcott, Chiba, Franseen, and Rotex needles, which range in size from 20 to 23 gauge. Larger-gauge needles are smaller in caliber and less rigid in design, which can limit their use. The Westcott needle has the advantage of having a trough close to the needle tip, which captures small cores of tissue in approximately 50% of cases. The main use of FNA is to obtain nodal aspirates.

Core biopsy specimens are obtained using cutting needles, which are larger in diameter (14 to 18 gauge) and are available in different lengths (6-, 9-, and 15-cm lengths are commonly used). These needles are more sturdy, allowing greater control in placement. Cutting needles are typically mounted on a spring-loaded mechanism. Older designs such as the Bard Biopty biopsy system, when triggered, simultaneously fire an inner notched stylet and an outer cutting cannula. The handle of the Bard system is bulky but reusable (**Figure 13-4**). Newer, lighter designs include the Cook Quickcore and Bauer Temno devices, which allow the inner notched stylet to be advanced and secured within the lesion before the cutting cannula is activated. The throw can be increased from 1 to 2 cm to obtain better core samples (**Figure 13-5**). The Cook device seems to have a slightly sharper needle tip, which in practice can be advanced through tougher tissues.

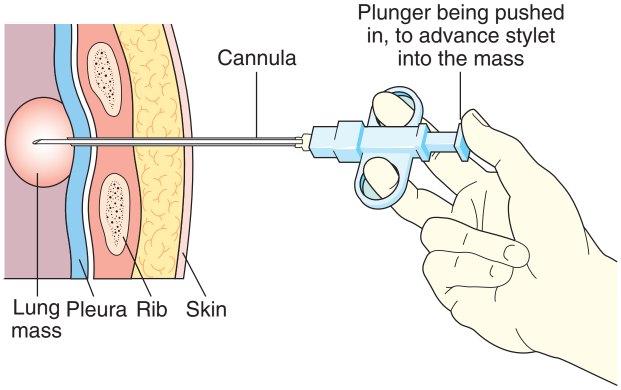

Figure 13-5 The Bauer Temno biopsy instrument. The cutting needle is positioned within the lesion to be biopsied by pushing the plunger. The advantages include that the instrument is lightweight and requires use of only one hand, and that it is easy to use under computed tomography or ultrasound guidance.

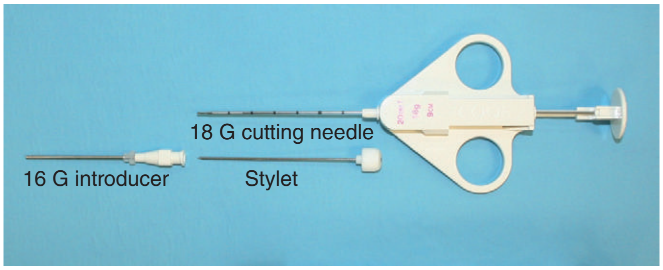

Figure 13-6 The Cook coaxial system. A 16-gauge introducer needle, together with its stylet and 18-gauge inner cutting needle, is shown.

Historically, it was believed that use of larger cutting needles carried higher complication rates than those associated with fine needles. A 2002 study of practice based in the United Kingdom analyzed data from 5444 lung biopsy and FNA procedures and found no difference between the two methods, a conclusion supported by other studies (Richardson et al., 2002).

With transpulmonary biopsy, the risk of pneumothorax is more closely related to the number of pleural passes. The introduction of a coaxial system has transformed lung biopsies. A single pleural pass is made with a thin-walled introducer needle (usually 16 gauge). A smaller cutting needle (usually 18 gauge with a 1- or 2-cm throw) is inserted through the introducer and multiple cores are taken without repuncturing the pleura. The process is quicker, simpler, and safer than attempting multiple pleural passes, leading to a reduction in the complication rate with an improved diagnostic yield (Figure 13-6).

PERCUTANEOUS BIOPSY OF INTRAPULMONARY LESIONS

Indications

The role of percutaneous lung biopsy in diagnosing malignant disease is well established, with a sensitivity of 90% to 95%. Its main application is in patients with inoperable lung cancer, when sputum cytology and bronchoscopy are nondiagnostic, to provide a means of establishing cell type before chemotherapy and radiotherapy. In the past, both FNA and core biopsy have been comparable in diagnosing and distinguishing small cell lung cancer (SCLC) from non-SCLC (NSCLC), providing oncologists with sufficient information to make choices regarding appropriate chemotherapy regimens. New targeted chemotherapy and biologic agents (e.g., the epidermal growth factor receptor [EGFR] inhibitor drugs) have proven prognostic benefit with particular histologic subtypes. This has meant that core sampling is essential to allow routine performance of detailed tissue analysis. FNA can be adequate to differentiate between subtypes of NCSLC, but it remains less accurate overall than core biopsy. The latter allows sufficient material to

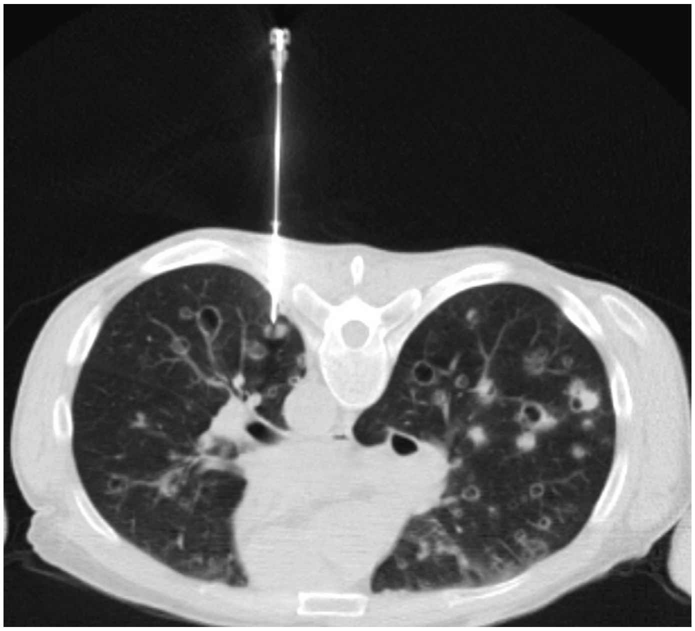

Figure 13-7 Computed tomography (CT)-guided biopsy of a pulmonary nodule using a coaxial system. The patient is in the prone position. Multiple cystic and solid pulmonary nodules in a patient with a history of lymphoma. The diagnosis was Langerhans cell histiocytosis.

be obtained for both accurate histologic subtyping and molecular testing (e.g., to determine EGFR mutation status) (Barnes et al., 2010).

Biopsy also is widely used to exclude lung metastases in patients with potentially operable lung tumors, and in those with extrathoracic malignancies (Figure 13-7).

With solitary pulmonary lesions, core biopsy remains the prudent approach for confirming benign disease. The combined use of CT guidance and the coaxial biopsy system, which allows multiple cores to be taken safely, has improved the diagnostic accuracy of this technique in both benign and malignant disease. If malignancy is strongly suspected, it may be best to avoid biopsy and proceed straight to surgery.

Transthoracic biopsy and FNA also have a role in the diagnosis of non-neoplastic disease. Both techniques are increasingly being used to obtain samples for identification of microorganisms, particularly in immunocompromised patients with consolidation and masses. All samples are routinely sent to both histology (or cytology) and microbiology. Communication with the referring clinician is essential. In cases in which infection is suspected, the first sample should be sent to microbiology should the procedure need to be unexpectedly abandoned. The converse is true in suspected cases of malignancy where the first sample is sent to histology. The working diagnosis may also influence the choice of needle size.

Contraindications

The contraindications to percutaneous lung biopsy are largely relative and are summarized in Table 13-1. In general, patients need to be able to cooperate, including lying still in the desired position, resisting excessive coughing, and controlling breathing. In patients with very poor lung function, biopsy of a lesion is still possible, provided that the lesion is peripheral and a carefully considered route is identified (usually with CT) that does not traverse lung parenchyma. In performing the biopsy, care is taken to avoid creating a pneumothorax, which could be life-threatening. Before the procedure, a coagulation screen is performed according to local protocol, and bleeding diatheses are corrected, when appropriate, to keep within safe guidelines. Biopsy of parenchymal hydatid lesions has been documented, but an increased and probably unacceptable risk of anaphylactic reaction has been documented in patients with such lesions.

Table 13-1 Contraindications to Needle Biopsy

Type of Contraindication	Comment
Relative	Inability of patient to cooperate: uncontrollable cough, inability to lie prone or supine
	Poor lung function/chronic obstructive pulmonary disease (FEV_1 <40% of predicted normal or multiple bullae)
	Pneumonectomy
	Bleeding disorder
	Pulmonary hypertension
	Pulmonary fibrosis
	Small nodules (<5 mm in diameter)
	Hydatid disease (associated with risk of anaphylactic reaction)
Absolute	Arteriovenous malformation with high pulmonary artery pressure

FEV_1, forced expiratory volume in 1 second.

Method

Pulmonary lesions are usually sampled under CT guidance using cutting needles rather than fine needles. The coaxial technique is preferred because it allows multiple consecutive cores to be obtained without delay, helping to improve diagnostic accuracy while minimizing risk. The number of biopsy specimens varies, but in practice, two to five samples are required (fewer if the patient is at high risk of complications). The aim is to obtain a diagnosis without compromising patient safety.

Peripheral lesions located away from fissures and large vessels are ideally targeted, to minimize complications of pneumothorax and hemorrhage. When possible, the approach should cover the shortest distance from the skin surface to the lesion, using a route that allows the patient to be positioned comfortably for a period of at least 30 minutes. The latter consideration is important, because patients are often elderly or frail and breathless at rest.

In lesions obscured by atelectasis, intravenous contrast can be administered to localize abnormal tissue from collapsed lung. PET-CT is useful in identifying avid foci in these cases. If the lesion is cavitating or exhibits central necrosis, the biopsy must be taken from the periphery of the lesion.

Procedure

Preparation

Percutaneous biopsy procedures are arranged as short-stay cases, with the expectation that patients will return home the same day, after a period of observation.

Before the appointment, all patients must have a complete blood count (CBC), and the international normalized ratio (INR) must be checked and corrected when appropriate, to reduce the risk of bleeding. A platelet count greater than 150 $\times 10^9$/L and an INR of 1.4 or less are acceptable lower and upper limits, respectively. Antiplatelet agents (e.g., aspirin, clopidogrel) should be withheld for several days preceding intervention (5 days for aspirin, 7 to 10 days for clopidogrel).

Percutaneous lung biopsy requires that the patient fast beforehand. On the day of the procedure, the patient is admitted to the programmed investigation unit (PIU), where a baseline set of observations are recorded (including heart rate, blood pressure, and oxygen saturation).

The radiologist performing the procedure explains the process, enquires about relevant allergies, and after addressing any queries, obtains written informed consent, documenting potential complications, which occur at a rate greater than 1%. The patient is informed that several samples may need to be taken. Sedation is rarely required but can be used in anxious patients. For administration of such agents, intravenous access is established, and cardiorespiratory monitoring is required. Audio aids (e.g., iPods) are invaluable in relaxing younger patients and adults who are restless.

Practical Aspects

The patient is positioned supine or prone, depending on the anteroposterior location of the lesion. Pillows are used to elevate one side of the chest if necessary, and the arms are positioned to optimize access, avoiding elevation above the head, which typically causes shoulder discomfort in elderly persons.

Radiopaque surface skin markers are placed 0.5 to 1.0 cm apart over the region of interest, and a limited CT scan covering the area is performed with the patient in gentle respiration (Figure 13-8). Once the target lesion is identified, the safest percutaneous route to the lesion is mapped along the axial and sagittal axes, using the CT slice number and surface markers, respectively, as a guide. A cross is drawn on the patient's skin to mark the corresponding entry site and a sterile field is created. Lidocaine 1% (10 to 15 mL) or 2% (5 mL) is infiltrated down to the pleura, with care taken not to puncture the visceral pleura or lung. The patient is warned that it is not always possible to anesthetize the pleura fully, because of the risk of pneumothorax from the anesthetic needle.

With use of the coaxial system, the introducer needle is advanced first, through a small skin incision. Because formal breathing instructions can be confusing to the patient, the respiratory phase is judged from movements of the chest wall. A slight "give" is felt when the pleura is breached, and this thrust should be performed with a smooth, firm motion to avoid shearing the pleura, thereby increasing the chance of a pneumothorax. The progression of the needle toward the lesion and the final position of its tip are intermittently checked by repeating the initial scan as required. One-centimeter markers visable along the length of the introducer needle are a useful guide when advancing the needle. Accurate placement of the needle tip is essential and may take time with small and mobile lesions.

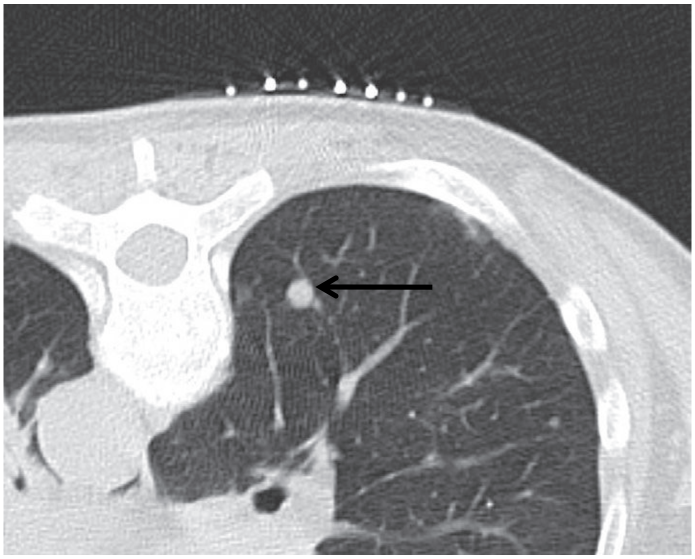

Figure 13-8 Computed tomography (CT)-guided biopsy of a right lower lobe nodule (*arrow*). Surface grid markers, together with slice position, are used to determine the site of needle insertion.

Once the introducer needle is optimally positioned, the central stylet is removed and a finger placed over the hub to prevent air embolism. The cutting needle is then inserted through the lumen of the introducer, and multiple cores are taken, with replacement of the stylet between biopsy maneuvers. The tip of the cutting needle can be angled differently with each thrust, to obtain a representative sample—a technique that is particularly useful when tumors show histologic heterogeneity. Saline (2 to 3 mL) can be injected and aspirated through the introducer needle to obtain microorganisms, when indicated.

Once sufficient samples are obtained safely, the introducer needle is removed in a single swift motion during expiration, and a postbiopsy scan is performed if a pneumothorax is suspected.

Specimen Handling

Specimens should be handled appropriately and sent to the laboratory promptly. Aspirated material is smeared onto slides, with some fixed in alcohol and the rest air-dried, and sent for cytologic studies. A saline wash of the needle is taken for microbiologic analysis. Cores of tissue are placed in formalin for histopathologic examination and in saline for microbiologic studies. Advanced cytologic procedures such as flow cytometry for lymphoma, estrogen receptor status assay for metastatic breast cancer, and immunohistochemistry staining for malignancies are additional useful tests.

Patient Aftercare

After lung biopsy, the patient is monitored in the hospital setting for 4 to 5 hours. A biopsy side–down position should be maintained whenever possible, and excessive talking, laughing, and coughing should be avoided to reduce the risk of pneumothorax. Hourly observations are recorded, and a chest radiograph is taken at 1 and 4 hours after biopsy, to identify any pneumothorax and to monitor its size. If a pneumothorax is detected, high-flow oxygen (10 L/minute) is given, because it improves the rate of reabsorption by up to four-fold. Patients with a small, stable pneumothorax who are otherwise clinically well can still be discharged home safely, provided that they are able to return without delay if signs or symptoms develop.

Complications

A risk-benefit analysis should always be made before any procedure, particularly in high-risk groups (Table 13-2).

The most common complication after lung biopsy is pneumothorax (Figure 13-9). Most pneumothoraces are small (less than 2 cm on chest film) and are managed conservatively. Those requiring intervention usually are detected early: 88% immediately after biopsy and the remainder after 1 hour. A delayed presentation is rare. Intervention can involve aspiration by way of a three-way tap or drainage through a one-way (Heimlich) valve; drainage is performed at a frequency of 0 to 17%. Positioning the patient with the puncture site dependent can reduce the pneumothorax rate and should be considered

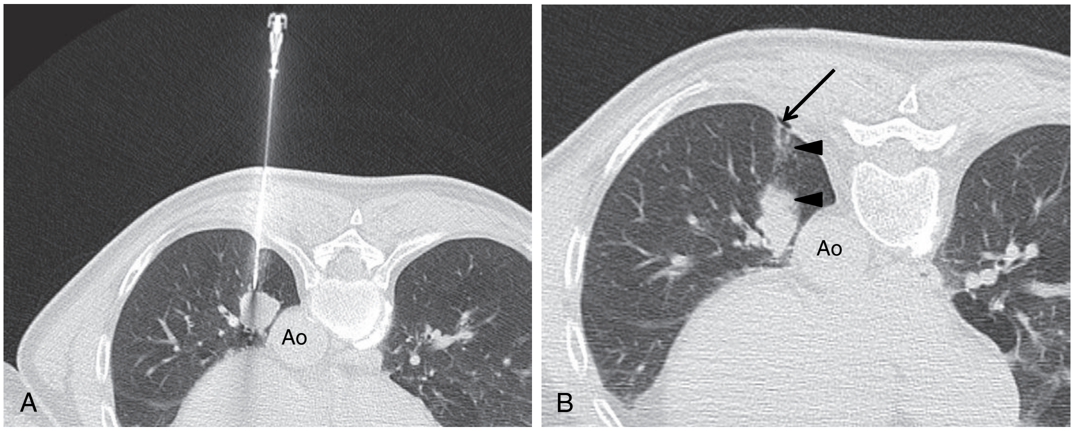

Figure 13-9 **A,** Coaxial computed tomography (CT)-guided biopsy of a solitary pulmonary nodule in the left lower lobe in a patient with a history of colonic carcinoma. The needle is angled away from the aorta (Ao). **B,** After biopsy, a tiny pneumothorax (*arrow*) can be seen, along with the needle tract and perilesional hemorrhage (*arrowheads*). The diagnosis was carcinoid.

Table 13-2 Complications of Needle Biopsy

Category	Complication/Cause
Early complications	Pneumothorax: 5-50% Hemoptysis: 5-10% Hemorrhage: 10-40% Air embolism: rare
Late complications	Tumor seeding: extremely rare Empyema Bronchopleural fistula
Increased risk of pneumothorax	*Common associations*: • Chronic obstructive pulmonary disease or bullae • Uncontrollable coughing during the procedure • A small central lesion *Less common associations*: • Multiple pleural passes during procedure • Passage of instrumentation across fissure during procedure • Prolonged procedure

in patients at high risk. Surprisingly, use of a cutting needle does not increase the incidence of pneumothorax over that with fine needle aspiration, the pneumothorax rate being in the range of 3% to 42%. Tension pneumothorax is rare but may be seen in patients with emphysema. It develops within minutes and constitutes a medical emergency.

Minor perilesional hemorrhage is common (see Figure 13-9); however, actual hemoptysis occurs in only 4% to 5% of biopsy procedures (Richardson et al., 2002) and is more common in patients with pulmonary hypertension. It often follows a bout of coughing and can be extremely frightening for the patient. Supportive measures are initiated with the patient positioned biopsy side down. Treatment is rarely required, because spontaneous recovery is rapid. Massive hemoptysis rarely occurs and can be fatal.

Although rare, a systemic arterial air embolism is a serious and increasingly recognized complication of interventional lung procedures, and its effects can be clinically subtle (Hiraki et al., 2007). It occurs when air enters into the pulmonary venous circulation, is pumped through the left side of the heart, and subsequently enters the cerebral and coronary arteries, which become occluded. Air may enter the pulmonary veins by two main processes. It can be drawn in from the atmosphere, through the introducer needle on deep inspiration, when the hub is temporarily exposed in between biopsies. Entry of air through this route is avoided by promptly covering the hub with the thumb each time the cutting needle or stylet is withdrawn, and by asking the patient to hold the breath during the process. Alternatively, air can enter the pulmonary veins through the airways along the needle tract during a bout of coughing. To prevent this from occurring, needles should be removed during uncontrollable coughing. Rapid diagnosis and treatment of a pulmonary venous air embolism are essential. The patient should be placed in the right lateral decubitus position, and 100% oxygen should be administered while awaiting transfer to a hyperbaric oxygen chamber if available. A CT scan of the head and chest should be performed to confirm the diagnosis.

Reported mortality rates for transpulmonary biopsy range from 0.07% to 0.15% (Richardson et al., 2002; Tomiyama et al., 2006). Death may result from cardiac arrest, systemic arterial air embolism, tension pneumothorax, or hemorrhage.

Pitfalls and Controversies

In malignant disease, percutaneous sampling of pulmonary lesions carries a high sensitivity with use of the coaxial system, even if the nodules are small. This has reduced the need to recall patients for repeat biopsies, because the sensitivity for detection of malignancy has risen to 90% to 95%.

In benign disease, FNA has a relatively poor diagnostic yield. Sensitivity is improved by obtaining multiple cores using a cutting needle and the coaxial system, a technique that has been used in the diagnosis of cryptogenic organizing pneumonia, Wegener granulomatosis, and some infections.

Diagnostic difficulties still arise with lesions exhibiting a high level of fibrosis—for example, metastatic breast carcinoma and Hodgkin disease. Excess mucus production as in bronchoalveolar carcinoma also can interfere with establishing the diagnosis.

Biopsy of a solitary mass with suspected malignancy that is potentially operable remains controversial, because the lesion is likely to need removal. In any case, the advantages of biopsy are that the patient and the surgeon are better informed, and that the operation time is shortened by avoiding the need for frozen sections.

There remain four indications for biopsy of a noncalcified solitary pulmonary nodule: First, if benign disease is suspected, biopsy may obviate the need for surgery; second, in a lung

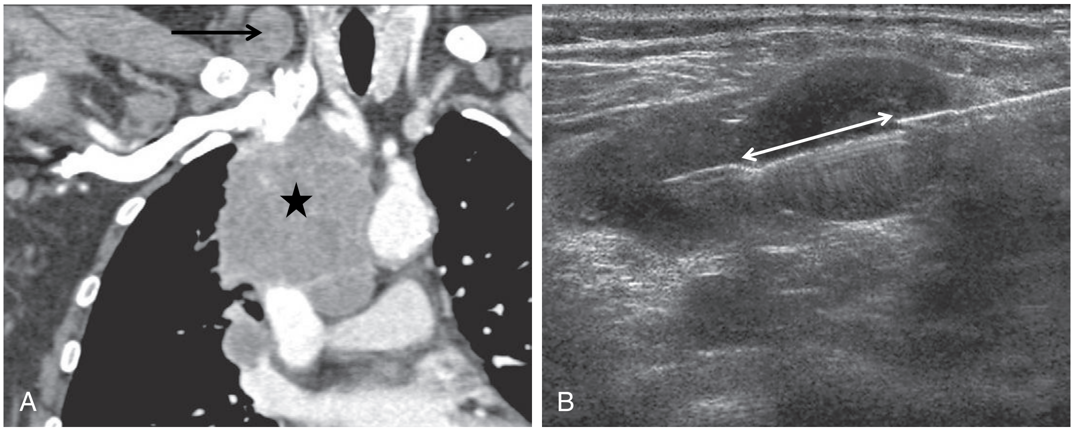

Figure 13-10 **A,** Coronal computed tomography (CT) image showing a large right paratracheal lymph node mass (*star*) and right supraclavicular lymphadenopathy (*arrow*). **B,** Ultrasound-guided biopsy of the supraclavicular lymphadenopathy in the same patient. Two adjacent nodes have been targeted, allowing for a longer, 2-cm sample to be taken. The recess of the biopsy needle is seen (*double arrow*) before triggering of the cutting mechanism. The diagnosis was small cell lung cancer.

cancer patient who is a poor operative candidate, it may be necessary to obtain tissue to optimize treatment with nonsurgical therapies (radiotherapy with curative intent); third, in a patient with an extrathoracic malignancy where a metastasis is suspected; fourth, a fully informed patient may wish to confirm the diagnosis of cancer, even if the suspicion of cancer is high, before proceeding to surgery.

ULTRASOUND-GUIDED BIOPSY: GENERAL PRINCIPLES

Preparation

Ultrasound-guided sampling of superficial lesions usually requires no fasting or formal hospital admission, and observations are recorded only if the patient history includes clinical concerns. Hematologic indices are checked and optimized beforehand, and antiplatelet therapy is withheld, in accordance with protocols for CT-guided procedures.

Practical Aspects

The site of the lesion or tissue usually determines the optimal positioning of the patient. For example, nontargeted pleural biopsy requires that the patient sit upright, facing away from the radiologist, with the arms folded to spread apart the shoulder blades. Supraclavicular node sampling, on the other hand, is performed with the patient supine, with the shoulders raised on a pillow, allowing the neck to be slightly hyperextended. Time spent ensuring that both patient and radiologist are comfortable helps ensure a quick procedure, avoiding unwanted “shuffling.”

With targeted biopsy procedures, the ultrasound probe (curvilinear or linear) is adjusted until the lesion can be seen along its greatest length. Once this is achieved, the probe is held secure, and a line is drawn on the patient’s skin to mark the orientation of the probe, which is then removed. The skin entry site is prepared, and a cryogesic (ethyl chloride) freezing spray can be applied to numb the skin, particularly in young patients.

Under sterile conditions, the probe is reapplied to the skin (using the marker as a guide to positioning), and local anesthetic (up to 10 mL of 1% lidocaine) is infiltrated down to the lesion using a 21 gauge (green) needle. Deep to the skin, the needle is kept in view by advancing it directly in line with the transducer. The angle between the needle and the skin is adjusted depending on the depth of the lesion. Administering local anesthetic reduces discomfort for the patient, creates a passage to the lesion, and also gives the radiologist an idea of how to angle the larger biopsy needle.

Depending on the size of the lesion, a cutting needle with a 1- or 2-cm throw is selected. Adjacent lymph nodes can be lined up and sampled simultaneously, enabling the 2-cm throw to be used more often, which is preferable, because it provides a better specimen (Figure 13-10). After a small skin incision is made, the biopsy needle is introduced and carefully observed as it is advanced toward and into the lesion. With the tip of the needle secured well within the lesion (which often requires a firm nudge to pierce its capsule or wall), the whole apparatus can be flattened out, so that the inner stylet can be advanced through but not out of the lesion. Once the stylet is optimally positioned, the biopsy specimen is taken by pushing the trigger, after the patient is warned to expect a clicking sound. The needle is then swiftly withdrawn, and pressure is applied to the skin to control any bleeding; the process is repeated as appropriate after the first sample is retrieved.

Aftercare

After an uncomplicated superficial biopsy procedure, the patient can be discharged home after a brief period of observation, if clinical stability is maintained. Advice is given on necessary precautions and signs and symptoms necessitating urgent medical attention. High-risk patient groups (e.g., elderly persons and those with an underlying coagulopathy) and high-risk procedures (e.g., targeted liver biopsy, as discussed later on), are the exceptions and require closer observation or an overnight stay.

PERCUTANEOUS SAMPLING OF EXTRAPULMONARY INTRATHORACIC TISSUES

MEDIASTINAL NODES AND MASSES

Method

Depending on the location, mediastinal lesions can be accessed endoscopically (by the transbronchial or transesophageal route), surgically with VATS or through an anterior mediastinotomy, or percutaneously under image guidance, if a safe route that avoids traversing the lung is available.

CT is preferred to ultrasound imaging to guide percutaneous mediastinal biopsy, because it helps to map a direct route

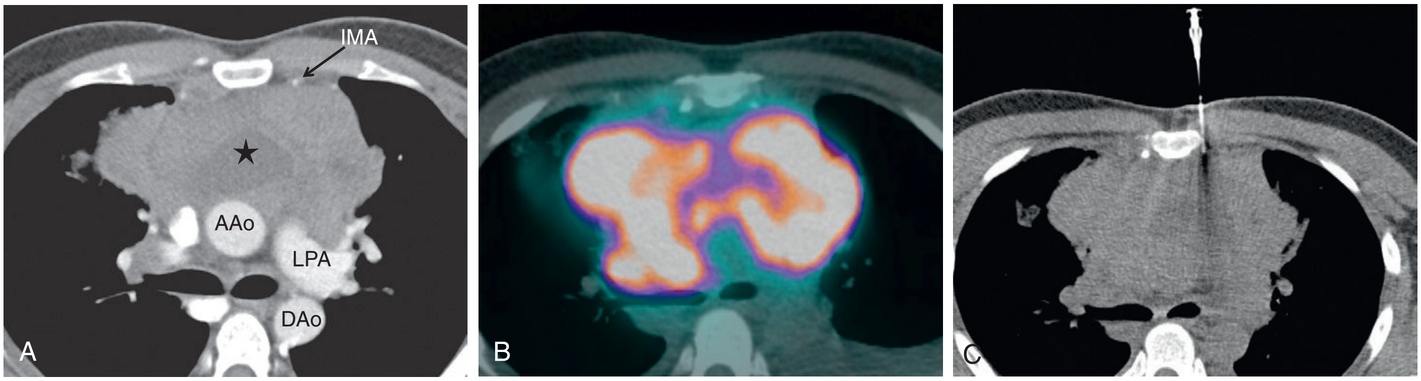

Figure 13-11 **A,** Contrast-enhanced computed tomography (CT) scan shows a large anterior mediastinal mass with central low-density necrosis (*star*). **B,** Integrated CT–positron emission tomography (PET) study shows FDG avidity within the mass, with a central photopenic area corresponding to the necrosis on CT scan. **C,** CT=guided biopsy. The approach is medial to the left internal mammary artery and targets the non-necrotic portion of the tumor. *AAo*, ascending aorta; *DAo*, descending aorta; *FDG*, ^{18}F-fluorodeoxyglucose; *IMA*, internal mammary artery; *LPA*, left main pulmonary artery.

through the chest wall to the mass, which avoids puncturing lung or vessels (particularly the internal mammary vessels). Contrast-enhanced CT and color Doppler ultrasound techniques are essential tools for assessing vascularity.

With large mediastinal masses abutting the chest wall, a biopsy route that avoids the lung parenchyma is readily available (Figure 13-11). With smaller lesions, a safer route may be achieved with use of a transpleural approach through an existing effusion or pneumothorax. Saline can be injected into the pleural space where there is no effusion, or directly into the mediastinum, providing an extrapleural route. Placing the patient in the lateral decubitus position to shift the mediastinum also can help to create an extrapulmonary route. These alternative approaches are associated with reduced incidence of complications.

Core biopsy specimens are necessary to diagnose primary mediastinal tumors (e.g., lymphomas, thymomas). Multiple cores for immunohistochemistry studies are required to differentiate lymphoma from other lesions and can be obtained using the coaxial needle technique.

Limitations and Complications

Breathing can cause small lesions to move out of the biopsy plane and, with use of the extrapleural route, can result in inadvertent introduction of the biopsy needle into the lung or pleura. With biopsy of anterior mediastinal lesions, damage to the internal mammary vessels can result in serious hemorrhage. When feasible, a parasternal approach is adopted, with use of CT guidance to minimize this risk. With biopsy of posterior mediastinal lesions, a paravertebral route can occasionally cause injury to the paravertebral and intercostal neurovascular structures, and the azygous vein.

MEDIASTINAL COLLECTIONS

Mediastinal abscess secondary to esophageal rupture is a life-threatening condition associated with high mortality. Percutaneous aspiration or drainage is considered a useful alternative to surgery, particularly in patients unfit for a general anesthetic procedure.

Method

Mediastinal drainage is performed under CT guidance using a Seldinger technique. After administration of a local anesthetic, a 17 or 18 gauge, long puncture needle is advanced into the collection, often under gentle suction applied with a syringe. This technique allows aspiration of the contents when the fluid collection is breached and also helps to confirm the position of the needle tip. The syringe is removed, and a guidewire is fed through the needle into the fluid collection. With the guidewire held firmly at the entry site, the needle is withdrawn and a tract is dilated over the guidewire. The drain then replaces the dilator, and the guidewire is withdrawn. Usually size 10 or 12 French (10F or 12F) drains are used, depending on the viscosity of the fluid.

HILAR LESIONS

Percutaneous CT-guided biopsy of hilar lymph nodes and masses has been performed, but the technique is limited by the depth of the location, proximity to major vessels, and the associated risks of pneumothorax and hemorrhage. Endobronchial ultrasound (EBUS) has largely replaced CT-guided biopsy for this indication, providing better access to the central thoracic structures and a safer route for sampling hilar and mediastinal tissues.

PLEURAL AND CHEST WALL DISEASE

Non-targeted pleural biopsy often is performed to diagnose benign conditions such as pleural tuberculosis. Targeted pleural and chest wall biopsies usually are undertaken to exclude malignant disease, which may be suggested by focal FDG avidity detected on PET imaging. Cores of tissue are essential in differentiating mesothelioma from metastatic adenocarcinoma.

Method for Non-targeted Pleural Biopsy

If no discrete pleural mass is present, or there is simply diffuse pleural thickening, a non-targeted ultrasound-guided biopsy is performed. This procedure can be undertaken only if sufficient pleural fluid is present. A suitable biopsy site is identified on ultrasound imaging, and the depth from the skin to the parietal pleura is measured. Local anesthetic is administered down to the pleural space until fluid is aspirated. The depth of the anesthetic needle at this point also gives an estimate of the distance from the skin to the parietal pleura. Guided by these measurements, the tip of the biopsy needle is positioned proximal to the parietal pleura, so that when the stylet is advanced, the notch traverses the width of the pleura to enter the pleural space. The core obtained should therefore contain the full thickness of the pleura and some pleural fluid.

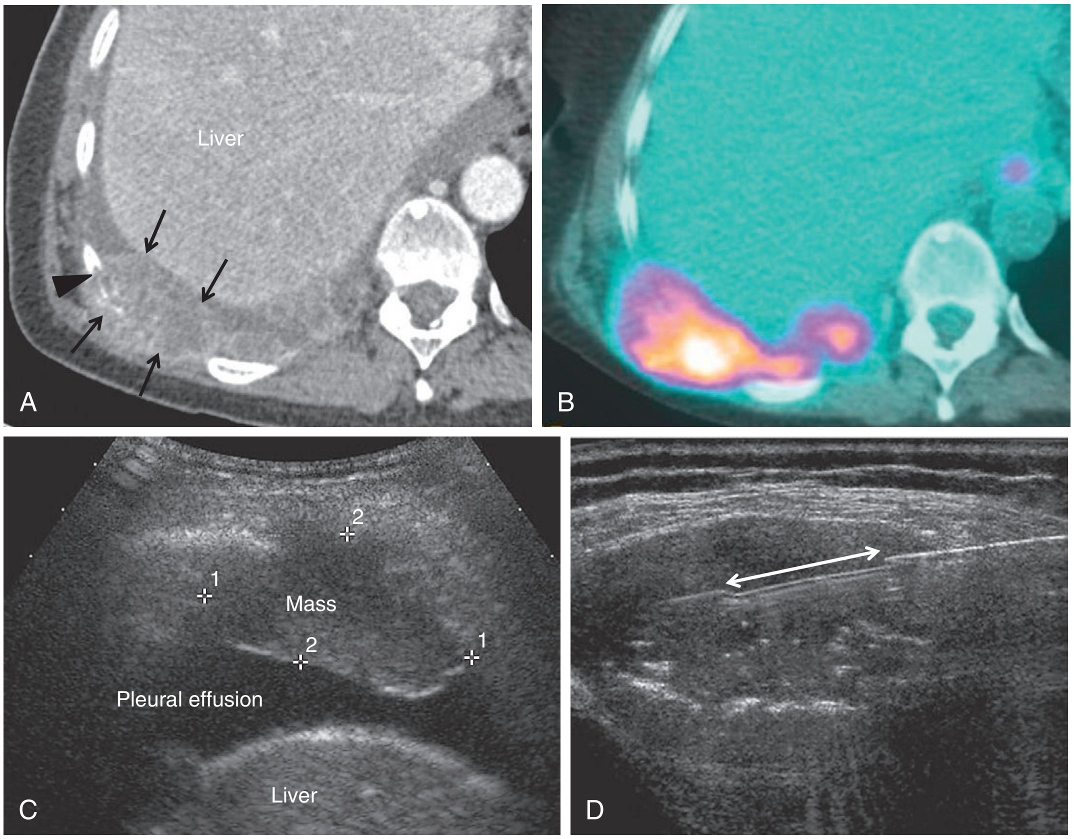

Figure 13-12 **A,** Contrast-enhanced computed tomography (CT) scan shows a heterogeneous pleural mass (*arrows*) that is invading the chest wall and destroying the adjacent rib (*arrowhead*). A small pleural effusion is evident. **B,** CT–positron emission tomography (PET) study was performed for staging and shows that the mass is FDG-avid. **C,** Ultrasound image demonstrates the mass (*cursor* at *1*, *2*). **D,** Ultrasound-guided biopsy, with the recess of the needle advanced through the tumor (*double arrow*). The diagnosis was metastatic adenocarcinoma. *FDG*, ^{18}F-fluorodeoxyglucose.

Method for Targeted Pleural and Chest Wall Biopsies

Targeted pleural and chest wall biopsies are indicated to sample a discrete mass and are usually performed under ultrasound guidance (Figure 13-12). If visualization is difficult with use of ultrasound imaging, or if the lesion is small, with insufficient pleural fluid, biopsy is performed under CT guidance. The optimum route is one that runs along the main axis of the pathologic process (i.e., an oblique tract), allowing more of the lesion to be sampled with less risk of pneumothorax (Figure 13-13).

Several cores (at least three) are taken, and if the pleura is not particularly thickened, multiple passes may be required. Radiologists favor the 18 gauge Cook Quickcore or Temno cutting device. The coaxial system can be used for pleural biopsy procedures performed under CT guidance. Samples are sent for microbiologic and histologic examination. If the pleural lesion is large and the patient remains asymptomatic after biopsy, no chest radiograph is required before discharge.

Diagnostic Yield

Imaging-guided pleural biopsy using a cutting needle has a sensitivity of 88%, specificity of 100%, and an overall accuracy of 91% for detection of malignant disease.

PERCUTANEOUS SAMPLING OF EXTRATHORACIC LESIONS

During staging of thoracic malignancies, lesions may be identified in the liver, adrenal glands, lymph nodes or bones. If

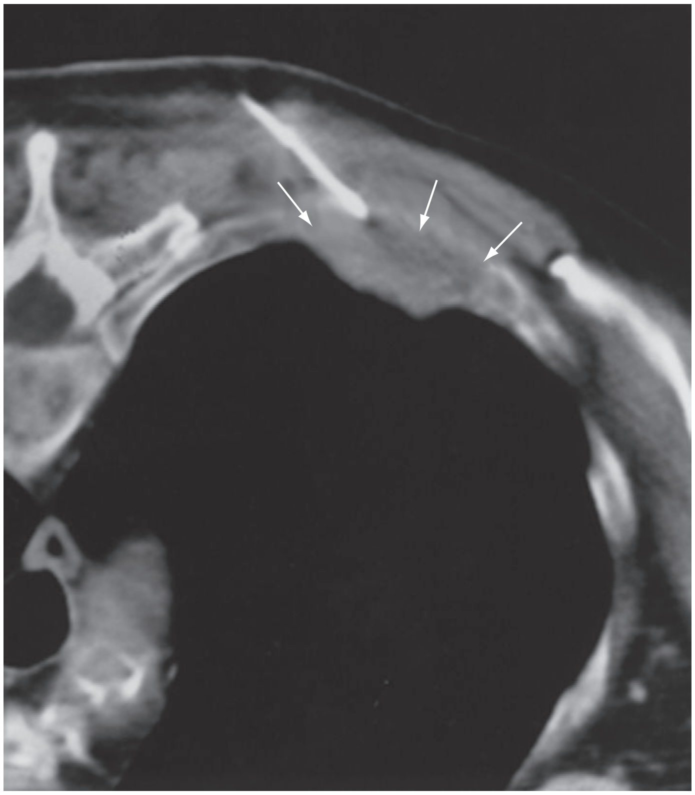

Figure 13-13 Computed tomography (CT)-guided biopsy of a rib metastasis (*arrows*). The diagnosis was non–small cell carcinoma.

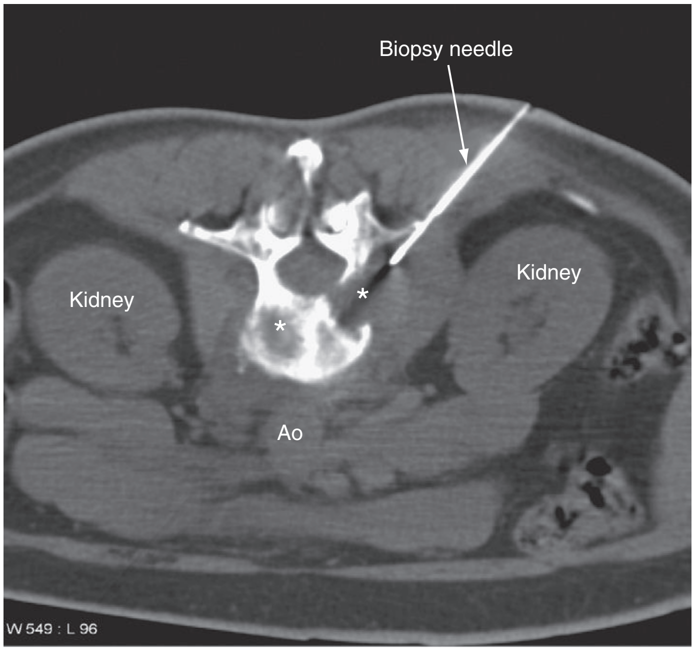

Figure 13-14 Computed tomography (CT)-guided biopsy of a lytic vertebral lesion (*star*). *Ao*, aorta.

appearances suggest metastases (e.g., increased FDG avidity on PET imaging), it is essential to perform a biopsy to confirm inoperability (**Figure 13-14**). If multiple sites are involved, several factors are considered in deciding which tissue to sample—for example, the extent of the disease, the likelihood of obtaining a diagnostic sample safely, and how accessible the site is with a minimally invasive approach.

LIVER

Method

Hepatic lesions usually are biopsied under ultrasound guidance, where they are easily imaged and rapidly sampled (**Figure 13-15**). Owing to the risk of bleeding and the potential need for intervention, preoperative preparation of the patient includes fasting for 6 hours before the procedure.

Ultrasound scanning is performed with the patient supine, with the right arm elevated to allow access to the right upper quadrant. The liver is scanned with a curvilinear probe, and the optimum target is identified. Metastatic deposits can be well- or ill-defined and will vary in size, number, echogenicity, and echotexture, but most often they are solid and hypoechoic relative to the surrounding parenchyma. The lesion that can be reached by the shortest intraparenchymal route while avoiding the gallbladder and the hepatic and portal vessels (which are highlighted on color Doppler) is selected for sampling.

With strict adherence to aseptic technique, local anesthetic is infiltrated down to the liver capsule, which has a rich neurovascular supply. The tip of the anesthetic needle is kept in full view to avoid breaching the capsule, because this can increase the risk of bleeding. A small skin incision is then made, and a larger cutting needle is introduced (usually 18 gauge); radiologists at our institution favor the traditional Bard Biopty biopsy system, which obtains a 1-cm core. The biopsy sample is taken with the patient in arrested respiration to limit movement. If insufficient tissue is obtained with a single core, the biopsy can be repeated. However, careful risk-benefit analysis should be made, owing to the increased risk of hemorrhage associated with multiple passes (Grant et al., 1999). In practice, no more than two cores are usually taken. Although multiple cores are avoided, the coaxial system can still be useful, as hemostatic agents (such as Gelfoam sponge) can be inserted down the introducer needle as it is withdrawn, helping to control bleeding along the biopsy tract.

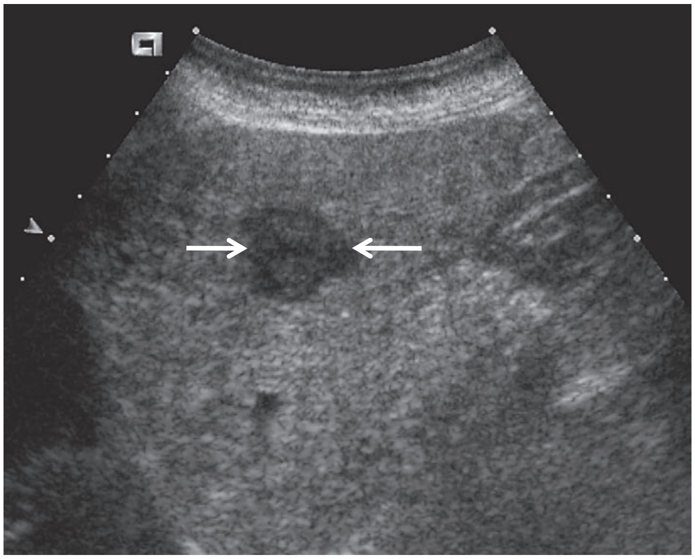

Figure 13-15 Ultrasound image showing a hypoechoic liver metastasis (*arrows*), which can be targeted for biopsy.

Aftercare

Post biopsy, patients are observed for at least 6 hours. Blood pressure and pulse are recorded at gradually increasing intervals to observe for signs of early bleeding, and analgesia is prescribed if pain develops. Patients can remain supine or lie right side down, with no evidence to support a particular position.

A study of more than 9000 liver biopsies showed that the risk of hemorrhage not only is related to the number of passes made but also is closely associated with the presence of malignancy and the age of the patient (McGill et al., 1990). Given these risk factors, in the context of malignant liver disease, patients undergoing targeted biopsy usually are admitted overnight for careful observation.

A retrospective study of 68,276 percutaneous liver biopsy procedures (performed over a decade) demonstrated that the majority of complications occur early on (61% in the first 2 hours), with most detected within a day (96% within 24 hours). Death was uncommon (with 9 deaths reported per 100,000 procedures) but occurred in patients with either underlying malignant disease or cirrhosis and was due to intraperitoneal hemorrhage, with signs of bleeding seen within 6 hours (Piccininio et al., 1986). After 24 hours, if clinical status remains stable and pain has subsided, the patient can be discharged home with advice to return if any delayed symptoms are experienced.

ADRENAL GLANDS

Biopsy of adrenal lesions is usually performed under CT guidance (**Figure 13-16**). It may be necessary to traverse the pulmonary or hepatic parenchyma to enter the adrenal mass. If the mass is on the side opposite the primary lung carcinoma, the pulmonary parenchymal route should be avoided, because a pneumothorax could delay surgery or result in significant

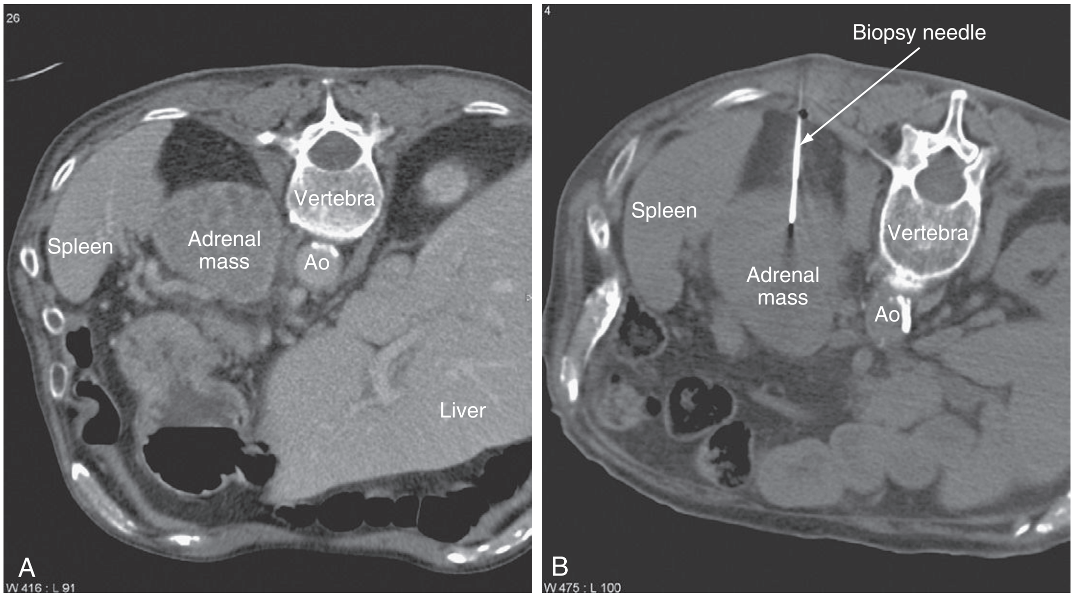

Figure 13-16 **A,** Contrast-enhanced computed tomography (CT) scan shows a large adrenal mass lateral to the vertebral body and aorta (Ao). **B,** CT-guided biopsy with the patient in the prone position. The needle tip is in the mass. The diagnosis was metastatic lung cancer.

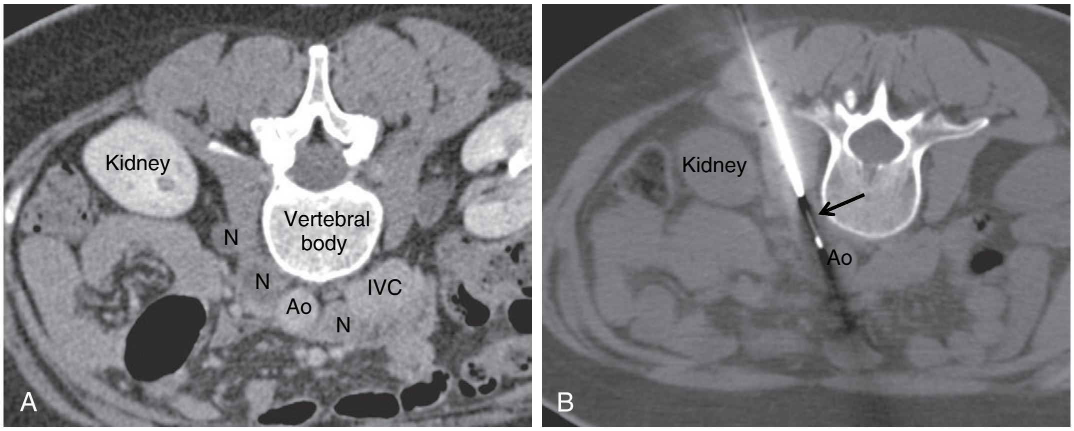

Figure 13-17 **A,** Contrast computed tomography (CT) scan shows necrotic retroperitoneal lymph nodes (N). *Ao*, aorta; *IVC*, inferior vena cava. **B,** Coaxial CT-guided biopsy. The patient is prone, and the outer needle has been advanced through the left psoas muscle. The inner cutting needle also has been advanced, the recess of which can be seen within the lymph node (*arrow*).

respiratory compromise. A coaxial system is invaluable, allowing several aspirates or cores to be obtained with a single pass of the introducer needle.

LYMPH NODES

Biopsy of enlarged lymph nodes (greater than 1 cm in short axis) often provides diagnostic tissue when it is difficult to obtain from the primary lung lesion and also aids staging. Smaller, subcentimeter nodes can be targeted if increased FDG activity on PET imaging suggests early metastatic involvement.

The supraclavicular regions, axillae, and retroperitoneum are the usual sites of lymphadenopathy in primary diseases of the lung. In lung cancer, detecting supraclavicular lymph node metastases is crucial, because it constitutes a contraindication to surgery (stage IIIB).

Ultrasound imaging is commonly used to identify and sample abnormal nodes. Nearly a third of patients with lung cancer have nonpalpable supraclavicular nodal metastases, detectable on ultrasound-guided FNA. This frequency increases to almost 50% in patients who have mediastinal nodal metastases. The advantage of ultrasound imaging is that it allows accurate assessment of nodal size and can identify pathologic features (e.g., rounded morphology, loss of echogenic hilum, peripheral vascularity) that are not detectable clinically.

Superficial nodes, including supraclavicular and axillary, are amenable to ultrasound-guided biopsy, which is a simple and safe procedure. Biopsy of retroperitoneal masses (including lymph nodes) requires CT guidance (Figure 13-17). Core biopsy is preferable to FNA. A 16 or 18 gauge cutting needle is used, depending on the site.

BONE LESIONS

The presence of bone metastases confirms stage IV lung cancer. Lesions are typically osteolytic and common sites for metastasis include the spine, ribs, and pelvic bones. The indications for bone biopsy are variable but typically include a suspicious bone lesion (usually detected on CT, PET-CT, or bone scan) in a patient with potentially curable disease. A bone biopsy is considered to complete the staging process, if no other tissue amenable to sampling (e.g., a lymph node) is available. If the bone lesion is superficial (e.g., a rib metastasis), biopsy can be performed under ultrasound guidance. CT guidance is preferred if the lesion lies deep and is close to major neurovascular structures.

PLEURAL DRAINAGE

Indications and Contraindications

Common causes of exudative effusions are malignancy and empyemas. In patients with a community-acquired pneumonia, 40% develop a parapneumonic effusion. Most cases resolve spontaneously, but the effusion can progress to form an empyema. Early and rapid drainage of an empyema is essential to prevent fibrin deposition, which potentially leads to pleural fibrosis and possibly a restrictive defect. An esophageal rupture or endobronchial lesion should be considered in a patient with an empyema without an obvious predisposing cause.

A pleural effusion can be tapped for diagnostic purposes, and a pleural biopsy performed at the same time if indicated. A pleural effusion can be drained for therapeutic purposes if it is large and the patient is symptomatic (usually with a malignant effusion), if it is infected or is an empyema (if the glucose is low, or the pH is less than 7.2), or if a hemothorax is present (usually after trauma). A bleeding disorder is a relative contraindication to pleural drainage, predisposing to hematoma formation.

Technique

Ultrasound imaging is the easiest and quickest way to confirm the presence and volume of pleural fluid and also demonstrates the presence of echogenic material, septa, and multiple locules, which may require multiple drainage tubes (Figure 13-18).

CT has an advantage in evaluating any underlying lung or mediastinal pathology. In empyemas, the pleurae characteristically are smooth and diffusely thickened and enhance after intravenous contrast injection.

Procedure

A large effusion can be drained without image guidance, but smaller or multiloculated effusions are better drained by the radiologist. For this procedure, the seated patient leans forward, "hugging" a pillow against the chest to bring the arms forward and clear the scapulae from the back. A small stool placed under the feet makes the patient feel more comfortable, and the optimum skin position is marked, just above a rib to avoid the intercostal vessels and nerves. A sterile technique with local anesthetic is used. The size of the drainage catheter varies, ranging between small pigtail catheters and large catheters for empyemas.

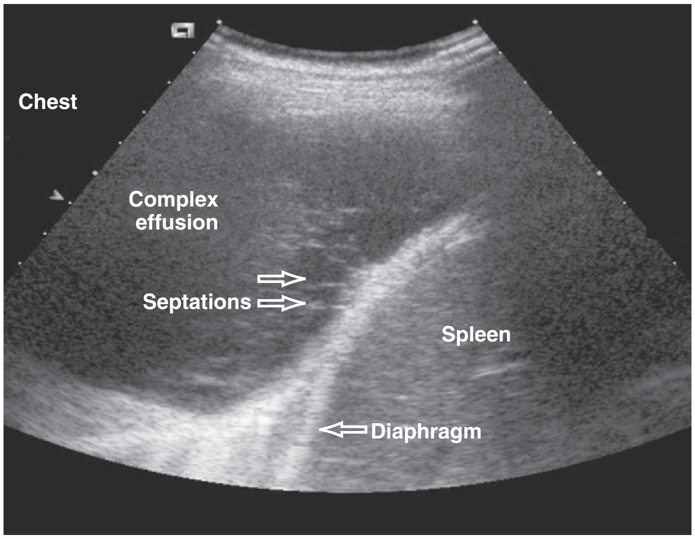

Figure 13-18 Ultrasound image showing a complex pleural effusion with multiple septations.

The depth of the effusion can be judged by both ultrasound imaging and with use of the local anesthetic needle. The catheter can be positioned by means of a Seldinger technique or with a single-step procedure. The latter is often used and involves advancing the catheter with its central stylet into the pleural space. A slight "give" is felt when the pleura is breached, and at this point the catheter is advanced into the effusion while the central stylet is simultaneously withdrawn. The catheter is connected rapidly to a drainage bag and a three-way tap. Samples for cytologic, microbiologic, and biochemical analysis are taken. If drainage is for a short time (24 to 48 hours), use of a bag will normally suffice. If drainage is required for a longer duration (normal with empyemas) or if the effusion is large—presumably because of active fluid production, the drainage bag is replaced by an underwater drainage system.

If aspiration is undertaken, no more than 1.5 L of fluid should be removed at any one time because of the risk of reexpansion pulmonary edema. Larger catheters can be used, but smaller catheters usually are adequate and more comfortable. The catheters should be securely fastened to the skin, and regular saline irrigation should be performed to maintain patency (20 mL of saline every 4 to 6 hours). In some patients, intrapleural fibrinolytics (e.g., streptokinase) given early may improve drainage but are not routinely used, because use of such agents has not been found to reduce long-term mortality or complication rates and may be associated with adverse reactions.

Complications

Complications are few, provided that no bleeding disorder is present. Pneumothorax occurs in less than 5% of cases. Puncture of other viscera can be avoided by inserting the catheter under ultrasound guidance and with blunt dissection through the chest wall to avoid traumatizing the catheter. Pain may occur at the site of insertion, but this is minimized by inserting the catheter laterally for patient comfort. Reactions to streptokinase are much fewer when the purified form is used but previously have included anaphylaxis and bleeding, both intrapleurally and systemically, with larger doses.

Pitfalls and Controversies

The routine use of intrapleural streptokinase has still not been widely adopted because of the expense and the complications associated with the use of the less purified form and the occasional occurrence of large hemorrhages. Its efficacy in the overall management of empyemas remains uncertain.

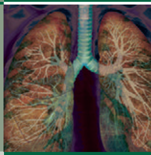
Section 2
DIAGNOSTIC TECHNIQUES



Chapter 14
Echocardiography in Respiratory Medicine

Jonathan R. Spiro • Richard P. Steeds

The role of echocardiography within clinical medicine has grown dramatically over recent decades, for several reasons. First, the progressive increase in use of echocardiography has mirrored a decline in clinical examination skills previously required for cardiorespiratory diagnosis. Second, it generally is recognized that the clinical diagnosis of many common cardiac conditions such as pericardial effusion, early ventricular dysfunction, and silent valvular disease is a challenge for even the most experienced clinician, yet such conditions can be rapidly diagnosed by echocardiography. Third, early etiologic diagnosis leads to rapid institution of an appropriate management plan, as evidenced by the fact that the frequency of cardiorespiratory misdiagnosis in unselected patients who died while hospitalized has halved over the past 20 years, in parallel with the increasing use of echocardiography. The combination of sophisticated technology, powerful computing, and improved operator ability has, however, translated to the production of large amounts of data, often highly complex in nature, which can be difficult to interpret. Consequently, training in performing and interpreting an echocardiogram has become significantly more rigorous.

Owing to the inherent interrelationship of the cardiovascular and respiratory systems, important clinical and prognostic information may be obtained from echocardiographic evaluation of patients with acute and chronic respiratory disease. Advantages of the technique include wide availability, portability, low cost, and provision of high-quality diagnostic imaging without the use of ionizing radiation. Despite many favorable characteristics, echocardiography has important limitations. Accuracy of data is reliant on the availability of a high-quality acoustic window, which often may be limited in respiratory disease, when hyperexpansion of lungs or the use of ventilatory support may limit ultrasound transmission. In such circumstances, echocardiography is technically challenging. This chapter provides an overview of the important components of the echocardiographic examination, including techniques, views, and structurally based measurements, in evaluation for specific respiratory disease states. The information thus obtained may assist or influence decisions regarding diagnosis, management, and prognosis.

ECHOCARDIOGRAPHIC PLANES AND RIGHT-SIDED HEART STRUCTURES

The right ventricle (RV) is located anterior to the left ventricle (LV) and is positioned just behind the sternum. When viewed anteriorly, the right ventricular cavity appears triangular in shape; however, it takes a crescentic shape in cross section. This anatomic orientation means that no single acoustic window allows visualization of the whole of the RV, so multiple transducer positions must be used. Standard echocardiography of the right side of the heart includes use of the parasternal (long-axis, right ventricular inflow, short-axis) (see Videos 1 and 2), apical (four-chamber) (see Video 3) and (modified four-chamber), and subcostal acoustic windows (see Video 4), generating a report that includes a qualitative description of right-sided heart anatomy and function, with at least one measurement of right atrial and right ventricular size, and a quantitative assessment of right ventricular function (**Table 14-1**). The venous inflow to the right side of the heart comprises the coronary sinus, superior vena cava, and inferior vena cava. The venous inflow is easily visualized from the parasternal acoustic window, in the right ventricular inflow view (**Figure 14-1**, *A*, and Video 5) and from the parasternal acoustic window, in the right ventricular inflow view (see Figure 14-1, *B*, and Video 4). The right atrium, tricuspid valve, and RV (inlet, free wall, apex, and infundibulum) are seen from the parasternal short axis (see Figure 14-1, *C*) and modified apical four-chamber views (see Figure 14-1, *D*). The tricuspid valve comprises septal, anterosuperior, and posterior leaflets, attached by chordae tendineae to papillary muscles located within the septum and lateral walls of the RV. Unlike with the aortic and mitral valves, it is not possible to see all three leaflets of the tricuspid valve from any single two-dimensional view—the septal and anterosuperior leaflets are seen in the apical four-chamber view, with the posterior and anterosuperior leaflets seen in the right ventricular inflow view. The pulmonary valve consists of three cusps without subvalvular apparatus and, along with the main pulmonary artery and proximal branch pulmonary arteries, is best seen on the parasternal short axis (see Figure 14-1, C, and Video 6) and rotated subcostal views. Normal ranges for right ventricular and right atrial size have been derived from normal healthy populations. An important point in this context is that these measures are not indexed to body surface area, so reported values may lose discriminatory power in assessment of these structures at either end of the normal distribution curve for size.

ASSESSMENT OF RIGHT VENTRICULAR FUNCTION BY ECHOCARDIOGRAPHY

The orientation of the myocardial fibers within the right ventricular wall is different from that within the LV, leading to three definable modes of contraction. First, the right ventricular contraction is sequential and peristaltic, from inlet to infundibulum, and results in *longitudinal shortening*, which is the main driver behind right ventricular stroke volume. Second, the right ventricular free wall is observed to move inwards toward the interventricular septum (IVS), contributing to stroke volume through a bellows-like effect. Third, twist or torsion of the RV is less important than in the LV but arises

Data from Rudski L, Lai W, Afilalo J, et al: Guidelines for the echocardiographic assessment of the right heart in adults: a report from the American Society of Echocardiography, *J Am Soc Echocardiogr* 23:685–713, 2010.

predominantly from contraction against the insertion points of the RV into the septum. Although longitudinal (rather than radial) shortening is most important, the IVS contributes between 20% to 40% of right ventricular stroke volume. Echocardiographic evaluation of right ventricular function is complicated, because volumetric assessment of the RV (using end-diastolic and end-systolic volumes to calculate an ejection fraction) cannot be performed without advanced three-dimensional techniques. Visual assessment of right ventricular function may provide an initial qualitative evaluation of the function of the right side of the heart but suffers from interstudy variability of up to 15%; however, one or more of the following quantitative measurements should be incorporated.

TRICUSPID ANNULAR PLANE SYSTOLIC EXCURSION

Tricuspid annular plane systolic excursion (TAPSE) is measured using M-mode echocardiography in the apical four-chamber view to generate an image that illustrates the systolic longitudinal displacement of the lateral tricuspid annulus toward the apex (**Figure 14-2**, *A*). Because the septal attachment of the tricuspid annulus is relatively fixed, the major component of longitudinal systolic motion occurs at this point. The greater the displacement, the better is right ventricular function—a value less than 16 mm is considered abnormal. TAPSE correlates closely with right ventricular ejection fraction (RVEF) measured by radionuclide angiography, the “gold standard” modality for assessment of right ventricular function. TAPSE is simple to perform, with reproducible results, and is less dependent on optimal image quality than other measurements. It does not require complex calculations (the result obtained may be multiplied by 3.2 to give a value for RVEF, if desired) and can predict likelihood of death among patients with pulmonary arterial hypertension (PAH). However, TAPSE makes the assumption that displacement of a single segment represents function of the entire RV, which does not apply in the presence of regional dysfunction, particularly that affecting the septum. TAPSE is afterload dependent and falls with increasing severity of PAH.

PEAK SYSTOLIC VELOCITY OF LATERAL TRICUSPID ANNULUS DISPLACEMENT

Tissue Doppler imaging (TDI) can be used to measure the velocity of longitudinal displacement of the lateral tricuspid valve annulus during systole (S′) (see Figure 14-2, *B*). S′ values correlate closely with radionuclide angiography findings, and population-based validation studies indicate that a value less than 10 cm/s is abnormal. The data share the disadvantage of TAPSE in assuming that the velocity of a single wall region reflects the entire function of the complex three-dimensional shape of RV. Velocities are measured using Doppler imaging and therefore can underestimate function if measured off-angle by more than 20 degrees.

Myocardial Performance Index

The right ventricular myocardial performance index (MPI), also known as the Tei index, is the ratio of isovolumetric relaxation time (IVRT) plus isovolumetric contraction time (IVCT) to ventricular ejection time (see Figure 14-2, C). This index gives an accurate, global estimate of both systolic and diastolic right ventricular function. It avoids the need to use the geometric assumptions that are required for volumetric measurement of global right ventricular function, because MPI is based on time intervals from either blood pool Doppler (right ventricular outflow tract [RVOT] and tricuspid valve inflow) or tissue Doppler (lateral tricuspid valve annulus) measurements. A value greater than 0.4 is abnormal for blood pool Doppler, and a value greater than 0.55 is abnormal for tissue Doppler. Advantages of this technique include high reproducibility and the fact that it is relatively unaffected by variation in heart rate. The MPI can be falsely low under conditions of raised right atrial pressure, which may decrease the IVRT.

Fractional Area Change

Fractional area change (FAC) is obtained by tracing the endocardial border of the right ventricle in systole and diastole in the apical four-chamber view (see Figure 14-2, *D*). The percent FAC is then calculated using the formula (end-diastolic area − end-systolic area/end-diastolic area) × 100%, with a value below 35% considered abnormal. This method correlates closely with magnetic resonance imaging (MRI) assessment of right ventricular function, and reduced FAC is an independent predictor of adverse outcome after pulmonary embolism. The main practical disadvantage arises in defining contours in highly trabeculated RVs.

Three-Dimensional Volume Estimation

Three-dimensional volume estimation of right ventricular function correlates closely with radionuclide angiography and with MRI estimates of right ventricular function. It delivers accurate and reproducible measurements, but at present, the methodology is complicated and time-consuming, and the

Figure 14-2 Assessment of right ventricular systolic function by various modalities: **A,** tricuspid annular plane systolic excursion (TAPSE); **B,** S′ wave measurement by tissue Doppler imaging; **C,** myocardial performance index (MPI), or Tei index, calculated as isovolumetric relaxation time (IVRT) plus isovolumetric contraction time (IVCT) divided by ventricular ejection time (ET), or *a*/*b* – *a*; **D,** fractional area change (FAC)—here, from 9.6 cm^2 to 4.9 cm^2 = 49%. E/E′ is calculated as follows: peak velocity of pulsed-wave Doppler E wave (measured at the tips of the tricuspid valve; see Figure 14-3, *A*) divided by peak velocity of the E′ wave (measured using tissue Doppler imaging at the lateral tricuspid valve annulus).

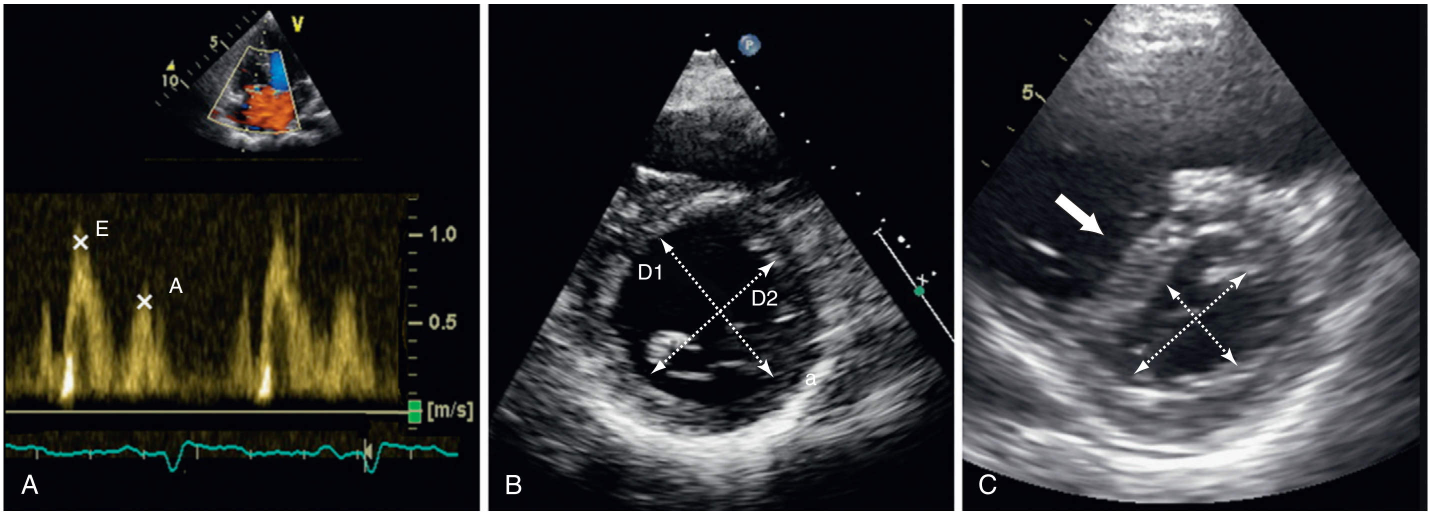

Figure 14-3 **A,** Pulsed-wave Doppler assessment of tricuspid valve inflow from the apical four-chamber view. E wave velocity reflects passive ventricular filling, whereas A wave velocity represents ventricular filling secondary to atrial systole. **B** and **C,** Flattening of the interventricular septum (*arrow*). *D1*, minor axis dimension perpendicular to and bisecting septum; *D2*, minor axis dimension parallel to the septum. Eccentricity index (EI) is calculated as *D2/D1*. Normal EI value is 1.0; EI greater than 1.0 at end-diastole is indicative of volume overload of right ventricle, whereas EI greater than 1.0 at end-systole is indicative of pressure overload.

equipment not widely available. The lower limit of normal is 44%, lower than that for the LV.

RIGHT VENTRICULAR DIASTOLIC FUNCTION

Diastolic function, which reflects the relaxation and filling of the RV, can be a useful early marker predicting deterioration in right ventricular function and may be of prognostic utility in patients with a number of acute and chronic respiratory conditions, although further data are needed. The parameters used for assessment of right ventricular diastolic function are essentially the same as those used in left ventricular diastolic assessment, including pulsed-wave Doppler-derived transtricuspid E/A ratio, tissue Doppler–derived E/E′ ratio, IVRT, and right atrial size (**Figure 14-3**, *A*). IVRT is a tissue Doppler measurement of the time taken for the right ventricle to relax, which is made at the basal right ventricular free wall. This relaxation period occurs after pulmonary valve closure (end of the S′ wave) and before tricuspid valve opening (beginning of the E′ wave) (see Figure 14-2, C). A prolonged IVRT (longer than 75 ms) may represent impaired myocardial relaxation and can be highly suggestive of PAH. Diastolic measurements should be acquired in end-expiration, and interpretation of the results should take account of the age of the patient (see Table 14-1). One additional important finding is the presence of late antegrade flow measured by pulsed-wave Doppler midway between the pulmonary valve leaflets and the pulmonary artery bifurcation, which is a sign of restrictive right ventricular filling and is associated with a poor prognosis.

HEMODYNAMIC ASSESSMENT OF THE RIGHT SIDE OF THE HEART BY ECHOCARDIOGRAPHY

In health, the right side of the heart ejects blood into a low-resistance, highly distensible pulmonary vascular bed. The RV is thin-walled and more compliant than the LV (so it adapts well to increases in volume) but demonstrates heightened sensitivity to change in afterload (so it adapts poorly to increases in pulmonary vascular resistance). The LV and RV interact with one another during systole, and this ventricular interdependence is mediated mainly by the motion of the IVS. Both changes in volume (preload) or pressure (afterload) within the right side of the heart will have an impact on the motion of the IVS. Under normal conditions, the higher intracavity pressure in the LV, as compared with that in the RV, helps to maintain a circular shape of the LV when imaged in cross section (see Video 2). Pressure loading of the RV results in a “flattening” of the IVS during systole, creating a more D-shaped left ventricular cavity. Volume loading of the RV results in a “flattening” of the IVS during diastole (see Figure 14-3, *B* and C; see also Video 7). This is an important marker of loading conditions within the RV, which can be measured by calculating the “eccentricity index” of the LV in the parasternal short-axis view (i.e., the ratio of the anterior-posterior dimension to septal-lateral dimension of the left ventricular cavity).

A number of direct parameters can be used for hemodynamic assessment of the right ventricular and pulmonary circulations, the most common being measurement of right ventricular systolic pressure (RVSP) estimated from the velocity of the jet of the tricuspid regurgitation (**Figure 14-4**, *A* and *B*, and Video 8). Using the simplified Bernoulli equation,

$$\text{RVSP} = 4v^2 + \text{Right atrial pressure}$$

where v = maximal velocity of the jet of tricuspid regurgitation (in m/s) and right atrial pressure is estimated from resting inferior vena cava diameter taking into account the degree of inspiratory collapse (see Figure 14-4, C, and Video 9). In the absence of a gradient across the pulmonary valve or RVOT, RVSP equals the *systolic* pulmonary artery pressure (PAP). Care must be taken to ensure that this measurement is made with an adequate Doppler signal; if the signal is not clear, it can be improved with the injection of an agitated mixture of blood, saline, and air for contrast. The measurement should be made several times, and the highest velocity obtained used in calculation. A normal value for a peak tricuspid regurgitation signal is less than 2.6 m/s (equivalent to a pressure of 27 mm Hg + right atrial pressure), but this value increases with age and with increasing body mass index. This method may underestimate RVSP when severe tricuspid regurgitation is present.

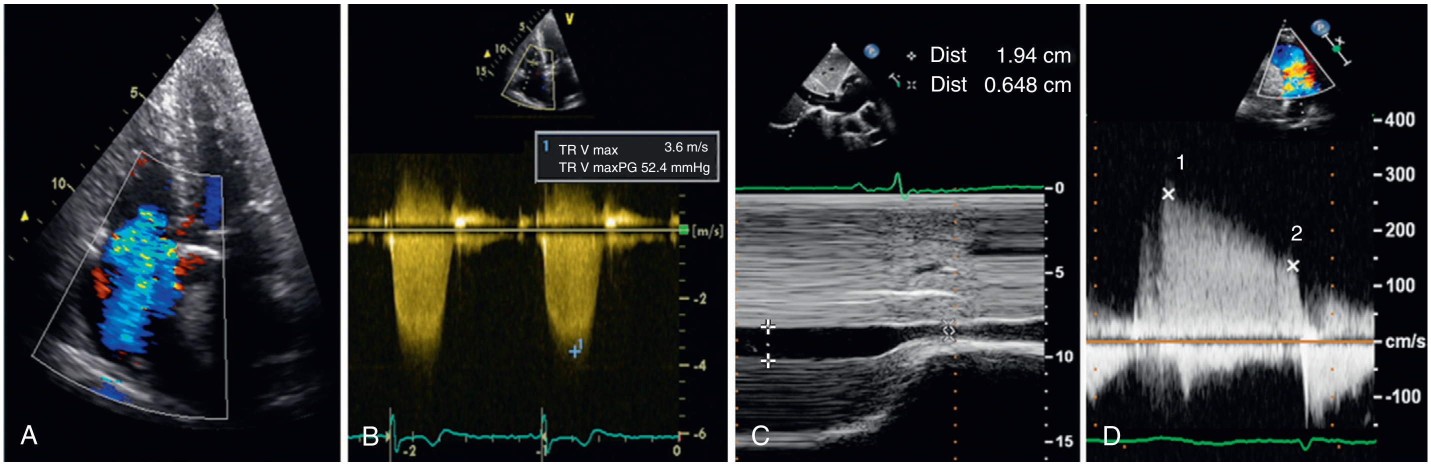

Figure 14-4 Hemodynamic measurements in echocardiography. **A,** Color flow Doppler imaging demonstrating tricuspid regurgitation (TR), with blood being ejected back into the right atrium. **B,** Continuous-wave Doppler interrogation of the regurgitant jet. Point *1* denotes peak jet velocity, which measures 3.6 m/s in this example. **C,** M-mode assessment of the inferior vena cava (IVC) from the subcostal acoustic window. The IVC can be seen to collapse with short sharp inspiration, decreasing in size from 1.94 cm to 0.648 cm in this example. Right atrial pressure can be estimated by assessing the diameter of the IVC at rest and then recording the change in size in response to inspiration: normal IVC diameter (i.e., less than 1.5 cm) with full collapse, 0 to 5 mm Hg; IVC diameter 1.5 to 2.5 cm with greater than 50% collapse, 5 to 10 mm Hg; IVC diameter 1.5 to 2.5 cm with less than 50% collapse, 10 to 15 mm Hg; IVC diameter greater than 2.5 with less than 50% collapse, 15 to 20 mm Hg; and IVC diameter greater than 2.5 cm with no change, 20 mm Hg or greater. **D,** Echocardiographic determination of diastolic and mean pulmonary artery pressure (PAP) by continuous-wave Doppler assessment of the signal generated by pulmonary regurgitation (PR). Point *1* indicates the maximal velocity of the jet of pulmonary regurgitation at the beginning of diastole. Mean PAP can be calculated as 4 × (early pulmonary regurgitation jet velocity)^2 + estimated right atrial pressure. Point *2* indicates the pulmonary regurgitant jet velocity at end-diastole, with diastolic PAP calculated as 4 × (end pulmonary regurgitant jet velocity)^2 + estimated right atrial pressure.

The simplified Bernoulli equation also can be used to estimate diastolic PAP from the end-diastolic velocity of the pulmonary regurgitant jet: diastolic PAP = $4v^2$ + right atrial pressure (see Figure 14-4, *D*), where v = terminal velocity of the regurgitant jet (in m/s). Mean PAP can then be calculated using a standard formula: mean PAP = 1/3 systolic PAP + 2/3 diastolic PAP. It also can be estimated directly from the early peak of the regurgitant jet velocity: mean PAP = $4v^2$ (v = early maximal velocity of the regurgitant jet [in m/s]) plus right atrial pressure (see Figure 14-4, *D*). Echocardiography also can deliver measurements of pulmonary vascular resistance, pulmonary capillary wedge pressure, and pulmonary capacitance, although these are not in routine use. These measurements provide important insights into right ventricular and pulmonary hemodynamic status, although any conclusions should be based not only on a single hemodynamic parameter, such as jet velocity in tricuspid regurgitation, but also in the context of a full assessment of right ventricular and right atrial size, shape, and function.

Right ventricular adaptation to disease is complex and depends on many factors. The most important factors appear to be the type and severity of myocardial stress, the time course of the disease (acute or chronic), and the time of onset of the disease process (young age or adult years). The remodeling of the right side of the heart produces classic anatomic and hemodynamic characteristics that are used by echocardiographers to diagnose and assess prognosis in specific disease states, as discussed next.

ECHOCARDIOGRAPHY IN EVALUATION OF SPECIFIC DISEASE STATES

PULMONARY ARTERIAL HYPERTENSION

PAH is a hemodynamic and pathophysiologic condition defined as an increased mean PAP of 25 mm Hg or more at rest, as assessed invasively at right-sided heart catheterization. The evaluation process in a patient with suspected PAH requires a number of investigations, but echocardiography should always be performed. The primary rationale is to provide an estimate of PAP, although the echocardiographic study most often measures the systolic and not the mean pressure, and this method is no longer recommended for screening patients with mild PAH.

The principal technique used to estimate PAP from Doppler ultrasound measurement of the maximal velocity of the tricuspid regurgitation jet consists of application of the simplified Bernoulli equation and addition of estimated right atrial pressure, as discussed previously. Historically, Doppler echocardiography has been considered to correlate well with direct (invasive) measurements of PAP; more recent studies, however, have brought this relationship into question. Indeed, in a study of 163 patients recruited to the National Emphysema Treatment Trial, who were assessed by both Doppler echocardiography and right-sided heart catheterization, echocardiographic estimates of PAP correlated weakly with invasive measurements, with investigators reporting poor sensitivity (60%), specificity (74%), and positive (68%) and negative (67%) predictive values for Doppler imaging. Poor image quality was common and was thought to be a major factor in the relative inaccuracy of PAP estimation in this study. However, these findings were replicated in a more recent study of 65 patients with PAH secondary to a variety of conditions, in which Doppler imaging and right-sided heart catheterization were performed “simultaneously” (within 1 hour). Once again, Doppler echocardiography continued to provide inaccurate estimates of PAH. The accuracy of the measurement can be limited not only by poor image quality but also by extremes of jet velocity or character, observed as trivial, severe, or eccentric, resulting in an incomplete regurgitation signal. Estimation of right atrial pressure from inferior vena cava dimensions and collapsibility may contribute to this inaccuracy, because correct identification of right atrial pressure, within a range of 5 mm Hg, may be achievable in only about half of all cases. Accuracy of this estimation can be improved by an assessment of hepatic vein flow, because increasing right atrial pressure is associated with a relative decline in systolic forward hepatic vein flow relative to atrial reversal. In summary, although a strong correlation is recognized between jet velocity in tricuspid regurgitation and pressure gradient, Doppler echocardiography may not be accurate in the individual patient to assess systolic PAP. An alternative approach to the use of a Doppler-derived pressure gradient is simply to measure the jet velocity in tricuspid regurgitation and compare this against values from the normal population. This approach has the disadvantage that the value does not directly link to the accepted pressure-derived definition of PAH; use of velocity alone, however, does avoid the cumulative error that arises in calculating pressure.

Attention should always be paid to other echocardiographic features that may reinforce the suspicion of PAH. These include dilatation of the RV and right atrium (see Videos 10 to 12), the presence of right ventricular hypertrophy (greater than 5 mm in cross section) measured from the subcostal acoustic window, early systolic flattening of the IVS, and dilatation of the pulmonary artery. The sensitivity of such findings is likely to be low, as they are late pathologic consequences of PAH. Other indirect measures resulting from high afterload in the pulmonary circulation are useful and include prolongation of the right ventricular IVRT (greater than 75 ms) and shortening of the acceleration time of right ventricular ejection into the pulmonary artery (less than 105 ms). High afterload also results in a fall in longitudinal contraction within the RV, resulting in a negative correlation with S′ wave velocity on TDI (less than 12 cm/s) and TAPSE (less than 18 mm). Finally, the degree of PAH correlates with an increase in the velocity of the jet of pulmonary regurgitation, measured on pulsed Doppler in the parasternal short-axis view.

Echocardiography can not only be helpful as a screening tool in patients with suspected PAH but can also provide useful prognostic information. Multivariable analysis of various echocardiographic parameters has demonstrated prognostic utility for (1) the presence of pericardial effusion (hazard ratio, [HR], 2.08 [95% CI = 1.12 to 3.86; $P = .017$]), (2) indexed right atrial area (HR, 1.33 [95% CI = 1.06 to 1.66; $P = .012$]), (3) left ventricular eccentricity index greater than 1.7 (HR, 1.45 [95% CI =1.12 to 1.86; $P = .004$]), (4) right ventricular systolic function as determined by FAC, (5) right ventricular tissue Doppler, (6) right ventricular MPI, and (7) TAPSE less than 15 mm (HR, 2.74 [95% CI = 1.11 to 6.77; $P = .022$]).

Furthermore, echocardiography also may provide information regarding the cause of PAH—for example, significant left-sided heart disease, which may include left ventricular or valvular dysfunction. Echocardiography is vital in the exclusion of significant congenital heart disease and in the identification of systemic to pulmonary shunts. Detection of high pulmonary blood flow on Doppler interrogation of the RVOT or two-dimensional detection of an enlarged right heart chamber in the absence of a clear shunt on transthoracic echocardiography (TTE) should precipitate a more intensive examination using transesophageal echocardiography (TEE). This modality not only provides a closer inspection of the atrial septum but also ensures that a sinus venosus–type septal defect can be excluded (which cannot be seen on TTE) and that anomalous pulmonary venous drainage is not present. The latter defects are of particular importance to distinguish from atrial septal defects, because these are not amenable to percutaneous closure. The accuracy of both TTE and TEE can be improved by the use of an agitated mixture of saline, air, and blood contrast, which also can be used to identify intrapulmonary shunts in patients with portal vein and pulmonary artery (porto-pulmonary) hypertension.

Thus, echocardiography is an integral part of the diagnostic algorithm for investigation of suspected PAH and may provide quantitative data useful for the assessment of prognosis in patients with proven disease.

ACUTE RIGHT-SIDED HEART FAILURE

Acute right ventricular dysfunction may occur as a consequence of various disease processes, which include ischemic heart disease, myocarditis, and pulmonary embolism. Among patients presenting with suspected acute pulmonary embolism, neither TTE nor TEE have sufficient sensitivity to be used as the primary imaging modality for diagnosis but may provide useful supportive data and can identify those persons at high risk for adverse outcomes. Typically, the abrupt vascular obstruction sets up a cascade of adverse hemodynamic effects that not only exert strain on the RV but also may impair left ventricular function and coronary artery perfusion (Figure 14-5).

Although echocardiography may be normal in up to 50% of patients with confirmed pulmonary embolism, sensitivity is increased with increasing hemodynamic compromise from the event. Typical echocardiographic findings include dilatation of the RV with reduced thickening of the free wall, flattening of the IVS in systole, dilatation of the right atrium due to elevated right ventricular end-diastolic pressure, paradoxical atrial septal motion due to high right atrial pressure, which also is associated with dilatation of the inferior vena cava, and loss of respiratory variation. Hemodynamic measurements altered by acute pulmonary embolism include increased jet velocity in tricuspid regurgitation (more than 2.7 m/s) and reduction in TAPSE and S′, together with shortened RVOT acceleration time. Rarely, thrombus may be seen in the right side of the heart or pulmonary artery. The McConnell sign, consisting of hypokinesis of

Figure 14-5 The vicious circle of detrimental pathophysiologic events that may occur in the setting of acute vascular obstruction, such as with acute pulmonary embolism. *CO*, cardiac output; *IVS*, interventricular septum; *RV*, right ventricle; *RVEDP*, right ventricular end-diastolic pressure.

the mid–free wall in the presence of normal apical wall motion, is reported to be 77% sensitive and 94% specific for acute pulmonary embolism.

In the setting of acute pulmonary embolism, the presence of right ventricular dysfunction and/or elevated PAP has been shown to predict poor outcome. Consequently, using echocardiography early in the assessment of patients with acute hemodynamic instability may assist with rapid detection of these high-risk features and may identify a cohort of subjects who may benefit from more aggressive management, perhaps involving the use of thrombolysis. An important point in this context is that these changes occur in patients with acute pulmonary embolism who have no preexisting thromboembolism or PAH, in which case the effect of chronic pressure overload on the RV modifies the appearance of the right side of the heart.

CHRONIC RIGHT-SIDED HEART FAILURE (COR PULMONALE)

The most common cause of chronic right-sided heart failure is chronic left ventricular failure (LVF). Both in LVF and in chronic lung disease, such as chronic interstitial disease, chronic obstructive pulmonary disease (COPD), or chronic thromboembolic disease, the pulmonary vasculature gradually remodels over time from a low- to a high-pressure system. This insidious transformation exerts an impact on the function and architecture of the RV as it attempts to maintain stroke volume and is characterized by right ventricular hypertrophy (RVH). This hypertrophy is not similar to that seen in the physiologically trained or athletic heart but involves other processes that include myocardial fibrosis, inflammation, and myocyte apoptosis and necrosis. The RV in general responds better to chronic volume than to pressure overload, which leads to a more pronounced increase in the density of myocardial connective tissue observed at histologic examination. Initially on visual inspection, right ventricular systolic function appears to be maintained, although a reduction in systolic contraction is preceded by impaired right ventricular diastolic function and by changes in myocardial strain. *Strain* is an echocardiographic measure of myocardial deformation in thickening or shortening that is independent of myocardial velocity and translational cardiac motion. Ultimately, however, the effect of the continued pressure overload on the hypertrophied right ventricular myocardium predisposes the patient toward full decompensation in function, which is reflected in right ventricular dilatation, thinning of the right ventricular free wall, and fall in right ventricular systolic function.

Right ventricular function is a strong and independent predictor of mortality in LVF. Progressive reduction in right ventricular FAC is associated with worse outcomes in patients with heart failure after myocardial infarction, independent of severity of reduction in left ventricular ejection fraction. Other independent right-sided indices of adverse outcome in patients with LVF include reductions in right ventricular MPI and TDI S′. Adverse prognosis in RVH, secondary to chronic lung disease and in the absence of LVF, is similarly predicted by reductions in TAPSE and TDI S′, but increased right ventricular dilatation assessed by right ventricular end-diastolic volume index is an additional predictor of death.

PERICARDIAL EFFUSION AND TAMPONADE

The pericardium consists of a monolayer of mesothelial cells that directly overlie the epicardial fat (visceral layer) and reflects back upon itself to form a second (parietal) layer. In health, the pericardium contains a small volume (15 to 35 mL) of plasma ultrafiltrate, which acts as a lubricant. Under physiologic conditions of low stress, the pericardium is elastic, but under higher stress, it has the tensile strength of rubber and becomes stiff and resistant to stretch. This transition in mechanical properties occurs close to the upper limit of normal pericardial volume. As the pericardial reserve volume is exceeded, pressure within the pericardium increases rapidly. This rise in pressure is dependent not only on the volume but also on the rate of accumulation, which explains why large pericardial effusions may cause no hemodynamic compromise if they have developed slowly, whereas very small volumes can cause hemodynamic collapse if the ultrafiltrate accumulated rapidly. Under conditions in which pericardial pressure rises, the mechanical properties of the pericardium become an important determinant of right atrial and right ventricular filling, and cardiac function may be adversely affected, with loss of normal ventricular interdependence.

Pericardial effusion is detected easily by TTE and is distinguished from pleural fluid by its presence anterior to the descending aorta in the parasternal long-axis view (**Figure 14-6** and Video 13). Pericardial fluid almost never overlaps the left atrium and usually collects behind the right atrium and then the RV and extends to the lateral wall of the LV. This localization obviously depends on patient position, but the effusion can be a focal process with a localized accumulation of fluid—for example, after cardiothoracic surgery. Assessing the size of a pericardial effusion is important for prognostication: The larger the collection, the worse the outcome. The presence of even a small pericardial effusion, however, is a marker for increased risk of death.

Although cardiac tamponade remains a clinical diagnosis, certain echocardiographic features are often used to confirm the presence of a hemodynamically significant pericardial collection. As the pericardial pressure increases, the first effect is for ventricular interdependence to be exaggerated—this means that respiratory variation in tricuspid valve inflow measured at the tips of the valve on pulsed-wave Doppler imaging is exaggerated at the expense of mitral valve inflow. On inspiration, for example, tricuspid valve inflow velocity and volume increase, whereas mitral valve inflow velocity and volume decrease. As pressure rises further and diastolic filling of the heart is impaired, the chambers of the heart start to “collapse” in order of intracavity pressure—first the right atrium, then the RV, and subsequently the left atrium (see Videos 14 and 15; see also Video 13). Abnormal posterior motion of the anterior right ventricular free wall during diastole seen in the parasternal long-axis view should prompt urgent review, with consideration of pericardiocentesis. TTE can then play a vital role in guiding percutaneous needle aspiration, or drain insertion, which may rapidly alleviate symptoms. Echocardiography-guided aspiration has a high procedural success rate and carries a risk of major complications of only 1% to 2%.

PERICARDIAL CONSTRICTION

The pericardium can be affected by a variety of inflammatory, infective, or neoplastic insults that may trigger a healing process characterized by granulation and scar tissue formation, promoting fibrosis sufficient to obliterate the pericardial space. Under such conditions, the pericardium becomes a firm and poorly compliant structure that can encase, or “constrict,” the heart, leading to impairment of ventricular diastolic filling.

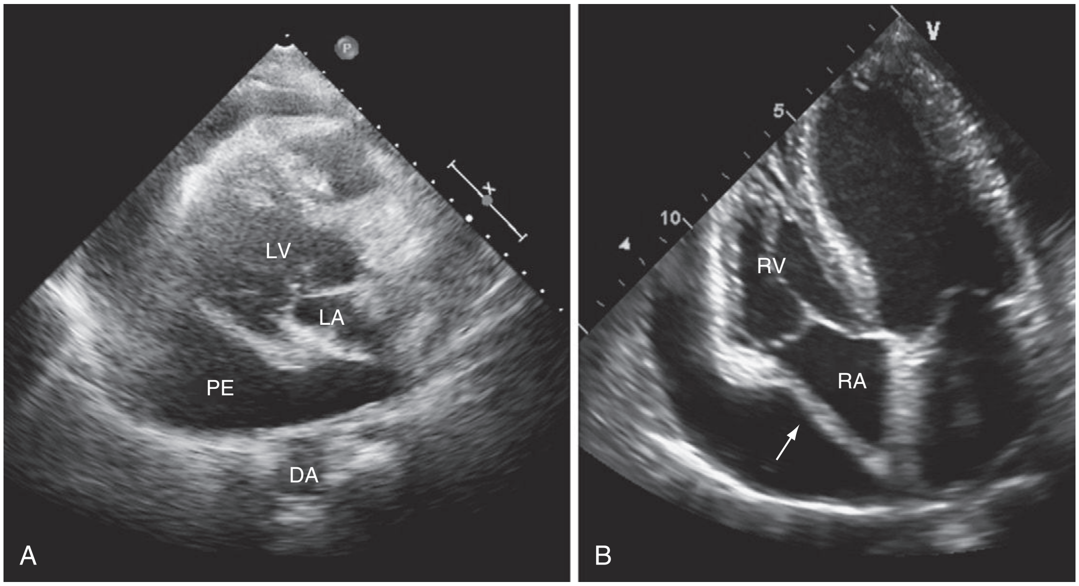

Figure 14-6 A large pericardial effusion, viewed from the parasternal long-axis (PLAX) (**A**) and apical four-chamber (**B**) acoustic windows. In **A,** the effusion can be seen to lie anterior to the descending thoracic aorta (DA), thereby differentiating it from a left-sided pleural effusion, which usually is seen to extend posteriorly to the descending aorta. In this example, the effusion extends alongside the left atrium (LA), which is unusual. In **B,** the right atrium (RA) is seen to collapse during diastole *(arrow)*, which may be a feature of significantly increased intrapericardial pressure and may be an early sign of tamponade.

Historically, tuberculous pericarditis was the most common cause of pericardial constriction; today, however, the most common causes include healing after cardiac surgery, neoplastic pericarditis, mediastinal irradiation, chronic uremia, inflammation associated with pulmonary asbestosis, and recurrent pericarditis secondary to connective tissue disorders.

It can be difficult to differentiate between pericardial constriction and a restrictive cardiomyopathy, because both manifest with signs and symptoms suggestive of right ventricular failure and a restrictive filling pattern on pulsed-wave Doppler, assessed at the tips of the mitral and tricuspid valves. Early diastolic filling is rapid, owing to raised intraatrial pressure, which is seen as an elevated E wave velocity. However, intraventricular pressure rises abruptly, as a consequence of the lack of either pericardial or myocardial compliance (from pericardial constriction or restrictive cardiomyopathy, respectively), so that by mid-diastole, rapid cessation of passive filling is seen, corresponding to a shortened E wave deceleration time (less than 150 ms). Owing to high interventricular pressure, atrial systole does not contribute as much as normal to ventricular filling, so the A wave velocity is reduced, resulting in an E/A ratio greater than 2. Although these echocardiographic features are shared by the two conditions, clinical distinction is vital, because the treatment of choice for pericardial constriction is pericardiectomy, which carries a high risk and is of no benefit in restrictive cardiomyopathy.

RESTRICTIVE CARDIOMYOPATHY SECONDARY TO CHRONIC RESPIRATORY DISEASE

Cardiomyopathies (CMs) are a group of conditions characterized by abnormalities of the myocardium. CMs are broadly divided into three main functional categories: dilated, hypertrophic, and restrictive. Among patients with certain respiratory diseases, such as sarcoid or hypereosinophilic (Löffler) syndrome, cardiac involvement caused by infiltration of the myocardium may give rise to a restrictive cardiomyopathy. The hallmark of a restrictive cardiomyopathy is a stiff and poorly compliant myocardium that limits diastolic filling, resulting in elevated end diastolic pressures and the characteristic echo features as described. The diagnosis of cardiac involvement in patients with established respiratory disease often is difficult, but TTE is an important first step. On two-dimensional echocardiography, the left ventricular cavity size is often normal or reduced, in contrast with left ventricular wall thickness, which may be normal or increased—the presence of concentric LVH in the absence of a history of systemic hypertension should prompt further investigation (see Video 16). Being compliant chambers, both the left and right atria are considered "barometers" of ventricular filling pressure. This means that biatrial enlargement is often present in restrictive cardiomyopathy as a result of increased biventricular filling pressures. The RV may be hypertrophied and ultimately dilated, in the presence of elevated pulmonary artery pressure. Right-sided heart failure is a final common pathway, often as a sequel to chronic PAH driven by the underlying respiratory disorder.

Echocardiographic features that support a diagnosis of pericardial constriction, rather than restrictive cardiomyopathy, may include the presence of an echodense or thickened pericardium (often, however, it may appear normal), normal chamber size, normal wall thickness, and preservation of systolic function. Other data in support of pericardial constriction include the finding of a normal early annular myocardial relaxation velocity on TDI, exaggeration of the usual variation in tricuspid and mitral valve inflow observed during respiration, and reversal of the normal annular early relaxation velocities measured by TDI (a higher E′ velocity is found in the septum compared to the lateral annulus). Conversely, in restrictive cardiomyopathy early annular myocardial relaxation may be reduced (E′ is less than 7 cm/s), variation in tricuspid and mitral inflow is within normal range, and annular early relaxation velocities are higher laterally than in the septum (lateral E′

higher than septal E′). Finally, paradoxical motion of the IVS is observed in pericardial constriction and not in restriction and represents an exaggeration of the normal physiologic ventricular interdependency secondary to the equalization of intraventricular pressures after encasement of the heart within the noncompliant diseased pericardium, with increased right ventricular filling on inspiration (shift of the IVS toward the LV) and increased left ventricular filling on expiration (movement of the IVS toward the RV).

CONCLUSIONS

Traditionally, the right side of the heart has often been ignored relative to the LV, but right ventricular function is well recognized to play a vital role in determining clinical outcome in both acute and chronic respiratory disease. Careful qualitative and quantitative examination of the right side of the heart with echocardiography can provide valuable data to assist in diagnosis, guiding treatment, and establishing prognosis in patients with cardiorespiratory disease. Echocardiography provides this information cheaply and at no risk to the patient. Those clinicians limiting their understanding of echocardiography to the reading of report conclusions may be limiting the care that they are providing to their patients. When interpreting echocardiographic reports, however, clinicians should pay particular attention to the quality of the data presented to them, because acquisition of good-quality images can be challenging, especially in patients with respiratory disease.

RESPIRATORY PHARMACOLOGY

Chapter 15

Bronchodilators

Peter M.A. Calverley

Bronchodilator drugs are among the most widely used respiratory medicines, and substantial developments, particularly in duration of action, have increased their effectiveness in recent years. Essentially these drugs act to increase airway caliber and permit faster and more effective lung emptying. The concept of bronchodilatation has evolved as well, and the designation “bronchodilator” is now largely synonymous with any drug that acts relatively rapidly to cause relaxation of airway smooth muscle.

Breathlessness and wheezing are cardinal symptoms of many respiratory diseases, and from the 19th century it was recognized that smoking cigarettes made from the leaves of the plant *Atropa belladonna* lessened the symptoms of asthma. This therapy was largely superseded when epinephrine (adrenaline) was purified in the early 20th century. Subsequently, synthetic analogues of epinephrine were developed, as was atropine, the first synthetic antimuscarinic agent. Both atropine and epinephrine could be added to organ baths containing airway smooth muscle, and their potency in relieving or preventing induced smooth muscle contraction could be measured. These developments led to the current understanding of the control of airway smooth muscle, as shown in **Figure 15-1**. Changes in airway smooth muscle length translate into changes in airway caliber—an especially important issue when airway diameter is reduced, as in chronic obstructive pulmonary disease (COPD) (**Figure 15-2**). In clinical practice, this aspect of pulmonary function is assessed indirectly as an increase in the forced expiratory volume in 1 second (FEV_1) after drug administration. When a bronchodilator is given orally, the time to onset of action (i.e., improvement in lung function) is prolonged, reflecting the absorption and circulation of the drug; this time can be considerably shortened when treatment is administered by inhalation. Of note, not all drugs that increase FEV_1 do so by changing airway smooth muscle activity; for example, antiinflammatory agents can reduce the mucosal thickening and thickening of the airway wall, thereby leading to improvements in FEV_1. These processes take some time to develop, however, because agents such as corticosteroids have both nuclear and extranuclear effects on protein synthesis, which reduce the number of proinflammatory messenger molecules. Hence, for practical purposes, bronchodilators can be considered as those drugs with a proven direct effect on airway smooth muscle and a relatively rapid onset of effect (minutes to several hours) in clinical circumstances in which some measure of airway resistance is the marker for effectiveness.

This chapter presents an overview of the principal classes of bronchodilator drugs, including their mechanisms of action and specific indications. As background for these considerations, it is useful first to examine why these drugs should be so useful in respiratory disease, and to identify those settings in which they should be deployed.

PHYSIOLOGIC BASIS FOR BRONCHODILATOR ACTION

Under resting conditions in healthy people, the work of breathing performed by the respiratory muscles is relatively small. Inspiration is an active process, and sufficient flow has to be generated by overcoming respiratory resistive, elastic, and frictional loads to ensure adequate alveolar ventilation. Expiration is passive and ends when the expiratory recoil pressure of the lungs and the chest wall are balanced. There is little expiratory flow resistance within the bronchial tree, and expiratory flow limitation (no increase in flow despite increasing expiratory driving pressure) is detected only during the last part of the maximum forced expiration (**Figure 15-3**, *top*). Ventilation increases during exercise but not to the point at which flow limitation significantly limits performance.

Airway resistance is influenced significantly by the caliber of the bronchial tree (see Figure 15-2). In health, most of the resistance lies in the region of the larynx, with less than 20% coming from the periphery of the lung. The evidence points to resting airway smooth muscle tone that decreases physiologically during exercise to reduce the resistive work required when ventilation has to increase. Bronchodilator drugs abolish this smooth muscle tone in both healthy persons and patients with disease. In healthy people, the increase in FEV_1 after administration of a β-agonist is between 50 and 120 mL, a value similar to that in patients with COPD, whose baseline FEV_1 usually is much lower. By contrast, in patients with asthma, in which airway smooth muscle bulk is greater and resting muscle tone may be increased by indirect reflex mechanisms, the response to bronchodilator drugs is more dramatic, and substantial increases in lung function occur after the acute administration of a bronchodilator. The improvement in lung emptying that results from bronchodilation has important effects on the operating lung volume and hence on the work of breathing.

In general, wheezing reflects areas of local flow limitation within the airway. Expiratory flow limitation can occur in the absence of audible wheeze and contributes to the slow emptying of the lungs and the higher lung volumes that lead to breathlessness and chest tightness in obstructive lung disease. Expiratory flow limitation may be abolished completely after a bronchodilator drug in asthma (see Figure 15-3), although asthmatic symptoms often will recur when the effects of the bronchodilator wear off (see further on). In COPD, the absolute change in lung function is much smaller than in asthma,

Figure 15-1 Control of airway smooth muscle in humans. Preganglionic and postganglionic parasympathetic nerves release acetylcholine (ACh) and can be activated by airway and extrapulmonary afferent nerves. There is no direct sympathetic innervation to the airways. Mediators released from inflammatory cells directly activate airway smooth muscle cells, as well as acting through a cholinergic reflex. This may explain why antimuscarinics are less effective than β_2-agonists as bronchodilators in asthma, because the latter drugs counteract the effect of all bronchoconstrictors. *(From Barnes PJ: β_2-Agonists, anticholinergics, and other nonsteroid drugs. The normal airway has a certain degree of vagal cholinergic tone caused by tonic release of acetylcholine, which is blocked by muscarinic antagonists. This effect may be exaggerated in patients who have COPD, because of fixed narrowing of the airways as a result of geometric factors. The absolute increase in forced expiratory volume in 1 second (FEV_1) after administration of these agents is similar to that seen in healthy smokers, but the relative change is much greater, reflecting the lower initial airway diameter. *(From Barnes PJ: β_2-agonists, anticholinergics, and other nonsteroid drugs. Figure 15-3 Expiratory flow limitation in health and disease. *Top,* The pressure change within and outside the airway in health. Intraluminal driving pressure producing expiratory flow declines owing to frictional resistance. The *opposing triangles* mark the point at which pressures within and outside the airway are equal (choke point) when expiratory flow limitation is present. This occurs outside of the thorax in healthy people (*dotted line*) and only during a maximum forced expiration. *Bottom,* The resistive pressure drop is greater, the choke point is more proximal in the airway, and expiratory flow limitation occurs within the thorax and can be present in tidal breathing. The bronchodilator moves the choke point distally and thus may abolish resting flow limitation altogether or allow more lung emptying to occur before onset of flow limitation.

and flow limitation often persists, particularly in severe disease, although to a less severe degree. These subtle changes in lung mechanics, however, can produce clinically relevant changes in operating lung volumes, particularly in the end-expiratory lung volume, which is significantly elevated in many patients with COPD and constitutes is a good guide to the degree of exercise impairment experienced by affected persons. A further effect of bronchodilator drugs is to increase the threshold at which symptoms are induced. This increased threshold is important in the prevention of exercise-induced asthma and also in the reduction of symptoms produced more predictably by exercise, as occurs when patients with COPD undertake certain daily activities. This ability to increase baseline lung function and reduce the impact of external stimuli on the airways is likely to be important in explaining why bronchodilator drugs are associated with fewer exacerbations of airways disease when given in effective doses over the long term.

A different situation obtains in patients with restrictive lung function secondary to diffuse pulmonary fibrosis or chest wall disorders, in which the work of breathing is increased because of the greatly increased elastic load on the inspiratory muscles and the airways are largely spared from involvement. In such patients, bronchodilator drugs will have little effect on breathlessness, and their use is associated with unwanted side effects, rather than clinical benefit. Thus, bronchodilators are indicated only for the relief of symptoms that are caused by obstructive lung disease and not when a restrictive disorder is the dominant clinical problem.

PHARMACOLOGIC BASIS OF BRONCHODILATOR ACTION

Although by definition the focus of action of bronchodilator drugs is the airway smooth muscle, a number of other secondary or incidental effects occur that can be clinically useful. The balance of these nonbronchodilator effects differs significantly between the two main classes of bronchodilator drugs.

β-AGONISTS

Based on the classical work of Ahlquist in defining different subtypes of adrenoreceptors, a range of relatively specific β-agonist agents were developed. Because β_2-receptors are almost the only subtype expressed on human airway smooth muscle, it makes sense to use highly selective β-agonists and there is no place for nonselective agents in clinical practice today. The chemical structures of the principal β-agonists are shown in **Figure 15-4**.

β_2-Agonists produce bronchodilatation by directly stimulating β_2-receptors in airway smooth muscle, which leads to relaxation. This can be demonstrated in vitro by the relaxant effect of β-agonists on human bronchi and small airways—an effect confirmed in humans by a rapid decrease in airway resistance after administration of drug by inhalation. β-Receptors have been demonstrated in airway smooth muscle by direct receptor-binding techniques, and autoradiographic studies indicate that β-receptors are localized to smooth muscle of all airways from the trachea to the terminal bronchioles, although a wide distribution within the lungs as a whole, including the alveoli, is characteristic.

The β-receptor is a seven transmembrane–spanning G protein. Binding of the β_2-agonist to the disulfide bonds on the extracellular surface leads to activation of adenylate cyclase and a consequent increase in intracellular cyclic adenosine-3′,5′-monophosphate (cAMP). This leads in turn to activation of a specific kinase (protein kinase A) that phosphorylates several target proteins within the cell, resulting in several specific effects:

- A fall in the intracellular calcium ion (Ca^{2+}) concentration by active removal of Ca^{2+} from the cell into intracellular stores
- Inhibition of phosphoinositide hydrolysis
- Direct inhibition of myosin light chain kinase
- Opening of large-conductance, calcium-activated potassium channels (K_{Ca}) that repolarize the smooth muscle cell and may stimulate the sequestration of Ca^{2+} into intracellular stores
- β_2-Agonists act as functional antagonists and reverse bronchoconstriction, irrespective of the contractile agent. This is an important property, because multiple bronchoconstrictor mediators (inflammatory mediators and neurotransmitters) are released in asthma.

β_2-Agonists may have other effects on airways, and β_2-receptors are localized to several different airway cells. Thus, additional effects may include the following:

- Inhibition of mediator release from mast cells and other inflammatory cells
- Inhibitory effects on neutrophil migration and activation
- Reduction and prevention of microvascular leakage and, consequently, development of bronchial mucosal edema after exposure to mediators such as histamine and leukotrienes
- Increased mucus secretion from submucosal glands and ion transport across airway epithelium (effects that may enhance mucociliary clearance, thereby reversing the defect in clearance found in asthma)
- Reduction in neurotransmitter release from airway cholinergic nerves, thus reducing cholinergic reflex bronchoconstriction
- Inhibition of the release of bronchoconstrictor and inflammatory peptides, such as substance P, from sensory nerves

How relevant any of these effects are to the observed clinical effects in disease is hard to determine. They may be more important in preventing bronchoconstriction from other stimuli in asthmatic patients than in directly influencing airway dimensions. The immediate impact on airway smooth muscle remains the most important of these various mechanisms, as illustrated in **Figure 15-5**. Recognized polymorphisms of the β-receptor show variable responses to agonist drugs in vitro. Translation of these observations into clinically noticeable differences in response in the clinical setting has been difficult, however, and at present these observations remain primarily of academic interest.

Antiinflammatory Effects of β_2-Agonists

The inhibitory effects of β-agonists on the release of mast cell mediators and on microvascular leakage can be considered to be antiinflammatory effects, although this term is not well defined. Nonetheless, available data suggest that β-agonists may modify acute inflammation. How well sustained such actions are remains unclear. To date, β-agonists have not been shown to modify chronic inflammation, but whether this reflects their basic pharmacology or is simply a result of a limited duration of action is less clear. The advent of very long-acting agents (see below) may resolve this point if any investigators have the courage to test this application in asthmatic patients without a

background of other antiinflammatory treatment. Bronchial biopsy specimens in asthmatic patients who regularly take β-agonists show no significant reduction in the number of or activation in inflammatory cells in the airways, in contrast with suppression of inflammation that occurs with inhaled corticosteroids.

ANTIMUSCARINIC AGENTS

Antimuscarinic agents are specific antagonists of muscarinic receptors and inhibit cholinergic nerve–induced bronchoconstriction. Muscarinic receptors bind to acetylcholine released after stimulation of the parasympathetic nerves. These nerves innervate the bronchi and small airways of the human bronchial tree but do not extend to the respiratory bronchioles and alveoli. The receptor has seven membrane-spanning loops, the third of which shows considerable heterogeneity—explaining the existence of several different functional variants. Many of these receptors (M_1 to M_3) occur in different sites and with rather different functions, as shown in Figure 15-6.

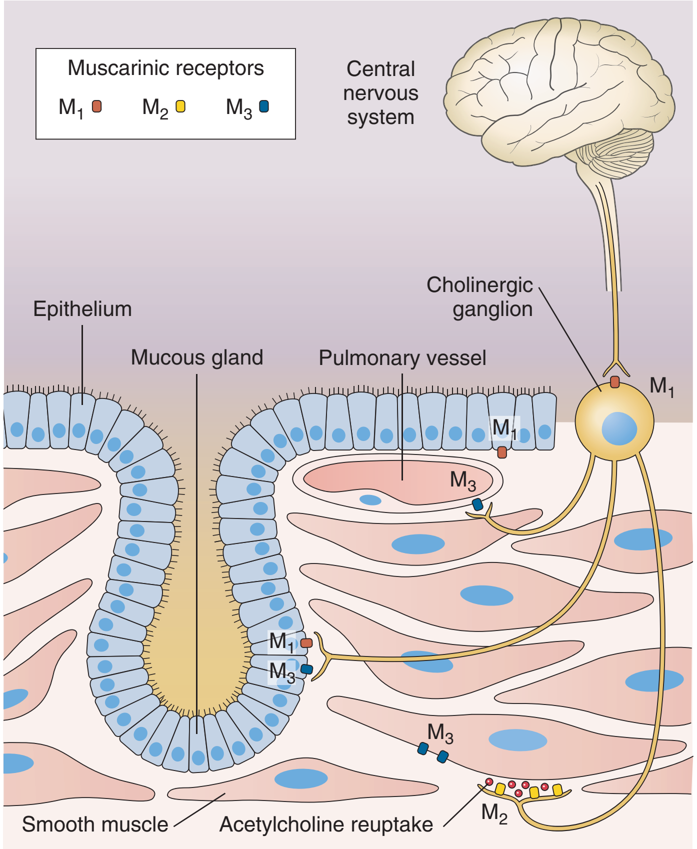

Figure 15-6 Distribution of muscarinic receptors in the lung. Note that different receptors have different roles, so their blockade will have different effects. M_1 receptors on the ganglia in the airway wall seem to regulate overall bronchomotor tone. M_2 receptors are involved in the autoregulation of acetylcholine reuptake from the synaptic cleft. M_3 receptors are postsynaptic on airway and pulmonary vascular smooth muscle, and their blockade leads to smooth muscle relaxation.

A small degree of resting bronchomotor tone is caused by tonic cholinergic nerve impulses, which release acetylcholine in the vicinity of airway smooth muscle, and cholinergic reflex bronchoconstriction may be initiated by irritants, cold air, or stress. Although anticholinergics offer some protection against acute challenge by sulfur dioxide, inert dusts, cold air, and emotional factors, they are less effective against antigen challenge, exercise, and fog. This is not surprising, because anticholinergic drugs only inhibit reflex cholinergic bronchoconstriction and have no significant blocking effect on the direct effects of inflammatory mediators, such as histamine and leukotrienes, on bronchial smooth muscle. Furthermore, cholinergic antagonists probably have little or no effect on mast cells, microvascular leak, or the chronic inflammatory response. For these reasons, in patients who have asthma, anticholinergics are less effective as bronchodilators than β_2-agonists. In COPD the drugs appear to be more equivalent, although differences in their duration of action are as likely to explain their relative benefit as are fundamental pharmacologic differences.

β_2-AGONISTS: CLINICAL CONSIDERATIONS

Although historically, nonselective adrenaline derivatives such as isoprenaline were used to treat airway disease, cardioselective β_2-agonists are now recognized as being the safest and most effective compounds in this class. The most widely prescribed drug at present is salbutamol (albuterol in the United States), although the closely related compound terbutaline is popular in some parts of Europe. Fenoterol, a more potent β_2-agonist, was widely used in the 1980s, although it was associated with an increased risk of asthma death in New Zealand. Whether this association was causal or coincidental remains a subject of heated debate, which still affects current attitudes toward drugs in this class today. Although oral β-agonists were popular for many years, their slow onset of action and significant side effect profile have led to a decline in their use, and the inhaled route is now preferred, because the effects develop more rapidly and the total dose of drug given is smaller. In general, drugs such as salbutamol and terbutaline are considered short-acting β-agonists (SABAs), to distinguish them from long-acting agents such as salmeterol and formoterol (LABAs), which also are given by inhalation. Once-daily long-acting β-agonists, such as indacaterol and vilanterol, have been developed recently and, in the case of indacaterol, are now licensed for use in certain medical conditions. Intravenous treatment with β-agonist initially was used for emergency care and is still offered to some people in intensive care units; however, this regimen has declined in popularity, and higher doses of these drugs are now given principally by nebulization. The doses, duration of action, and formulations of the most widely used agents are presented in Table 15-1.

The relationship between increases in dose of β_2-agonists and the spirometric response in health and disease is at best a shallow one. This is most easily seen in people with asthma, in whom changes in FEV_1 after administration of these drugs are more dramatic and hence can be defined more reliably. A similar situation, however, applies in patients with COPD. The increase in adverse events is more clearly dose-related, thereby limiting the amount of drug that can be given.

In general, SABA drugs have a duration of action (assessed by a measurable difference in FEV_1 compared with that after administration of placebo) of 4 to 6 hours (Figure 15-7). Although the changes in lung function are statistically significant compared with either baseline or placebo, these effects really are very modest and often below the threshold of a clinically important difference, which for operational purposes is set at around 100 mL from baseline. Some evidence points to a much shorter period of protection against nonspecific challenges (e.g., to methacholine) than the total duration of effect measured in this way. By contrast, long-acting inhaled agents produce more substantial bronchodilation for at least 12 hours relative to their baseline value, and again, the duration of protraction against agonist challenges is much longer (see Figure 15-7). Salmeterol and formoterol are given twice-daily to maintain a bronchodilator effect over the 24-hour day. Salmeterol has a relatively slower onset of action, whereas formoterol, which is a full agonist, induces bronchodilation at a rate similar to that seen with salbutamol. This difference is important only when treatment is given on a maintenance basis, but the fast onset of action of formoterol allows it to be used as a rescue therapy; this has led to the "single inhaler" approach to asthma management. Newer data derived from patients with COPD managed with indacaterol and vilanterol show that these drugs have a rapid onset of action that lasts throughout the day after a single dose.

Although consideration has been given to the possibility of tachyphylaxis with β_2-agonists, it has been difficult to establish that this occurs in clinical settings. Some data suggest that it may happen to a minor degree with formoterol, but this does not seem to lead to any clinically important difference, and

Formoterol/budesonide	4.5/160, 9/320 (DPI)				
Salmeterol/fluticasone	50/100, 250, 500 (DPI) 25/50, 125, 250 (MDI)				

DPI, dry powder inhaler; *MDI*, metered dose inhaler; *SMI*, soft mist inhaler.
*Not all formulations are available in all countries; in some countries, other formulations may be available.
†Formoterol nebulized solution is based on the unit dose vial containing 20 μg in a volume of 2.0 mL.
‡In one inhaler.

there is certainly no waning of the bronchodilator and clinically relevant actions of any of these drugs when tested in clinical trials. By contrast, an oral agent, viozan, which was developed because of its combination of β_2 and dopaminergic agonist effects, is associated with dramatic tachyphylaxis after several months of use and was never taken forward. Hence, this can be a problem when β-agonists are delivered in certain ways, but it does not seem to be an issue when the inhaled route is adopted.

SIDE EFFECTS

The principal side effects associated with β_2-agonists are shown in Table 15-2. Although these are less evident with inhaled than oral therapy, they still occur, especially when recommended doses are exceeded, as happens in patients with poorly controlled disease with use of β_2-agonist rescue therapy. The metabolic effects associated with these drugs do show tachyphylaxis, which helps explain why reports of hypokalemia after acute administration of the drugs have not been confirmed during larger clinical trials in which the drugs are given repeatedly. Also reported, however, is a variable susceptibility to tachycardia and tremor, which can be very troublesome, particularly in elderly patients. Sleep disturbance and anxiety appear to be nonspecific effects of higher doses of inhaled β-agonists, although the mechanisms leading to such problems remain unclear.

Recently, most concern has been focused on the risk of death associated with these drugs. This problem is confined to patients with asthma, rather than those with COPD, for which large, appropriately powered clinical trials have shown a reduction rather than an increase in all-cause and cardiac-related mortality rates. Equivalent prospective control data on asthma are lacking, and the concerns associated with the use of long-acting

Figure 15-7 Schematic time course of inhaled bronchodilator action. This usually is expressed in terms of the change in forced expiratory volume in 1 second (FEV_1) from baseline and here is normalized as a percentage of maximum achieved in the disease under treatment. Graph segment *A* reflects changes in the first 2 hours after inhalation. *Red line* plots data for short-acting β-agonist (SABA); *blue line* represents formoterol or indacaterol; *purple line* represents salmeterol or long-acting muscarinic antagonist (LAMA). Graph segment *B* depicts action from 4 to 12 hours. Of note, the SABA has already passed its peak effect (*orange line*). The *purple line* reflects indacaterol and tiotropium dose profile, whereas the *red line* reflects both salmeterol and formoterol time courses. Graph segment *C* extends duration to 24 hours and represents the effect of tiotropium and indacaterol.

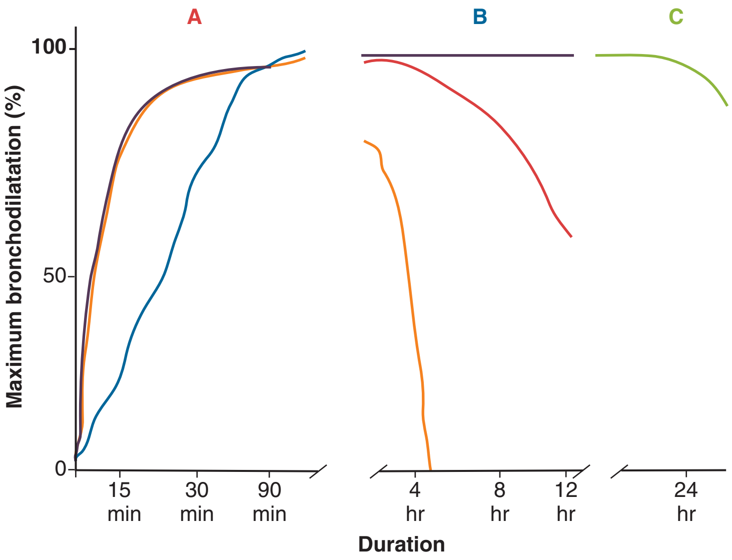

Table 15-2 **Side Effects of Bronchodilator Drugs**

	Side Effect(s)*		
Drug Class	**Minor**	**Troublesome**	**Major**
β_2-Agonists	Muscle tremor Tachycardia Palpitations Metabolic (increase in free fatty acids, pyruvate)† Hypokalemia† Worsening of hypoxemia due to ventilation-perfusion mismatch†		Perceived increase in risk of death (see text for discussion)
Antimuscarinics	Dry mouth Prostatism Blurred vision		Apparent increase in risk of death with soft mist formulation—disputed (see text for discussion)
Theophyllines	Diuresis	Headache Nausea Vomiting Gastric discomfort Behavioral disturbance (?)	Cardiac arrhythmias, including ventricular tachycardia Grand mal epileptic convulsions

**Minor*: side effects unlikely to modify treatment use, often decreasing over time; usually dose-dependent. *Troublesome*: side effects severe enough to lead to treatment discontinuation. *Major*: side effects severe enough to be life-threatening.

†Usually a first-dose effect in subjects previously naive to the drug. Patient often shows tachyphylaxis in the first weeks of treatment.

inhaled β-agonists have come both from earlier concerns about SABA use and from observational studies mainly conducted after the drugs have been licensed. The most important of these was a large observational trial of the use of salmeterol in asthmatic persons in the United States. This study found an apparent increased risk of death among African American asthmatic patients, many of whom were using these drugs for monotherapy, rather than in combination with inhaled corticosteroids. This observation has led to somewhat conflicting opinions across the Atlantic about the risks of β_2-agonist treatment. European clinicians, who have always been enthusiastic advocates of inhaled corticosteroids as a primary treatment for asthma, have been reassured by safety data about β_2-agonists, provided that they are used in combination with inhaled corticosteroids, while U.S. physicians remain concerned about the class effects of these drugs. Large monitoring studies are being conducted on the use of fixed combinations of these treatments in a single inhaler in U.S. asthmatics, with the goal of resolution of the concerns that still cling to use of this group of drugs.

ANTIMUSCARINIC AGENTS: CLINICAL CONSIDERATIONS

Antimuscarinic drugs (which also are called anticholinergic agents almost interchangeably, adding an element of confusion to any consideration of this topic) have been developed exclusively for use by the inhaled route. This limited approach reflects the significant side effect profile associated with systemically available drugs such as atropine, which produce a range of pharmacologically predictable adverse events including tachycardia, dry mouth, blurred vision, constipation, and prostatism. The pharmacologic manipulation of the atropine molecule by the addition of an ammonium residue greatly reduces the ability of the drug to cross lipid membranes and hence limits the action of the agent to the airways, rather than allowing systemic absorption. By far the most widely used agent in the past has been ipratropium, which is a short-acting muscarinic antagonist (SAMA) whose duration of effects measured by FEV_1 change is similar to and in general slightly greater than that for SABA drugs (see Figure 15-7). The development of tiotropium, an effective long-acting once-daily inhaled muscarinic antagonist (LAMA), has greatly reduced the use of ipratropium, and newer agents in this class also are being developed. Details of the dose, duration of action, and formulation of these drugs are presented in Table 15-1.

Inhaled antimuscarinic drugs are relatively nonspecific antagonists that block the uptake of acetylcholine at all three clinically relevant muscarinic receptor sites. The main benefit is the result of blockade at the M_3 receptors, but to some extent, blocking the M_2 receptors is a disadvantage because this reduces the reuptake of acetylcholine from the synaptic cleft and antagonizes the blockade of these receptors by the drug. It has been argued that this effect is less important with drugs like tiotropium, but in fact the relative kinetics of receptor occupancy, although longer with tiotropium than with ipratropium, are the same, so any specific advantage for this LAMA, beyond its extended duration of action as a bronchodilator, is unlikely. As with the β-agonists, there is a relatively shallow dose-response relationship with antimuscarinic drugs. These agents do protect against specific agonist challenge, such as with methacholine, and this protective effect has been demonstrated in asthmatic subjects. However, the efficacy of receptor antagonism appears to be less than that seen with agonist drugs, at least in asthma (see earlier), so the major portion of the data on antimuscarinic agents has come from patients with COPD. In this context, high doses of ipratropium (250 to 500 µg administered by nebulizer) have been shown to be more effective in improving lung function (as assessed by changes in FEV_1 and inspiratory capacity) than lower doses of ipratropium (40 µg). Although these differences appear to be small, they may be relevant, particularly when patients have difficulty using inhaled devices and when they are experiencing an acute exacerbation of disease. This explains the popularity of nebulized anticholinergic drugs for use in management of acute exacerbations of airways disease (see later).

As with β-agonists, the duration of effect of SAMA drugs is relatively brief, certainly compared with once-daily agents like tiotropium. And even when ipratropium is taken on a four-times-daily regimen, its clinical effectiveness is significantly less in patients with COPD than once-daily tiotropium, which is associated with better health status, fewer exacerbations, and better-maintained morning lung function. As a result, within the context of COPD, LAMA drug regimens are now the preferred form of maintenance bronchodilator therapy. Other agents in this class are currently being developed, such as glycopyrrolate and aclidinium bromide. The latter drug was believed to have a full 24-hour action, but clinical trials have suggested that it is likely to be more effective if used as a twice-daily inhaled drug. In general, little evidence of tachyphylaxis has been accrued for any of the antimuscarinic agents.

SIDE EFFECT PROFILE

The adverse events associated with inhaled antimuscarinic drugs follow those that would be anticipated with use of systemic available agents like atropine. The incidence of these side effects is much lower, however, although dry mouth is a frequent but not necessarily persistent reported change. This alteration reflects a direct local effect on salivary gland secretion, seen with all agents in this class but seldom sufficient to lead to discontinuation of treatment. When ipratropium is given in a wet nebulizer, it is possible, if a face mask is used, for some of the drug to enter the eye, and cases in which acute glaucoma was precipitated in this fashion have been reported. This is a rare problem, however, and does not seem to result in patients who take the drug by inhalation without the risk of direct contamination. As noted already, it is possible to administer high doses of ipratropium to increase the clinical benefit in certain circumstances, but there is less confidence that this is the case with tiotropium and related agents, so the stated dose of tiotropium (18 µg once daily) should not be exceeded.

As with β-agonists, cardiac events have been associated with the use of inhaled anticholinergic drugs. This risk is predominantly an issue for patients with COPD and was observed initially with ipratropium in the first Lung Health Study, a 5-year trial examining the effects of regular bronchodilator therapy and smoking cessation on the natural history of early COPD. A post hoc analysis of these data suggested a higher frequency of cardiac events in patients who received ipratropium. Although this finding fell short of statistical significance, it has contributed significantly to subsequent metaanalyses of data with these agents. Concerns about the use of long-acting drugs such as tiotropium have been raised, but the data from the large, 4-year randomized control Long-Term Impacts on Function with Tiotropium (UPLIFT) trial were very reassuring, with fewer, if any, cardiac events in patients who receive tiotropium. More recently, again based on metaanalysis, concern has emerged that the route of delivery may potentially influence the risk of death associated with tiotropium. Patients who receive tiotropium as a soft mist in the Respimat device demonstrated a 50% greater risk of dying during the clinical trials than in those who received this drug by Handihaler. The absolute number of events was small, however, and follow-up studies to the end of the trial, to determine mortality status, did not include all patients. A larger prospective, appropriately conducted study is under way to resolve these issues. It is difficult at present to see why a change in the delivery system should have such an apparently dramatic effect on mortality rates. The overall impression, however, is that these drugs are clinically safe and valuable, particularly in the context of COPD.

THEOPHYLLINE

Theophylline drugs have been used for many years in the treatment of airway disease. These drugs were developed after the original observation that xanthine-containing preparations such as coffee and tea had some mild bronchodilator action. Because this group of agents was in use before current drug licensing processes were developed, they have not been subjected to the same rigorous safety and efficacy evaluation required for newer drugs. Direct comparison of theophylline with those inhaled agents already described provides a fairly clear picture of their relative efficacy. Theophylline is the typical example of this class, although it has been modified as aminophylline for intravenous use. These drugs have complex pharmacologic effects, including inhibition of a range of phosphodiesterase enzymes with a rise in intracellular cAMP as a result, as well as adenosine antagonism and a range of potentially antiinflammatory actions. In terms of bronchodilatation, these seem to be associated mainly with antagonism of the phosphodiesterase-3 (PDE3) receptor. This is not necessarily a very potent way to produce

Table 15-3 Factors Affecting Theophylline Metabolism in Chronic Obstructive Pulmonary Disease (COPD)*

Increased	Decreased
Cigarette smoking^{++} Anticonvulsant drugs Rifampicin	Arterial hypoxemia (<45 mm Hg)$^{++}$ Respiratory acidosis^{+} Congestive cardiac failure^{+} Liver cirrhosis Erythromycin^{++} Ciprofloxacin (NOT ofloxacin) Cimetidine (NOT ranitidine) Viral infections Old age^{+}

*Factors posing particular problems in COPD are indicated by superscript plus signs, the number depending on the likely hazards.

Table 15-4 Technique for Use of Metered Dose Inhalers in Obstructive Lung Disease

Ideal Method	Difficulties Observed/Reported in Clinical Use
1. Remove cap.	Occasionally forgotten
2. Shake inhaler.	Occasionally forgotten
3. Hold inhaler upright.	Often forgotten
4. Tilt head back 10-55 degrees.	Often forgotten
5. Hold inhaler in front of open mouth.	Confusion about this step is common
6. Begin to inspire and activate inhaler.	Coordination problems
7. Breathe in slowly and deeply.	Difficult if lungs are hyperinflated already
8. Breath-hold for 10-15 seconds.	Breath-hold time reduced
9. Breath out slowly through the nose.	Harder with high respiratory rate
10. Use one puff at a time—wait 3-5 minutes between puffs.	Frequent use of multiple puffs in a single inspiration

bronchodilatation, and these agents are less effective, both in vitro and in vivo, than other, alternative medications.

Theophyllines can be used only by the oral or intravenous route and, for reasons that remain somewhat unclear, appear to be entirely ineffective when given by inhalation. This limitation is unfortunate, because these drugs have a significant adverse event profile, as summarized in Table 15-3. The most dramatic problems are those associated with the unanticipated onset of ventricular tachycardia and of grand mal epileptic convulsions. However, a number of other troublesome side effects are typical of this group and probably are mediated by PDE4 inhibition—namely, headache, nausea, insomnia, vomiting, diarrhea, and poor appetite. These effects occur frequently with theophyllines and are dose-related. Unfortunately, the pharmacokinetics of this class of agents is rather variable, and their absorption is influenced by food and the way in which the drug is presented. Although slow-release preparations have been developed, their use increases the cost of what would otherwise be relatively inexpensive medication. It has been suggested, but not conclusively established, that introducing these drugs in low doses with gradual buildup subsequently is associated with lower incidence of unpleasant adverse events. Nonetheless, it also is a requirement that theophylline levels be monitored to ensure that the patient is not exposed to undue risks of toxicity.

More recently, interesting experimental data have suggested that these agents when given at lower dose have an antiinflammatory effect, and a mechanism has been suggested to explain why this might be important in patients who are smokers, because it would overcome antagonism directly created by the effects of inhaled corticosteroids. This experimental data need to be translated into a clinical setting to ensure that the magnitude of benefit is worth the hazard associated with taking even low doses of these drugs. In most clinical guidelines, theophyllines are now regarded as drugs to be tried in patients where other therapies have not been effective, so their overall use has declined significantly in the past decade.

DRUG DELIVERY

As noted earlier, the most effective bronchodilator drugs are delivered by the inhaled route, which minimizes the dose to the patient while increasing the directly available concentration of the drug at the desired site of action within the airways. Inhalation therapy is more complex than oral treatment, however, and in some settings and cultures, barriers to its uptake remain. As noted in Table 15-1, short-acting inhaled bronchodilators are available both as metered dose inhalers and in dry powder devices. Long-acting inhaled β-agonists also are available in both these forms, but at present tiotropium, the most widely used LAMA drug, is available only as a dry powder. No standardization of inhalation devices used to deliver these drugs has been attempted, but the general requirements for effective inhaler use have been codified and are presented in Table 15-4. An assessment of the effectiveness of the patient's inhaler technique is one of the most important components of the clinical review on follow-up visits. The ability to use inhalers properly is not related to educational status or age and seems to be somewhat unpredictable. The use of spacer devices can improve the percentage of drug delivered and often can sidestep problems with incoordination. A variety of such devices are available for use with metered dose inhalers. Spacers can be helpful when the need to limit side effects due to inhaled corticosteroids is a primary consideration but also can increase the effectiveness of bronchodilator delivery if the drug is reaching the airway, rather than being swallowed and metabolized. Breath-activated inhalers help some patients who find it hard to coordinate inspiration and device actuation, and often a change to a different delivery system (e.g., switching to a dry powder formulation from a metered dose inhaler) can improve matters significantly. Wet nebulization formulations of both SABA and SAMA drugs are available, but their potential for greater effect reflects the much higher doses given, rather than improvement in the deposition of the drug. These systems are operator-independent and thus well suited for use by distressed patients experiencing exacerbations of symptoms. How much of this acute benefit derives from the drug and how much from the cooling effects on the face of the mist in which it is delivered remain to be quantified.

USE OF BRONCHODILATOR DRUGS IN CLINICAL PRACTICE

The uses of bronchodilators in specific diseases are considered elsewhere in this book. This section presents a brief overview of the main clinical indications for this group of agents at present.

AID TO DIAGNOSIS

Bronchodilator reversibility testing is still widely performed in many laboratories. The principle is simple: Lung function, normally assessed as the FEV_1, is measured before and at an appropriate interval after the inhalation of a bronchodilator. Any change greater than that expected by chance would represent a *positive response*, which has been defined operationally as a change greater than 12% of the baseline which also exceeds 200 mLs. This information can be helpful as an adjunct to other diagnostic and clinical assessments but unfortunately cannot be relied on by itself as a guaranteed way of defining specific diseases. In asthma, it is the within- and between-day variability in lung function that is more important than the acute response to a drug, although a return to normal lung function after a bronchodilator test on a day when lung function is impaired constitutes strong evidence for this diagnosis. If the patient is tested when lung function is close to normal, however, the bronchodilator test result may be negative, but the diagnosis will still be asthma. Similarly, in COPD, many patients show responses to drugs on some occasions but not others. This inconsistency reflects the categorical nature of the response criteria and the fact that even in COPD, some physiologic variation in day-to-day lung function is typical. In general, the likelihood of a response falls as the baseline lung function worsens, along with the degree of clinical emphysemas. If more than one drug is used, then the chance of a positive response increases, so testing the combination of a β-agonist and an anticholinergic will produce a prevalence of disease different from that observed with use of a β-agonist alone. The latter drug has the advantage that only 15 minutes is required before the patient can be retested, explaining its popularity in many laboratories.

MANAGEMENT OF STABLE DISEASE

Use of inhaled short-acting β-agonists is a valuable way of relieving acute symptoms, and the rapid onset of action of these agents is much appreciated in both patients with asthma and those with COPD. Short-acting bronchodilator treatment with any class of these drugs is not appropriate for the management of these diseases, however, and long-acting inhaled drugs are preferred. An important distinction emerges regarding how these drugs are used in combination with other agents: Fixed-dose drug combinations of inhaled corticosteroids and long-acting β-agonists in a single inhaler have been available for some years and have proved to be very effective in the management of both asthma and COPD. In the context of asthma management, inhaled corticosteroids should always be the first line of treatment before the addition of a long-acting β-agonist to improve asthma control. LABA treatment should not be used as monotherapy for this condition. In COPD, it is clear that long-acting β-agonists and especially long-acting antimuscarinic drugs can be safely used and are very effective in disease management. Here the decision to add a combination inhaler is guided more by symptom severity and complications, as indicated in recent treatment guidelines. As noted, the use of oral theophyllines remains a third-line therapy in both the major obstructive lung diseases. Data on the use of bronchodilators in conditions such as bronchiectasis are much more limited, and although these drugs are widely prescribed in this context, their use is based largely on extrapolation from pharmacologic management of clinical entities such as asthma and COPD, for which much more information is available.

MANAGEMENT OF ACUTE EXACERBATIONS OF DISEASE

High doses of nebulized bronchodilators, often as combinations of SABAs and SAMAs, are the mainstay of management of acute asthma and exacerbations of COPD that necessitate hospitalization. These drugs also are given to patients who require invasive ventilation, although in this context the β-agonist may be given intravenously. Intravenous therapy is not appropriate with antimuscarinic drugs but has been widely used to deliver aminophylline for both asthma exacerbations and acute COPD for many years. Evidence from metaanalysis of existing clinical trials shows no benefit in either setting from the use of aminophylline and is associated with a considerable risk of toxicity, especially when the patient has been receiving theophyllines as part of the regular medication regimen before intravenous therapy begins. Accordingly, intravenous aminophylline is no longer recommended in patients who can use appropriate nebulized short-acting bronchodilator drugs.

CONTROVERSIES AND PITFALLS WITH BRONCHODILATOR DRUGS

Despite the well-described pharmacologic properties and abundant clinical trial data on the use of bronchodilator drugs, some areas of controversy remain. It is now accepted that inhaled β_2-agonists produce greater degrees of bronchodilatation than those achievable with antimuscarinic agents in the treatment of asthma. This observation probably reflects the additional pharmacologic properties of these drugs as discussed, plus the potential advantages of an agonist over an antagonist agent in inducing smooth muscle relaxation. By contrast, antimuscarinic drugs such as ipratropium and tiotropium have been thought, on balance, to be more effective than inhaled β_2-agonists. As noted, however, this view is now being challenged with the advent of drugs such as indacaterol and oldanterol, which have a truly 24-hour duration of action and, in terms of lung function, appear to be as effective as antimuscarinic drugs in the management of COPD. Almost all available data on the action of bronchodilator drugs in lung disease come from studies in COPD and asthma, and these drugs commonly are used to help airflow obstruction in other settings, such as those of bronchiectasis and obliterative bronchiolitis. Whether these agents have equivalent effects in different disease states remains unclear, although it seems unlikely that their use will be prohibited on these grounds. Most of the data on bronchodilators come from trials of efficacy that established that the treatment is beneficial but have not necessarily studied how effective such treatment is in a "real-world" clinical setting. Here, many other factors come into play, such as adherence to treatment and patient choice, as well as perception and information, and optimizing these aspects of care is as likely to be important as any minor differences in the pharmacology of the agents selected. Finally, a much-needed look at these issues could be realized with good studies of the use of theophylline in stable lung disease on a background of other existing modern treatments. Implementation of such studies would be particularly problematic in the context of bronchial asthma, for which inhaled corticosteroids are seen as first-line therapy but would seem to be possible in COPD, a condition that affects many people, particularly those in the developing economies, who cannot afford more expensive combination treatment.

Concerns about safety of bronchodilator drugs have been present for many years since the first asthma epidemics were associated with excess use of nonspecific adrenergic stimulants such as isoprenaline and the subsequent problems associated with the use of fenoterol. These issues have not been helped by the sometimes overoptimistic promotion of new bronchodilator drugs by their advocates, including the manufacturers. The issues of β_2-agonists and asthma safety have already been considered, but it is unlikely that a clear-cut response to these concerns can be obtained until the large 6-month safety trials being conducted by the U.S. Food and Drug Administration (FDA) have been completed. Inevitably, some clinicians and patients will remain suspicious of the ultimate benefit of these agents in this context. Similar concerns about the cardiovascular safety of antimuscarinic drugs have been raised, although in general it has been possible to offer good clinical trial data that these risks have been exaggerated. The latest concerns, based on a metaanalysis of registration studies for the soft mist form of tiotropium, also have suggested a significant increase in the risk of death for patients who use this agent. A very large prospective clinical trial is now under way that should resolve this issue as well. Nonetheless, the requirement for large numbers of people who have to be studied to exclude a potential risk serves as a brake on development of new drugs in these classes.

Despite the foregoing concerns, bronchodilator drugs remain relatively safe and easy to administer. The pitfalls in their use are practical. In particular, failure to check that the patient is using the inhaler properly remains an issue with both metered dose and dry powder inhalers. Although new devices have been developed, adherence to treatment in a "real-world" setting is likely to be lower than in clinical trials. Use of "reliever" treatment is clearly preferred over maintenance therapy in patient-delivered management of many diseases, and this inclination is a particular concern in patients with asthma, in whom additional use of reliever therapy is a marker for poor asthma control. Understanding the reasons for such patient behaviors is key to effective bronchodilator use. Drugs such as theophyllines are no longer in widespread use, but patients on maintenance treatment, who often are suffering from COPD, are at serious risk for major complications if intravenous aminophylline is added to a regimen associated with already high theophylline levels. In view of the minimal evidence for efficacy of intravenous preparations, these agents are best avoided in the interest of patient safety.

THE FUTURE OF BRONCHODILATOR THERAPY

Although other mechanisms including potassium channel blockade have been explored, the risk of toxicity or lack of clinical effect with alternative approaches has meant that bronchodilator treatment is still focused on the manipulation of the adrenergic and cholinergic systems recognized more than a century ago. In practice, an easier approach has been to modify the duration of drug action rather than its potency, so new treatments are likely to be given once daily. The resulting consistent bronchodilation over the 24-hour day is a particular benefit in patients with COPD and other conditions associated with persistent airflow obstruction, as was seen when tiotropium became available. Indacaterol is the first inhaled once-daily long-acting β-agonist and has been licensed in Europe for treatment of COPD. It produces improvement in lung function comparable with that seen with tiotropium, and more studies are awaited to establish whether it is equivalent to or more effective than this agent. Vilanterol and oldanterol appear to have similar properties when given by inhalation, and clinical data have been presented in abstract, although these drugs are yet to be licensed. Like formoterol, both drugs have a relatively rapid onset of action; the importance of this property when the drug is used as for maintenance therapy remains unclear, however. New LAMA drugs are being developed, and an old agent, glycopyrrolate, has been revived and repackaged as an effective once-daily anticholinergic bronchodilator.

Combining drugs of different classes may potentially achieve greater effect for a given level of adverse effects associated with each agent. This approach proved popular in the 1990s, when the combination of salbutamol and ipratropium was widely used by patients with COPD, and the concept is now being revisited with different combinations of once-daily LAMA and SABA agents. Similarly, new inhaler regimens of once-daily LABA (and potentially LAMA) drugs plus an inhaled corticosteroid are being developed as successors to the single inhaler combinations noted previously. Although the combination of all three agents in a single inhaler is being considered, complex technical issues remain to be solved regarding the simultaneous administration of consistent doses of three chemically different agents.

The limiting factor for dual-agent bronchodilator drugs, and also for new LABA combinations in general, is the concern of the FDA that such treatment might be given to patients with asthma even if that is not the labeled indication. Reflecting FDA concerns already noted that treatment with LABA drugs in patients with asthma may be dangerous, as well as the possible cardiovascular risk associated with anticholinergic agents, large (comprising approximately 11,500 patients) and hence expensive clinical trials are now a regulatory requirement to ensure the safety of such drugs. This requirement can be expected to impede the development of new treatment formulations; accordingly, the agents already discussed in detail are likely to remain the mainstay of clinical management for some time to come.

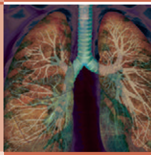
Section 3
RESPIRATORY PHARMACOLOGY



Chapter 16
Antiinflammatory Drugs

Klaus F. Rabe

Asthma and chronic obstructive pulmonary disease (COPD) are both inflammatory diseases. The nature of the inflammatory cascade is complex but different in each disease, asthma involving eosinophils and COPD and severe asthma involving neutrophils, among other inflammatory cell types. Therefore, asthma and COPD should be treated differently. Corticosteroids (also known as glucocorticoids or simply steroids), and particularly inhaled corticosteroids, constitute the most effective treatment for persistent asthma and are recommended as first-line agents in both adults and children. This group of drugs improves quality of life and lung function, by relieving symptoms, combating airway hyperresponsiveness, reducing inflammation, and limiting exacerbations. They are less effective at reducing COPD-specific inflammation and are not recommended until the disease has progressed to more advanced stages. Oral and systemic steroids are of benefit in treating COPD exacerbations, although their use is limited by side effects.

Bronchodilators, alone or in combination with an inhaled steroid, are the mainstay of COPD therapy, although a significant number of patients continue to suffer exacerbations while using these drugs. Only recently has a new class of antiinflammatory drug, the phosphodiesterase-4 (PDE4) inhibitors, been proved effective for the treatment of COPD, and at present only one drug in this class, roflumilast, has been approved for clinical use.

This chapter reviews these two classes of antiinflammatory drugs, highlighting their mode of action, clinical efficacy, and possible side effects. Some of the most commonly used systemic and inhaled corticosteroids are compared, with particular attention to dosing equivalence.

CORTICOSTEROIDS

Corticosteroids have been the cornerstone of treatment for various inflammatory diseases affecting any and all body systems and structures for more than 60 years. They were first applied to the treatment of inflammatory diseases of the lungs in 1949. The development of inhaled corticosteroids has revolutionized the treatment of asthma, providing local antiinflammatory properties while minimizing the side effects that limit the use of oral and systemic steroids.

PHARMACODYNAMICS

Cellular, Tissue, and Systemic Effects

The primary therapeutic effect of corticosteroids in respiratory disease results from reducing the number of inflammatory cells in the airways, such as eosinophils, T lymphocytes, mast cells, and dendritic cells. Corticosteroids inhibit the recruitment of inflammatory cells by reducing chemotaxis and adhesion, phagocytosis, and respiratory burst activity, as well as the production of inflammatory mediators such as cytokines and eicosanoids. Corticosteroids also have lytic effects on circulating lymphocytes and induce neutrophilia through decreased adhesion and demargination of polymorphonuclear cells. In particular, airway endothelia are thought to be a major target for the antiinflammatory properties of inhaled steroids in asthma.

In COPD, however, even high-dose inhaled corticosteroids have little effect on airway inflammation, although they are effective when combined with a long-acting β_2-agonist (LABA) (Figure 16-1).

MOLECULAR MECHANISMS

The primary effect of corticosteroids appears to be at the genetic level, activating transcription of antiinflammatory genes and repressing proinflammatory genes. They act primarily by binding to intracellular glucocorticoid receptors, which in turn regulate gene expression through glucocorticoid response elements (GREs) (Figure 16-2). Once inside the nucleus, glucocorticoid receptors dimerize and bind to GREs in the promoter regions of steroid-responsive genes, altering gene transcription and initiating a cascade of antiinflammatory effects downstream. Mediators affected by corticosteroids include cytokines, adhesion molecules, and chemokines. Nuclear glucocorticoid receptor monomers also interact with transcription factors such as nuclear factor (NF)-κB, to suppress expression of a number of proinflammatory genes. Corticosteroids can also decrease protein synthesis by decreasing messenger RNA (mRNA) stability.

Recent work has focused on the role of corticosteroids in regulating gene expression through effects on histone acetylation and chromatin compaction. Inflammatory signals cause chromatin unwinding by histone acetyltransferase activity. Corticosteroids can directly inhibit histone acetyltransferases and recruit histone deacetylases (HDACs) to their site of action, seemingly independent of glucocorticoid receptor binding to GREs. Corticosteroids interact with specific HDACs (such as HDAC2) that target specific histone proteins (e.g., histone H_4), regulating expression of particular regions of the genome. The net effect is to decrease histone acetylation, promoting chromatin compaction and downregulation of inflammatory gene expression (Figure 16-3).

SYNERGY WITH BRONCHODILATORS

Inhaled corticosteroids and β_2-agonists appear to work in synergy: The steroids upregulate β_2-adrenoreceptors and

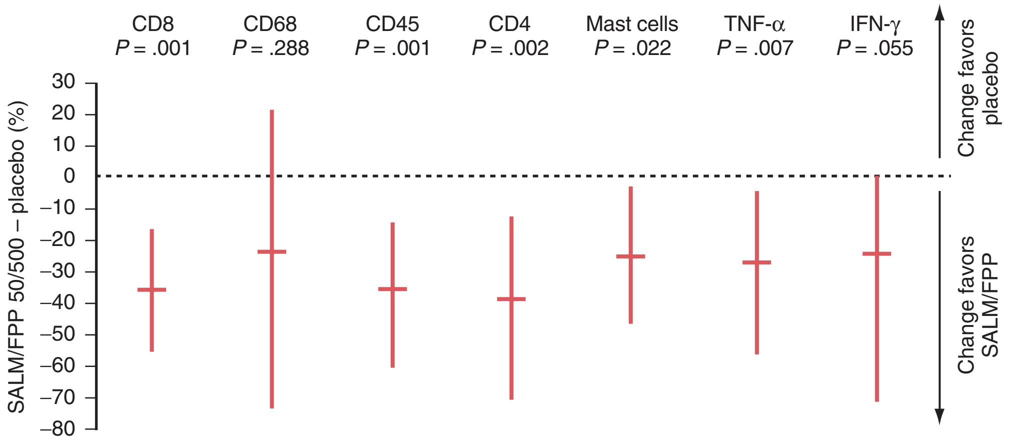


Figure 16-1 Inhaled corticosteroids and long-acting β-agonists reduce airway inflammation in chronic obstructive pulmonary disease (COPD). Figure 16-2 Molecular mechanisms of corticosteroid action. Corticosteroids diffuse readily across the cell membrane, where they bind glucocorticoid receptors. Corticosteroid binding causes dissociation of chaperone proteins (such as heat shock protein 90), thereby allowing translocation of the glucocorticoid receptor to the nucleus. Once in the nucleus, the glucocorticoid receptor can dimerize and bind to glucocorticoid response elements (GREs), or it can bind to other transcription factors (such as activator protein 1 and nuclear factor-κB) as a monomer. *(From McGhan RM: Corticosteroids. In Albert RK, Spiro SG, Jett JR, editors:* Clinical respiratory medicine, *ed 3, Philadelphia, Mosby, 2008, p 484.)*

prevent tachyphylaxis in response to β_2-agonists, while β_2-agonists increase translocation of glucocorticoid receptors from the cytoplasm to their site of action in the nucleus. As might be expected, then, these two important drug classes have an additive effect when given in combination, which may explain the greater efficacy of fixed-dose combinations in COPD compared with that achieved with inhaled steroid monotherapy.

STEROID RESISTANCE

Resistance to corticosteroids is problematic, because high doses are associated with side effects. Several mechanisms of steroid resistance have been described. Inactivating mutations in the glucocorticoid receptor occur in rare cases; these patients typically suffer no side effects of corticosteroid treatment. More commonly, steroid resistance is acquired during the course of inflammatory diseases and may, in fact, be induced selectively in inflamed tissues through the action of inflammatory cytokines. Alternative splicing of the glucocorticoid receptor may result in accumulation of β-glucocorticoid receptors that do not bind steroids, and may decrease the activity of steroid-bound α-glucocorticoid receptors through formation of heterodimers and through competitive binding to GREs. Additional mechanisms may include phosphorylation of glucocorticoid receptors that alters their pharmacologic activity and acquired HDAC deficiency, resulting in decreased steroid-induced chromatin compaction.

PHARMACOKINETICS

Systemic

The route of administration for systemic steroids depends, to some degree, on the indication. Very high doses of corticosteroids given for acute conditions generally require parenteral administration. When the prescribed steroid dose can be achieved by oral administration (e.g., prednisone, 1 mg/kg daily), there is no clear benefit to parenteral therapy. The pharmacologic activity of systemic steroids depends on both the pharmacokinetic and pharmacodynamic properties of the drug. Dosing equivalence is based on the biologic activity of a given dose, as measured by antiinflammatory activity and sodium-retaining activity.

Oral steroids are readily absorbed by the gastrointestinal tract. The degree of first-pass hepatic elimination varies, with oral bioavailability ranging from 60% to 90%. Cortisone and prednisone are prodrugs and require hydroxylation in the liver for activation. After absorption, steroids are bound to proteins such as albumin and circulate systemically. The rate-limiting

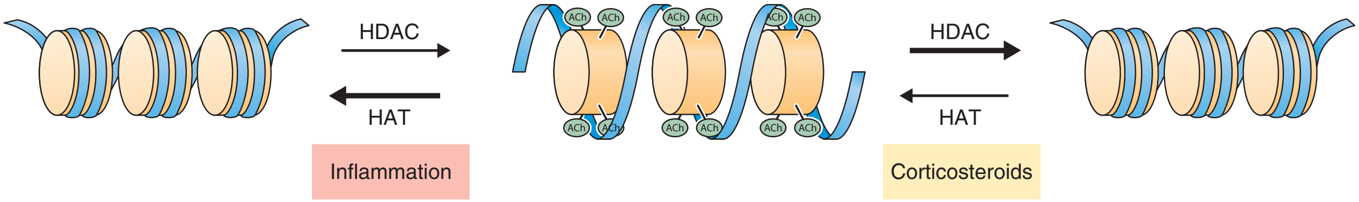

Figure 16-3 Effects of inflammation and corticosteroids on chromatin compaction. Inflammation promotes acetylation of histones by increasing histone acetyltransferase (HAT) activity; in addition, histone deacetylase (HDAC) activity is decreased in inflammatory lung diseases including asthma and chronic obstructive pulmonary disease (COPD). Corticosteroids promote chromatin compaction and silencing of gene transcription by inhibiting HAT activity and by increasing HDAC activity. *ACh*, acetylcholine. *(From McGhan RM: Corticosteroids. step in the elimination of a steroid drug is reduction and conjugation in the liver, although the final fate of these water-soluble metabolic end products is excretion in the urine. The metabolism of parenteral steroids is similar, except without first-pass elimination.

Inhaled

Between 10% and 60% of a dose of inhaled corticosteroid (ICS) is deposited in the lung, where it is absorbed into the systemic circulation and cleared through the liver. The remainder of the dose is deposited in the oropharynx, which can lead to local side effects. Any of the dose that is swallowed undergoes absorption into the portal circulation and undergoes first-pass elimination, as for oral steroids.

A number of methods have been developed for delivering inhaled steroids, including use of metered dose inhalers (MDIs), dry powder inhalers, and, less commonly, nebulizers. Historically, the propellants used in MDIs were chlorofluorocarbons, but recognition of the environmental impact of these agents led to the development of hydrofluoroalkanes as the propellant. All of these methods of delivery vary with respect to the particle size generated and velocity of delivered drug, resulting in small differences in equivalent dosing but similar efficiency of drug delivery.

The pharmacokinetic characteristics of inhaled steroidal agents are more complex than those of systemic steroids. These drugs have undergone extensive development to improve activity in the lungs while decreasing systemic activity. An "ideal" inhalational agent of this class would have a small particle size (to allow access to small airways of the lung), low oral bioavailability, long residence in the lung (through slow absorption and/or lipid conjugation), delivery of a lung-activated prodrug, high receptor affinity, and high binding to proteins in circulating blood. Table 16-1 reviews many of these properties for seven available ICSs.

Direct comparison of the pharmacologic activity of various inhaled agents is difficult but nevertheless important, because management of airway diseases requires the ability to titrate the potency of delivered drug to achieve the desired clinical effect. The National Asthma Education and Prevention Program (NAEPP) Expert Panel Report, the Global Initiative for Asthma (GINA), and the Global Strategy for Asthma Management and Prevention have integrated a large amount of clinical and pharmacokinetic data to classify equivalent doses of a variety of different ICSs (Table 16-2). In general, a dose-response relationship without increased systemic effects is typical in the low to medium dose range.

SIDE EFFECTS

Generally, side effects are more common with systemic steroids than with inhaled agents (Table 16-3). Tolerability can be improved further by reducing dosage or treatment duration where possible, and with improvements in formulation as described above. Long-term use of systemic steroids can be associated with weight gain, increased susceptibility to infection secondary to immunosuppression, growth retardation in children, and osteoporosis. All forms of corticosteroids can hinder growth in children, although growth retardation associated with inhaled steroids is transient and of no long-term significance. The Childhood Asthma Management Program study monitored growth in 1041 children treated with budesonide, nedocromil, or placebo for 4 to 6 years and found a 1.1-cm lag in height gained in patients taking budesonide

Table 16-2 Adult Dosing for Inhaled Corticosteroids*

Corticosteroid	Delivery	Dose Per Actuation (μg)	Low Dose (μg)	Medium Dose (μg)	High Dose (μg)

compared with placebo. This lag was experienced primarily during the first year of the study.

Corticosteroids adversely affect bone health, with osteoporosis, osteoporotic fractures, and avascular osteonecrosis being relatively common and severe toxicities resulting from systemic administration. The incidence of osteoporosis seems to be related to daily use, prolonged duration of use, and significant cumulative lifetime dose, and this complication has been seen with doses as low as 5 to 7.5 mg/day of prednisone.

Adrenal insufficiency is a well-described consequence of systemic corticosteroid use. The risk seems minimal with inhaled steroidal agents. Although suppression of morning cortisol levels does occur in response to these agents, the risk of clinically apparent adrenal insufficiency is small (although supported by published case reports).

Systemic corticosteroids are potent immunosuppressors, particularly when prescribed in higher doses and for prolonged periods of time. Courses of 2 to 8 weeks of systemic steroids used to treat acute exacerbations of COPD do not seem to be associated with increased rates of infection. Chronic corticosteroid use is recognized to carry a risk for *Pseudomonas* and *Pneumocystis* infections, tuberculosis, and herpes zoster.

Side effects of inhaled steroidal agents are mostly associated with deposition of the drug in the oropharynx, such as oral candidiasis (thrush) and dysphonia, although the incidence of these events can be reduced by rinsing the mouth after taking the drug. Inhaled formulations have been associated with decreased bone mineral density in at least one randomized controlled trial. Inhaled steroids initially were not thought to increase the risk of lung infections, but more recently, the TORCH (Towards a Revolution in COPD Health) trial found an increased frequency of pneumonia among patients receiving inhaled steroids (fluticasone propionate, with or without salmeterol), possibly a result of localized immunosuppression in the lungs.

PREVENTION AND MANAGEMENT OF CORTICOSTEROID TOXICITY

To reduce side effects associated with inhaled corticosteroid use, patients should be educated on proper inhaler technique and on washing out the mouth after use, and those who use MDIs should be given a spacer to add to their device. Symptoms associated with use of an MDI sometimes may be reduced or eliminated by a switch to a dry powder inhaler. Children who use a nebulizer for steroid delivery should wash the face after using the medication.

In patients on pharmacologic doses of systemic steroids, periodic ophthalmologic examination can detect the development of cataracts and glaucoma, which may respond to reduction in dose or, if the steroid dose cannot be reduced, other treatments. The role of ophthalmologic assessment in patients on inhaled steroidal agents is less clear, but these patients should certainly be referred for evaluation of any ophthalmologic symptoms and for routine, age-appropriate care.

Screening for and management of cardiovascular risk factors, including hypertension, hyperglycemia, and hyperlipidemia, also are warranted in patients receiving chronic systemic steroids.

Patients receiving chronic systemic or inhaled steroid therapy should have routine bone mineral density measurements (particularly in high-risk groups), and they should be encouraged to perform weight-bearing exercise and to take calcium and vitamin D supplements (in the absence of any contraindications). Hormone replacement, bisphosphonates, calcitonin, and hydrochlorothiazide (HCTZ) can be considered in patients with established osteoporosis.

Avoidance of nonsteroidal antiinflammatory drugs (NSAIDs) is appropriate in patients receiving systemic steroids. Vigilance for psychiatric symptoms is prudent; if such symptoms are present, the patient can be managed by reducing the dose of steroid and/or by pharmacotherapy targeting the psychiatric symptoms.

Patients receiving chronic steroid therapy should be alerted to the increased risk of infection and should be encouraged to seek prompt evaluation at the earliest sign of infection. If possible, any vaccinations that are appropriate should be administered before therapy starts. If long-term administration of moderate to high doses of systemic corticosteroids is anticipated, prophylaxis for *Pneumocystis* pneumonia may be appropriate.

Patients receiving chronic systemic steroid therapy should be alerted to the symptoms of adrenal insufficiency and should be encouraged not to skip doses.

PHOSPHODIESTERASE 4 INHIBITORS

PDE4 is one of 11 PDEs in the phosphodiesterase enzyme superfamily. It is expressed in many cell types, notably in inflammatory cells such as neutrophils, and in airway smooth muscle cells, where it regulates inflammation by means of the

Table 16-3 Adverse Effects of Inhaled and Systemic Corticosteroids

System/ Structure	Inhaled	Systemic	Prevention
Upper airway	Thrush	Thrush	Wash out mouth after using inhaled steroids
	Dysphonia		Use a spacer device
Musculoskeletal	Growth delay	Decreased adult height	Follow bone mineral density
	Decreased bone mineral density	Osteoporosis	Calcium/vitamin D
	Possible increase in fractures	Fractures	Bisphosphonates
		Avascular osteonecrosis	Weight-bearing exercise
		Myopathy	HCTZ
HPA axis	Suppression of cortisol secretion	Adrenal insufficiency well described	Avoid abrupt discontinuation of chronic steroids
	Case reports of clinical adrenal insufficiency		Stress dosing when appropriate
Ocular	Possible increase in posterior subcapsular cataracts, glaucoma	Posterior subcapsular cataracts Glaucoma	Serial ophthalmologic examination
Skin and soft tissues	Ecchymosis	Ecchymosis	Face washing after use of nebulized drug in children

second messenger cyclic adenosine monophosphate (cAMP). PDE4 was identified as a potential target for antiinflammatory therapies many years ago, and several PDE4 inhibitors have been developed specifically as treatments for respiratory disease. Most of these agents have failed in clinical testing owing to a high incidence of gastrointestinal side effects, although compounds with greater substrate potency and specificity have increased efficacy at low doses (Table 16-4).

Theophylline is a weak and nonspecific inhibitor of several PDE isoforms, often incorrectly considered to be a PDE4 inhibitor. It is associated with severe side effects, and its use in treating respiratory disease is becoming less common.

The focus of the remainder of this section is on roflumilast, the only PDE4 inhibitor approved to treat COPD (granted approval by the European Medicines Agency in 2010).

PHARMACODYNAMICS

Molecular Mechanisms

Roflumilast and other PDE4 inhibitors bind directly to PDE4 to block its activity, thereby reducing inflammation (Figure 16-4). PDE4 is expressed in many cells involved in the inflammatory response that underlies COPD.

Table 16-4 Relative Potency and Suggested Dosage of Selected Phosphodiesterase 4 (PDE4) Inhibitors and Theophylline for Chronic Obstructive Pulmonary Disease

	PDE4 Inhibition: IC_{50} (nM)*	Dosage
Roflumilast	0.8	0.5 mg once daily
Cilomilast	120	15 mg twice daily
Rolipram	1100	—
Theophylline	>10,000	100-600 mg daily

*Potency expressed as half-maximal inhibition concentration for PDE4 activity. Modified from Wang D, Cui X: Evaluation of PDE4 inhibition for COPD, *Int J COPD* 1:373-379, 2006.

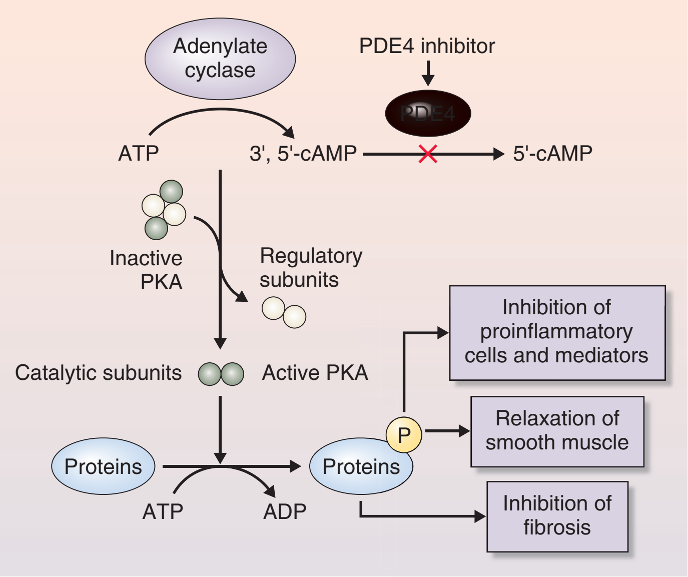

Figure 16-4 Molecular pathways affected by inhibition of phosphodiesterase 4 (PDE4). PDE4 inhibitors block the activity of PDE4, causing accumulation of cyclic adenosine monophosphate (cAMP) and downstream increase in protein kinase A (PKA) activation. This in turn leads to protein phosphorylation (P), resulting in an overall antiinflammatory effect. Although increased cAMP levels generally are associated with smooth muscle relaxation, this is not a characteristic of roflumilast. *ADP*, adenosine diphosphate; *ATP*, adenosine triphosphate. *(Modified from Rabe KF: Roflumilast for the treatment of chronic obstructive pulmonary disease,* Expert Rev Respir Med *4:543-555, 2010.)*

Cellular, Tissue, and Systemic Effects

PDE4 inhibitors work over many weeks to reduce the inflammation associated with COPD. Studies in animals have provided evidence that roflumilast can reduce smoke-induced inflammatory responses, remodeling in the airways and pulmonary vasculature, and oxidative stress. In a 4-week crossover study in patients with COPD, roflumilast significantly reduced the number of inflammatory cells and mediators in induced sputum samples. This finding correlated with improved lung function in the same patients, supporting an antiinflammatory basis for the clinical actions of the drug.

Synergy With Bronchodilators

PDE4 inhibitors have no immediate bronchodilatory effects but work over time to target chronic inflammation. Because bronchodilators work through a different mechanism of action, PDE4 inhibitors can offer additional clinical benefit when added to regimens of these drugs, such as reducing exacerbation rates even further. In fact, roflumilast currently is licensed only for add-on therapy to bronchodilators.

PHARMACOKINETICS

In humans, roflumilast is rapidly converted to roflumilast *N*-oxide, which is responsible for most therapeutic effects. It has a long half-life, which allows once-daily dosing, and is taken orally at the optimal dose of 500 µg. In clinical studies, the main benefit of this drug in patients with COPD was found to be reduction in the frequency of moderate to severe COPD exacerbations.

Phase III clinical testing has shown that roflumilast is most effective in a subpopulation of patients with COPD who are at increased risk for COPD exacerbations. The target subgroup includes patients with severe COPD (i.e., with a postbronchodilator forced expiratory volume in 1 second [FEV_1] less than 50%), symptoms of chronic bronchitis (which is linked to an increased risk of exacerbations), and a history of more than one exacerbation in the past year. These patients are most likely to suffer from repeated exacerbations (the "frequent exacerbator" phenotype) and therefore benefit the most from the clinical effects of roflumilast—that is, in reducing exacerbation frequency. Clinical studies have shown that roflumilast significantly improves lung function and reduces exacerbations when added to most COPD maintenance therapy regimens—including a LABA, a long-acting muscarinic antagonist (LAMA), or inhaled steroid—in this patient subgroup as described (Figure 16-5).

SIDE EFFECTS

All PDE4 inhibitors have been associated with gastrointestinal side effects such as nausea and diarrhea. Roflumilast is clinically effective at a relatively low dose (compared with other PDE4 inhibitors), thereby minimizing the risk of side effects. In 1-year phase III clinical studies, the incidence of side effects was 67% with roflumilast and 62% with placebo, although study discontinuations were more often associated with roflumilast (14%) than with placebo (11%). Diarrhea, headache, and weight loss appear to be the most limiting side effects associated with roflumilast, although in most cases, these appear to resolve with continued use of the drug. Further investigation has shown that the weight reduction associated with roflumilast was due mostly to loss of fat mass rather than fat-free body mass, and additional metabolic effects of this systemic drug are the subject of ongoing investigations.

PIPELINE PRODUCTS

A number of new inhaled steroid formulations are in development, either as monotherapy for COPD and asthma or in combination with bronchodilators. Since the approval of roflumilast, several PDE4 inhibitors have been investigated in clinical development, including oglemilast (which failed to meet clinical efficacy end point in midstage clinical testing) and tetomilast (currently in phase II testing). Inhaled formulations of PDE4 inhibitors have been investigated, showing promising efficacy in mild asthma, but with no proven efficacy in COPD to date.

At present, of the 17 antiinflammatory drugs in the pipeline for COPD treatment, none represents a new molecule or class of drug. Eleven of the 17 pipeline products are in phase III

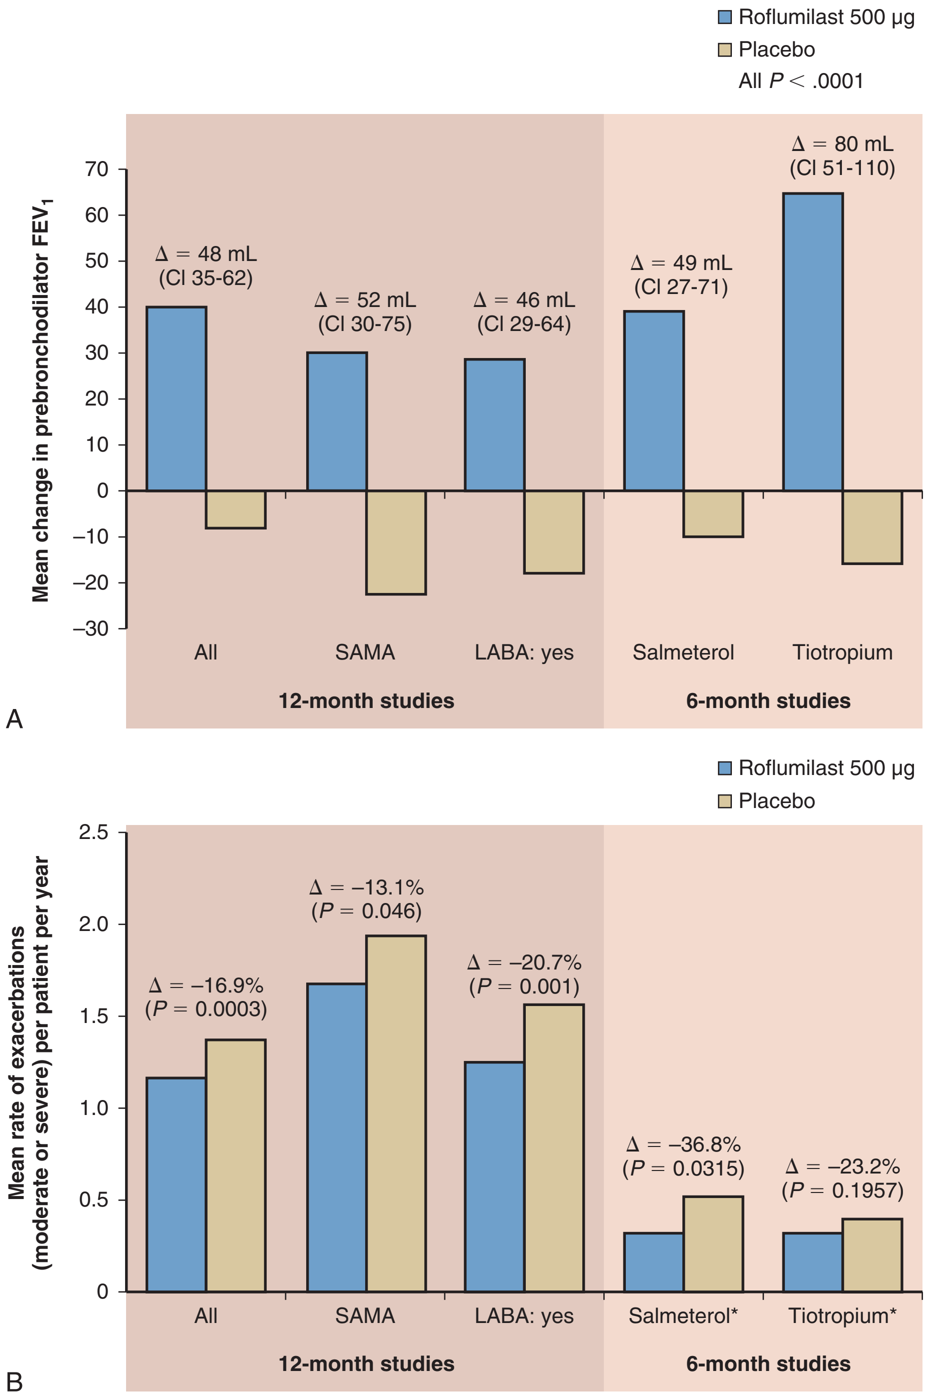

Figure 16-5 Clinical effects of roflumilast on lung function (**A**) and exacerbation rate (**B**). Both 12- and 6-month studies were performed in patients with chronic obstructive pulmonary disease (COPD), chronic bronchitis (not required in the salmeterol study), and at least one exacerbation in the past year. Patients were allowed to take long-acting β_2-agonists (LABAs) or short-acting muscarinic antagonists (SAMAs) as concomitant medications in the 12-month studies; all patients were taking salmeterol or tiotropium in the 6-month studies. Effects of roflumilast were observed on top of effects of concomitant medications. The 6-month studies were not powered to detect differences in exacerbation rate. *Indicates post hoc analyses. *CI*, confidence interval; *FEV*$_1$, forced expiratory volume in 1 second. *(Modified from Rabe KF: Update on roflumilast, a phosphodiesterase 4 inhibitor for the treatment of chronic obstructive pulmonary disease,* Br J Pharmacol *163:53-67, 2011.)*

testing, 3 are in phase II testing, and 3 are in phase I testing. Intracellular signaling proteins that have been researched as antiinflammatory agents for use in other diseases are now being investigated for treatment of COPD, including inhibitors of mitogen-activated protein (MAP) kinases (particularly p38), phosphatidylinositol 3 (PI3) kinase, and matrix metalloproteinases (MMPs). Many clinical trials with asthma treatments are ongoing, focusing on increasing the specificity for the targeted protein and identifying specific “responder populations” likely to experience the most clinical benefits. Monoclonal antibodies to various cytokines and cytokine receptors, notably the interleukins IL-5 and IL-17, currently are in phase II/III testing for asthma, with promising results.

In addition, stem cell therapy is an emerging area of research on treatment of respiratory disease. Figure 16-6 depicts novel molecular targets for COPD and asthma drugs.

CONTROVERSIES AND PITFALLS

Tolerability issues associated with systemic steroid use are well known and not specific to respiratory disease. Although inhaled steroidal agents are accepted as highly beneficial for asthma treatment, their role in the management of COPD remains unclear. It is known that the inflammatory pathways underlying asthma and COPD are different, and this may underlie the relative resistance to inhaled steroids in COPD. CD8$^+$

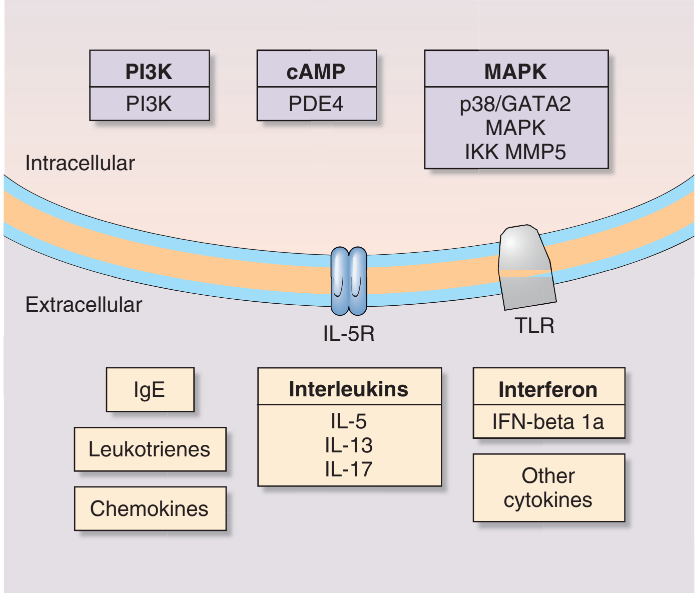

Figure 16-6 Novel targets for antiinflammatory treatments for chronic obstructive pulmonary disease (COPD) and asthma. Several components of inflammatory intracellular signaling pathways (including MAPK, PI3K, and cAMP-dependent pathways) are novel targets for respiratory drug development. *IFN-beta*, interferon-beta; *IgE*, immunoglobulin E; *IKK*, inhibitor of kappa B (IKK) kinase; *IL-5R*, interleukin-5 receptor; *PDE4*, phosphodiesterase 4; *PI3K*, phosphatidylinositol 3-kinase; *MAPK*, mitogen-activated protein kinase; *MMP5*, matrix metalloproteinase 5; *TLR*, toll-like receptor. *(Data from the National Institutes of Health–sponsored database of clinical trials www.clinicaltrials.gov; and from Gross NJ: The COPD pipeline x,* COPD *8:244–247, 2011.)*

lymphocytes and neutrophils appear to drive COPD-specific inflammation; airway biopsy studies have shown that an inhaled steroid–LABA combination reduces the number of airway $CD8^+$ cells to a greater degree than does an inhaled steroid alone. Another mechanism that could underlie resistance to inhaled steroids in COPD is the inactivation of nuclear translocation of glucocorticoid receptors and reduced activity of HDAC2, by both cigarette smoke and oxidative stress. These mechanisms both can lower the ability of inhaled corticosteroids to inhibit inflammatory gene expression.

The combination of inhaled steroid–LABA appears to have synergistic effects in COPD, as highlighted by trials such as the large TORCH study, in which a combination of a LABA and the inhaled steroidal agent fluticasone had a greater effect on exacerbations than that observed with the individual components alone. However, TORCH failed to show any significant effect of a LABA–inhaled steroid combination on long-term mortality, and a metaanalysis of inhaled steroid use in 13,000 patients with COPD reported no positive effect on FEV_1 decline or mortality, although a 25% reduction in exacerbations was noted. Additionally, the TORCH and INSPIRE (Investigating New Standards for Prophylaxis in Reducing Exacerbations) studies showed a small increase in episodes of nonfatal pneumonia in fluticasone-treated patients, which requires further study to confirm the exact nature of this relationship. However, the increased risk of pneumonia, which probably is associated with all types of inhaled steroids, should be balanced by the large reduction in exacerbations that these drugs can provide.

Development of alternative therapies therefore remains a priority in COPD management. The recent approval of roflumilast as the first antiinflammatory agent targeting COPD-specific inflammation has been a major advance, although the incidence of gastrointestinal side effects has been a concern with use of this drug. Much of this concern stems from the history of PDE4 inhibitor development—rolipram was associated with a high incidence of gastrointestinal side effects, and cilomilast was associated with nausea and vomiting. These compounds have lower potency than roflumilast, however, and have poor tolerability at the relatively high concentrations required for efficacy. Roflumilast is a potent and highly specific inhibitor of PDE4. The most limiting side effect of this agent is diarrhea, which resolves after a few weeks of treatment, and the long-term benefits on exacerbations appear to outweigh tolerability issues.

CONCLUSION

Inhaled corticosteroid regimens remain the most effective therapy for asthma, with innovations in formulation and delivery improving the efficacy of these agents and reducing side effects. Inhaled corticosteroids are less effective for treating COPD, and bronchodilators continue to be the mainstay of therapy for this disease. PDE4 inhibition is the only new approach to treating COPD in many years. Roflumilast currently is licensed as an agent for add-on treatment for a specific subpopulation of patients with COPD, in which its main benefit is reducing exacerbations.

Acknowledgments

This chapter was based in part on Chapter 37 on corticosteroids, by Ryan McGhan, in the third edition of this book. Sarah Nelson provided editorial assistance with preparation of the chapter.

RESPIRATORY PHARMACOLOGY

Chapter 17

Drug-Induced and Iatrogenic Respiratory Diseases

Philippe Camus

For both many older and newer therapeutic agents, the risk-benefit ratio is clearly in favor of treatment of many neoplastic conditions, rheumatoid arthritis, systemic or pulmonary hypertension, and cardiac dysrhythmias. In a small fraction of patients exposed to drugs taken at normal dosage to treat these conditions, adverse respiratory effects may develop. It is the duty of practitioners in oncology, cardiology, rheumatology, primary care, emergency medicine, pathology, and respiratory medicine to be cognizant of drug-induced respiratory diseases.

Recognition that a respiratory problem has been caused by the administration of a drug or a combination of drugs is of primary importance in the clinical setting. Patients may be spared unnecessary invasive evaluation including lung biopsy and/or empirical corticosteroid therapy for an alternative condition pending the results of a dechallenge-challenge test, which can be diagnostic. Further damage usually can be prevented if use of the offending agent is stopped early. Measures should be taken so that the underlying illness for which the drug was given is managed appropriately using other medications and so that the patient is not unduly reexposed to the culprit agent. In each individual case, careful exclusion of another cause is warranted, and considerations in the differential diagnosis will vary with the clinical presentation, pattern of respiratory injury, specific drug, and underlying illness.

An ever-increasing number of therapeutic drugs ($n = 455$), hormones, and investigational compounds have been associated with severe adverse respiratory reactions in adults, children, health care professionals, and persons who work in the drug industry or otherwise handle drugs, as well as in companion animals, horses, and cattle. A periodically updated online list of causal drugs is maintained on the Pneumotox website (www.pneumotox.com), sponsored by the GEPPI (Groupe d'Etudes de la Pathologie Pulmonaire Iatrogène) investigators. Agents of recent interest or concern are listed in **Table 17-1**. Adverse effects of drugs such as amiodarone, antineoplastic chemotherapy agents, nitrofurantoin, or nonsteroidal anti-inflammatory drugs (NSAIDs) are still commonly observed. Owing to their less trendy nature, however, the number of publications dealing with these medications represents an underestimate of the true incidence. With the recently renewed interest in nitrofurantoin for use as a urinary antiseptic agent, a resurgence of new cases of nitrofurantoin lung may potentially be expected. The same holds true for thalidomide. The clinical problem of drug overdose, although capable of producing severe pulmonary edema, is beyond the scope of drug-induced lung disease in this chapter.

Some presentations of drug-induced respiratory disease (DIRD) are distinctive clinically, radiologically, or histopathologically, and in such cases the evidence points almost unequivocally to the drug itself as the cause. Drug-induced anaphylaxis, angioedema, bronchospasm, noncardiac pulmonary edema (NCPE), diffuse alveolar hemorrhage (DAH), amiodarone-induced pulmonary toxicity, exogenous lipoid pneumonia, and the rare diffuse pattern of pulmonary calcification are classic examples of conditions highly suggestive of drug-induced injury.

A few drugs produce gender-specific adverse respiratory reactions because they are reserved for treating diseases that are more prevalent in or specific to one or the other gender (e.g., nilutamide and amiodarone in men, trastuzumab and nitrofurantoin in women). Still other drugs capable of causing lung damage, such as gold salts, penicillamine, or methyldopa, have been supplanted by novel agents and are falling out of favor. In addition, certain drugs—including aminorex, benfluorex, fenfluramine, dexfenfluramine, hexamethonium, L-tryptophan, and mecamylamine—have been recalled from the pharmaceutical lineup for the reason of respiratory or other adverse effects. Rare sporadic cases of adverse reactions from these agents are still being reported.

One of the greatest challenges in determining drug toxicity in suspected cases is that most patients are taking multiple medications to treat complex underlying conditions, and more than one drug may be capable of causing respiratory damage. Diagnosing drug-induced disease in this situation can be problematic, particularly if the underlying disease also manifests with interstitial lung disease (ILD) or is associated with opportunistic pulmonary infections. For instance, patients with rheumatoid arthritis may receive methotrexate or leflunomide in addition to an anti–tumor necrosis factor (TNF) agent; cardiac patients may receive anticoagulants, antiplatelets, and amiodarone; and patients with neoplastic conditions typically are exposed to several drugs, including chemotherapy agents, all capable of causing lung damage.

In addition to the usual over-the-counter and prescription drugs, numerous agents including whole blood, platelets, plasma concentrates, parenteral nutrition solutions, substances of abuse (e.g., cocaine, heroin, morphine, marijuana, propofol, anesthetic gases), herbal preparations (e.g., *Sauropus*), drug excipients (e.g., crospovidone, talc, cornstarch, lipids, sesame oil) present in therapeutic drugs, adulterants used in street drugs (e.g., brodifacoum, levamisole), illegally used chemicals such as fluid silicone or paraquat, and external or internal radiation therapy

Table 17-1 Drugs/Drug Families Recently Implicated as Agents of Respiratory Injury

Drug Family	Underlying Condition	Drug(s)	Pattern(s) of Respiratory Injury
TNF-α receptor inhibitors	Rheumatoid arthritis	Infliximab, etanercept, adalimumab	Infusion reactions, anaphylaxis Accelerated ILD ILD with granulomas Opportunistic pulmonary infections
		Leflunomide	ILD
		Tacrolimus	ILD
ACE inhibitors	LVF, systemic hypertension	Captopril, enalapril, lisinopril	Angioedema
EGFR TKIs	Non–small cell lung cancer	Gefitinib, erlotinib, ?cetuximab	ILD-DAD
Antineoplastic chemotherapy	Colorectal cancer	Oxaliplatin plus 5-FU and leucovorin (FOLFOX), irinotecan plus 5-FU and leucovorin (FOLFIRI)	ILD, DAD, BOOP
Multitargeted TKIs	Chronic myelogenous leukemia	Imatinib Dasatinib	ILD, pleural effusion Lymphocyte-rich or chylous pleural effusion
Anti-CD20 Mo-Ab	Malignant lymphoma	Rituximab	ILD, BOOP, DAH, ARDS
Platelet glycoprotein IIB-IIIA receptor inhibitors	Coronary heart disease	Abciximab, clopidogrel, eptifibatide, ticlopidine	Alveolar hemorrhage
Mo-Ab	Asthma	Omalizumab	Anaphylaxis
Leukotriene receptor antagonists	Asthma	Montelukast, pranlukast, zafirlukast	Churg-Strauss vasculitis
Antithyroid drugs	Hyperthyroidism	Propylthiouracil	ANCA-positive systemic vasculitis
mTOR receptor inhibitors	Transplantation	Everolimus, sirolimus, temsirolimus	ILD, DAH, BOOP, pulmonary vasculitis
HMG-CoA reductase inhibitors	Hypercholesterolemia	Statins	ILD, BOOP, ARDS
Opiates	Illicit drug use/abuse	Cocaine and adulterants thereof	ILD, vasculitis, DAH

ACE, angiotensin-converting enzyme; *ANCA*, antineutrophil cytoplasmic antibody; *ARDS*, acute respiratory distress syndrome; *BOOP*, bronchiolitis obliterans organizing pneumonia; *DAD*, diffuse alveolar damage; *DAH*, diffuse alveolar hemorrhage; *EGFR*, epidermal growth factor receptor; *5-FU*, 5-fluorouracil; *HMG-CoA*, hydroxymethylglutaryl coenzyme A; *ILD*, interstitial lung disease; *LVF*, left ventricular failure; *Mo-Ab*, monoclonal antibody; *mTOR*, mammalian target of rapamycin; *TKI*, tyrosine kinase inhibitors; *TNF-α*, tumor necrosis factor-α.

may injure the respiratory system by similar pharmacologic-cytopathic mechanisms.

Virtually any route of administration of drugs may be associated with increased risk for DIRD. The oral, parenteral (intramuscular, intravenous), inhaled, dermal, and topical routes are cited most often. Drugs instilled into the pleural space, coronary artery, hepatic artery, urinary bladder, uterine cavity, myometrium, subcutaneous fat, or vertebral body, or given intrathecally or aspirated into the bronchial tree, also can cause respiratory injury.

With reference to respiratory disease, the term *iatrogenic* encompasses pulmonary damage from medical or surgical procedures such as liposuction, chest tube placement, coronary artery bypass graft, and insertion of pacemaker leads or central venous line, as well as retained foreign bodies (also known as gossypibomas), all of which may cause potentially serious respiratory compromise.

Interstitial-infiltrative lung disease (i.e., ILD) is the most common clinical-imaging-pathologic pattern of respiratory involvement from drugs, accounting for about two thirds of all cases of DIRD. Conversely, drugs account for about 3% of all ILD cases. The relative preponderance of ILD must not overshadow other, less common DIRD patterns such as involvement of the upper or lower airways, pleural membrane, pericardium, heart, heart valves, pulmonary circulation, mediastinum, respiratory muscles and nerves, central respiratory oscillator, and hemoglobin, which may have detrimental clinical consequences.

DIRD may be detected at a subclinical stage on imaging or bronchoalveolar lavage (BAL) fluid analysis, or it can be clinically evident and serious, requiring prompt recognition, immediate drug withdrawal, and emergent management aimed at securing airway patency, restoring gas exchange, and correcting hemoglobin dysfunction. DIRD presentations that portend particular severity (Table 17-2) include drug-induced anaphylaxis, angioedema, and bronchospasm, which may cause acute airway obstruction; NCPE; diffuse alveolar damage (DAD); DAH; extensive ILD, including eosinophilic pneumonia; opportunistic infections including *Pneumocystis* and viral pneumonias; massive pleural effusion; methemoglobinemia; neuromuscular failure; and multiorgan dysfunction. Drug-induced and iatrogenic events that occur intraoperatively, including drug-induced explosive coughing, curare- or latex-induced anaphylaxis, opiate-induced pulmonary edema, transfusion-related acute lung injury (TRALI), protamine-induced acute pulmonary hypertension, or negative-pressure pulmonary edema, raise difficult diagnostic and management issues. Awareness and emergent management are essential; however, some DIRDs are not survivable (see Table 17-2).

Several drugs within certain pharmacologic classes—curares, opiates, angiotensin-converting enzyme (ACE) inhibitors, β-adrenergic receptor blockers, antidepressants, appetite

Table 17-2 Life-Threatening Drug-Induced Respiratory Conditions Requiring Emergent Management

Injury Pattern	Prototypical Causal Drugs	Time to Onset	Life-Threatening Pathomechanism(s)
Acute upper airway obstruction	ACE inhibitor–induced angioedema Drug/biologic-induced anaphylaxis	Minutes Minutes	Throat closure, airway obstruction, shock Airway obstruction, shock, pulmonary edema
Catastrophic bronchospasm	Beta blockers, NSAIDs (including aspirin)	Minutes	Locked airway, acute hypercapnic respiratory failure, hypoxic brain damage
Noncardiac pulmonary edema	Antineoplastic chemotherapy agents, chlorothiazide, aspirin	Typically minutes to a few hours	ARDS, ARF, hypoxemia
Diffuse alveolar damage	Antineoplastic chemotherapy agents, amiodarone	Hours to weeks	ARDS, ARF *Later:* pulmonary fibrosis
Diffuse alveolar hemorrhage	Anticoagulants, antiplatelet agents	Days	ARDS, ARF, diffuse clotting in airways
	Cocaine, propylthiouracil	Weeks to months	Pneumorenal syndrome, extrapulmonary involvement
Acute cellular interstitial lung disease	Methotrexate	Weeks to years	ARF
Amiodarone-induced pulmonary toxicity	Amiodarone	Weeks to years	ARF *Later:* pulmonary fibrosis
Acute eosinophilic pneumonia	Minocycline, tobacco smoke	Days to months	ARF
Acute radiation-induced lung injury	Radiation therapy	Weeks	ARF
Opportunistic infection	Corticosteroids, biologics	Weeks to months	ARF
Massive pleural effusion/hemothorax	Dantrolene, lupus-inducing drugs, anticoagulants	Weeks to months	Compression of heart, lung and venous return
Catastrophic pulmonary hypertension	Protamine	Minutes	Acute RHF, hypoxemia
Methemoglobinemia	Benzocaine, dapsone, oxidizing chemicals	Hours to days	Tissue hypoxia, pulmonary edema, brain damage
Neuromuscular failure	Aminosides, curares, dantrolene	Hours to days	ARF
Multiorgan dysfunction syndrome	Drugs that induce DRESS syndrome	Weeks to months	Multiorgan failure

ACE, angiotensin-converting enzyme; *ARDS*, acute respiratory distress syndrome; *ARF*, acute renal failure; *DAD*, diffuse alveolar damage; *DRESS*, drug rash, eosinophilia, and systemic symptoms; *NSAIDs*, nonsteroidal antiinflammatory drugs; *RHF*, right[-sided] heart failure.

suppressants (anorectics), anticonvulsants, antineoplastic chemotherapy agents, ergots and ergolines, leukotriene receptor antagonists (LTRAs), mTOR (*m*ammalian *t*arget *o*f *r*apamycin) inhibitors, NSAIDs, and statins—may cause similar kinds of DIRD, suggesting a common pharmacologic cytopathic mechanism (Table 17-3). Furthermore, patients who exhibit an adverse reaction from one drug are at risk for cross-reaction if challenged with another drug of the same family. In the case of anticonvulsants, relatives of patients with the syndrome of drug rash, eosinophilia, and systemic symptoms (DRESS) may be at risk for development of a similar complication with exposure to this class of medications.

Certain antineoplastic agents may cause acute or subacute lung injury when used in a single-drug regimen (e.g., azathioprine, bleomycin, busulfan, chlorambucil, cyclophosphamide, dasatinib, imatinib, methotrexate, nitrosoureas). Typically, however, these agents are given as part of a multiagent regimen, so that it is difficult to discern which drug caused the reaction, unless pulmonary toxicity is observed to occur only after addition of a specific drug to an otherwise nonpneumotoxic regimen. Toxicity in this latter setting has been documented for bleomycin, gemcitabine, methotrexate, radiation therapy, and rituximab. Combinations of certain chemotherapy agents, such as gemcitabine and bleomycin, or of drugs and radiation therapy may be particularly toxic, dramatically increasing the incidence of severe pulmonary toxicity. Oxygen also synergizes the pulmonary toxicity of chemotherapy agents, amiodarone, and radiation therapy. Radiation therapy may synergize chemotherapy-induced lung damage, causing augmented toxicity or rebound pneumonitis in the previously treated patient. Several antineoplastic agents of the newer generation—erlotinib, gefitinib, imatinib, dasatinib, everolimus, trastuzumab, temozolomide, temsirolimus, thalidomide, lenalidomide, omalidomide, and topotecan—may cause acute pneumonitis, DAD, pulmonary fibrosis, organizing pneumonia (the preferred designation for bronchiolitis obliterans organizing pneumonia [BOOP]), infusion reactions, bronchospasm, anaphylaxis, capillary leak, methemoglobinemia, and pulmonary hemorrhage. In addition to subacute and acute presentations, antineoplastic agents may cause subtle insidious pneumonitis or fibrosis particularly in children, typically noted years after completion of therapy, in the form of indolent or progressive restrictive lung dysfunction. In a few such patients, lung transplantation may be necessary.

Table 17-3 Specific Agents/Drug Families Implicated in Drug-Related Respiratory Disease

Drug Family	Specific Agent(s)	Frequency of Adverse Effects	Pattern(s) of Respiratory Damage	Comments
Abused drugs	Heroin, cocaine, crack, marijuana	++++	Airway burns	Suggestive of exposure to crack cocaine
			Severe bronchospasm	Suggestive of exposure to insufflated heroin
			Acute NCPE	Suggestive of heroin overdose
			DAH	Suggestive of exposure to cocaine
			Pneumothorax	May follow injection of drug in central vein
			Systemic vasculitis	Suggests exposure to drugs tainted with levamisole
ACE inhibitors	Captopril, enalapril	++++	Cough	Chronic, annoying cough; remits with drug avoidance
		+++	Angioedema	Drug etiology often missed
		++	Rare PIE	Rare
Anorectic agents	Aminorex, fenfluramine	+++	Pulmonary hypertension	Can be irreversible/progressive Drugs are recalled
Antibiotics	Minocycline, sulfasalazine, penicillin	+++	Anaphylaxis	Can cause ARF
			PIE	Can cause ARF
Anticonvulsants	Carbamazepine, phenytoin, lamotrigine	++++	DRESS	Cutaneous rash, deep organ involvement ± PIE
Anticoagulants: oral	Warfarin	++	Bland DAH	Risk increases in parallel with the INR
		++	Laryngeal, tongue, tracheal hematoma	May cause acute upper airway obstruction
		+	Pulmonary calcium deposits	Unusual
Anticoagulants: intravenous	Heparin, streptokinase, urokinase, alteplase	++	Bland DAH	
		++	Hemothorax	Can cause compression and circulatory failure
Antidepressants	Sertraline, venlafaxine	++	Eosinophilic pneumonia, DRESS	May cause respiratory failure
Antithyroid drugs	Propylthiouracil	+++	Vasculitis, capillaritis, DAH	Demonstrable pulmonary capillaritis; in some cases perinuclear or cytoplasmic ANCA detectable at high titers Renal involvement possible
β-Agonists (parenteral tocolytics)	Salbutamol, terbutaline, isoxuprine	+++	NCPE	Usually transient and benign
Beta blockers	Most β-blocking drugs	+++	Acute bronchospasm	Can be fatal
		++	Lupus syndrome	Pleural/pleuropericardial effusion and a positive ANA test result
		+	ILD/BOOP	Rare
Biologics	Anti-TNF agents, rituximab, omalizumab	++	Anaphylaxis	
		++	Acute ILD	More common with rituximab or infliximab
		++	Pulmonary granulomas	More common with etanercept
		++	Lupus syndrome	Serositis and a positive ANA test result and ds-DNA
Blood, blood products	Whole blood, platelets, FFP	++++	TRALI/NCPE	Early onset Diuretics detrimental
Curares	Pancuronium, tubocurarine	+++	Anaphylaxis	
		++++	Respiratory muscle palsy	

Table 17-3 Specific Agents/Drug Families Implicated in Drug-Related Respiratory Disease—cont'd

Drug Family	Specific Agent(s)	Frequency of Adverse Effects	Pattern(s) of Respiratory Damage	Comments
Cytotoxic agents	Busulfan, bleomycin, cyclophosphamide	+++	Transient pulmonary infiltrates	Caution, as rechallenge may cause full-blown NCPE/ARDS
	Gemcitabine, nitrosoureas, taxanes	++++	NCPE, DAH	May lead to an ARDS picture
			Later: pleuropulmonary fibrosis	Improvement may follow corticosteroid therapy
	Oxaliplatin	++	Anaphylaxis	Can be fatal Skin tests useful in diagnosis
DMARDs	NSAIDs	+++	Acute asthma, PIE	Class effect
	Methotrexate	++++	Acute cellular ILD	Must be separated from *Pneumocystis jiroveci* pneumonia
	Leflunomide	++	Cellular ILD	Described mostly in Japanese patients with RA
	Tacrolimus	+	ILD	Described in Japanese patients with RA
	Biologics			See biologics
Ergots	Bromocriptine, cabergoline	++++	Pleural effusion	Resolves with drug discontinuance
	Ergotamine, dihydroergotamine, methysergide	++++	Pleural thickening	Decreases with drug discontinuance
	Nicergoline, pergolide	+++	Acquired valvular heart disease	Reversal of changes possible with drug discontinuance
Interferon alfa/beta		+++	Cellular or granulomatous ILD	Clinical improvement with drug discontinuance/corticosteroid therapy
			BOOP	Reversal of changes with drug discontinuance/corticosteroid therapy
			Sarcoidosis-like reaction	Subsides with drug discontinuance/ corticosteroid therapy
Leukotriene receptor antagonists	Montelukast, pranlukast, zafirlukast	++	Churg-Strauss syndrome	Strong suspicion for a causal relationship
Lipids: aspirated/ inhaled	Paraffin	++++	Exogenous lipoid pneumonia	Lipid droplets present in sputum, BAL fluid, and alveoli
Lipids: infused	Parenteral nutrition, drug excipient	++	Fat embolism syndrome	May also cause DAH
mTOR inhibitors	Everolimus, sirolimus, temsirolimus	+++	Cellular ILD, BOOP, DAH	Dose-related Abates with reduced dosage or discontinuance
NSAIDs, including aspirin	ASA, ibuprofen, indomethacin	+++	Catastrophic bronchospasm	Can be fatal
	Naproxen, piroxicam	++	PIE	Remits with avoidance, relapses on rechallenge
	Aspirin	+++	NCPE	Anion gap, metabolic acidosis, elevated blood salicylate
Platelet glycoprotein IIb-IIIA inhibitors	Abciximab, clopidogrel, eptifibatide	++	DAH	More common in smokers and in presence of LVF
	Ticlodipine, tirofiban			DAH generally not associated with low platelet counts
Radiation—therapeutic				
Lung		++++	Radiation-induced lung injury	Localizes along the radiation beam
		+++	Stereotactic irradiation	Whorled appearance May be tracer-avid on PET scan

Continued

Table 17-3 Specific Agents/Drug Families Implicated in Drug-Related Respiratory Disease—cont'd

Drug Family	Specific Agent(s)	Frequency of Adverse Effects	Pattern(s) of Respiratory Damage	Comments
Mediastinum		++	Mediastinal fibrosis	
Trachea		++	Tracheal disruption	
Endobronchial		++	Airway damage	Dehiscence, fatal hemoptysis
Breast		+++	BOOP	Corticosteroids may be indicated
Liver		++	ARDS	^{131}I (radioiodine)
Statins	Fluvastatin, pravastatin, simvastatin	+++	Cellular ILD	Ground glass shadowing on HRCT scan
			BOOP	Fixed or migratory alveolar opacities Statin myopathy may be present
TKI inhibitors	Erlotinib, gefitinib	+++	DAD/ALI	Difficult to separate from disease progression or from an infection Previous ILD may increase risk
	Imatinib	++	Cellular ILD	
	Dasatinib	++	Pleural exudate, chylous effusion	
TNF-α antibody agents	Etanercept, infliximab, adalimumab	+++	Accelerated ILD	May mimic an infection or exacerbation of underlying rheumatoid lung
			Pulmonary granulomatosis	May mimic sarcoidosis
			Opportunistic infections including TB	Pretherapy evaluation for latent TB indicated using TST and IGRA

ACE, angiotensin-converting enzyme; *ALI*, acute lung injury; *ANA*, antinuclear antibody; *ANCA*, antineutrophil cytoplasmic antibody; *ARDS*, acute respiratory distress syndrome; *ARF*, acute renal failure; *ASA*, acetylsalicylic acid; *BAL*, bronchoalveolar lavage; *BOOP*, bronchiolitis obliterans organizing pneumonia; *DAD*, diffuse alveolar damage; *DAH*, diffuse alveolar hemorrhage; *DMARDs*, disease-modifying antirheumatic drugs; *DRESS*, drug rash, eosinophilia, and systemic symptoms [syndrome]; *ds-DNA*, double-stranded DNA; *FFP*, fresh frozen plasma; *HRCT*, high-resolution computed tomography; *IGRA*, interferon-gamma release assay; *ILD*, interstitial lung disease; *INR*, international normalized ratio; *mTOR*, mammalian target of rapamycin; *PET*, positron emission tomography; *RA*, rheumatoid arthritis; *TB*, tuberculosis; *TKI*, tyrosine kinase inhibitor; *TNF-α*, tumor necrosis factor-α; *TST*, tuberculosis skin test.

INCIDENCE AND RISK EVALUATION

The incidence of DIRD varies with the specific drug or agent. Amiodarone, antineoplastic drugs (bleomycin, cyclophosphamide, gefitinib, methotrexate, nitrosoureas), nitrofurantoin, disease-modifying antirheumatic drugs (DMARDs) (leflunomide, methotrexate, anti-TNF agents), NSAIDs, mTOR inhibitors, and radiation therapy are associated with the highest reported rates of DIRD. The true incidence is modulated by the number of patients receiving the drug. Although the incidence rate for mTOR inhibitor–induced ILD has been reported as up to 36%, the actual number of patients with the disease is low, because this class of medications is given mainly to patients with selected malignancies and to recipients of solid organ transplants. By contrast, the incidence rate of amiodarone pulmonary toxicity is 1% to 2%, but the number of affected patients is greater, because the drug is widely used to treat various forms of arrhythmias. Incidence of DIRD increases with age, in parallel with exposure to drugs.

Mechanisms and risk factors for DIRD have been deduced from studies in animals and in humans and in many cases have been matched with specific agents, as follows:

Pharmacokinetics and sequestration of the drug—amiodarone, desethyl-amiodarone, bleomycin, mTOR inhibitors
Albumin levels—methotrexate
Metabolic activation of drug in lung cells—paraquat and possibly nitrofurantoin
Cumulated drug dosage—amiodarone, bleomycin, nitrosoureas
Sequential exposure to the drug, an important consideration when retreatment is being considered—bleomycin, nitrosoureas
Combinations of pneumotoxic drugs—gemcitabine plus bleomycin, gemcitabine or other chemotherapy agent plus radiation therapy to the chest
Volume of irradiated lung
Cytochrome P-450 variant allele carrier status—oral anticoagulants, cocaine, and possibly other drugs
Impurities formed during drug synthesis—"peak E" contaminant of L-tryptophan
Extremes of age—amiodarone or bleomycin in older people, nitrosoureas in younger persons
History of smoking—amiodarone, bleomycin
Gender—amiodarone in male patients, bischloroethyl nitrosourea (BCNU) in female patients
Renal failure—bleomycin, amiodarone
Preexisting lung disease—amiodarone, DMARDs including methotrexate, leflunomide, anti-TNF agents, gefitinib
Atopy—minocycline, NSAIDs, drugs causing hypersensitivity or anaphylaxis
Ethnicity—enhanced risk for development of ACE inhibitor–induced angioedema in dark-skinned people, and of ILD in

association with use of gefitinib, bortezomib, leflunomide, and tacrolimus in persons of Japanese ancestry

Unfortunately, DIRDs often occur unexpectedly in predisposed persons and generally are not amenable to early detection with use of serial lung function tests, including diffusing capacity, although this parameter often decreases substantially concomitant with the administration of chemotherapeutic drugs without necessarily indicating clinical toxicity, or by imaging. Nevertheless, an appreciation of the aforementioned risk factors by physicians who prescribe those drugs is essential, particularly the dose-limiting toxicity of bleomycin and nitrosoureas, the hazard of bleomycin combined with gemcitabine, the 6- to 12-month time window for onset of amiodarone pulmonary toxicity, and the risk associated with use of excessive concentrations of oxygen in patients who have received chemotherapeutic agents, or amiodarone which may lead to acute deterioration of subclinical pneumonitis.

DIAGNOSING DRUG-INDUCED RESPIRATORY DISEASE

Diagnosing DIRD accurately is essential with regard to decisions to discontinue or continue the presumptively offending agent, because inappropriate drug withdrawal may have a negative impact on outcome, and because rechallenge may lead to fatal relapse. Issues regarding the diagnosis of DIRD and the corresponding differential diagnosis differ according to the underlying illness and specific clinical context (Table 17-4). Particularly difficult issues arise in patients with solid tumors, hematologic malignancies, or rheumatoid arthritis and in recipients of bone marrow or hematopoietic stem cell transplants, who are immunosuppressed under the combined influence of the underlying condition and the drugs (including corticosteroid therapy) and the radiation used to treat it.

Although the expression of bacterial and fungal pulmonary infections on imaging studies often is distinctive, viral and *Pneumocystis* pneumonias resemble drug-induced ILD, with no clinical or radiographic discriminator to separate these two entities. Therefore, meticulous examination of BAL and other body fluids is indicated. Further complicating the issue, recipients of hematopoietic stem cell transplants may develop diffuse nonspecific pulmonary complications unrelated to drugs, such as acute pulmonary edema, DAH, the periengraftment respiratory distress syndrome, and idiopathic pneumonia syndrome, leading to substantial diagnostic confusion. Drug-induced ILD also is difficult to diagnose in patients with rheumatoid arthritis and in those with certain other systemic conditions, for several reasons: such patients often receive more than one DMARD (e.g., NSAID, methotrexate, an anti-TNF drug, cyclophosphamide, or rituximab) each having the potential to cause lung damage. In addition, the underlying rheumatic or systemic condition itself may manifest with progressive ILD. Furthermore, opportunistic infections can occur as a consequence of the underlying disease and/or therapy with corticosteroids and anti-TNF agents. Similarly, ILD in cardiac patients who are taking amiodarone raises complex issues, because amiodarone-induced pulmonary toxicity must be reliably and noninvasively separated from heart failure and from any incidental ILD.

The evidence base for respiratory disease as being drug-induced is wide-ranging, because the literature on DIRD consists mostly of case reports and is subject to reporting bias. There is a paucity of epidemiologic studies showing a convincing association of exposure to a drug and occurrence of pulmonary events. Investigating a case of possible DIRD requires a high degree of awareness, careful exclusion of conditions that DIRD can resemble (e.g., *Pneumocystis* or viral pneumonia with use of BAL), cessation of administration of the suspected agent (underlying disease permitting), and discussion of whether corticosteroid therapy is indicated, bearing in mind that corticosteroid therapy itself may complicate evaluation of the effect of drug withdrawal on signs and symptoms (drug withdrawal may be without an effect in patients with explosive or severe presentations). Evidence indicating that a respiratory reaction is drug-induced consists of the following: (1) the likelihood of exposure to a compatible drug, particularly if given as a solo agent, (2) previous conclusive reports of reactions to the drug, (3) pattern of involvement compatible with the specific drug, (4) compatible temporal relationship of exposure and onset and progression of symptoms, best demonstrated in patients who experience an acute reaction such as acute bronchospasm, anaphylaxis, angioedema, or pulmonary edema; (5) abatement of signs and symptoms after cessation of drug administration; (6) supportive findings on BAL fluid and histopathologic analysis; (7) lack of an alternative diagnosis after meticulous investigation using BAL and, in selected cases, lung biopsy; and (8) relapse of signs and symptoms on rechallenge, a potentially hazardous test. Box 17-1 summarizes these diagnostic criteria and presents a useful approach to diagnosis and management of DIRD.

The Naranjo scale is well known for grading the evidence. Case histories are heterogeneous in the literature and rarely include all criteria. Patients may give a history of periods on and off the drug, and it is important to correlate timing of these with onset, fading, and recurrence of respiratory signs and symptoms. Although drugs are an important consideration in the differential diagnosis for ILD, video-assisted surgical lung biopsy (VATS) is rarely performed owing to its relative invasiveness and associated risks. The transbronchial approach is a valuable alternative, although the limited size of the sample obtainable with this technique confers a lesser degree of diagnostic certainty than that achieved with the open approach. Although the possibility of drug-induced ILD sometimes is raised by the pathologist on the basis of typical changes in the tissue, lung biopsy usually can be avoided, because lung tissue changes may lack specificity for the drug. Important exceptions include *amiodarone pulmonary toxicity*, which demonstrates features of dyslipoidosis; *chemotherapy lung*, characterized by DAD and an abundance of reactive epithelial cells; *lung injury from illicit drugs*, in which presence of carbonaceous deposits or drug excipient within and around the pulmonary vasculature is typical; *exogenous lipoid pneumonia*, in which oil is seen lying free in the alveoli and in the tissue; and *fluid silicone embolism*, associated with distinctive nonstainable vacuoles.

In most other instances, histopathologic examination discloses changes that are consistent with, rather than diagnostic for, the drug etiology. However, the lung biopsy has an important diagnostic role in that it may confidently exclude other potential etiologic disorders, including infection, if appropriate stains and molecular techniques are applied to the specimen.

PATTERNS OF DRUG-INDUCED RESPIRATORY DISEASE

More than 60 discrete clinical-imaging-pathologic patterns of DIRD have been identified. The most common presentation is

Table 17-4 Diagnosis and Differential Diagnosis of Drug-Induced Respiratory Disease

Setting/ Specialty	Prototypical Causal Drugs	Clinical Pattern of Involvement	Main Competing Diagnosis
Emergency department	ACE inhibitors, AA2R	Acute upper airway obstruction	Epiglottitis
	Drugs that cause NCPE, ALI, ARDS, DAH, ILD, PIE, BOOP	Diffuse pulmonary infiltrates with or without ARF	Infection, LVF
	Drugs that cause anaphylaxis	Shock, acute airway obstruction	Sudden severe asthma
	Anticoagulants, antiplatelet agents	DAH Hemothorax	DAH of other causes Spontaneous hemothorax, trauma
Oncology: solid tumors	Chemotherapy agents including TKIs (gefitinib, erlotinib)	NCPE, DAD, DAH, anaphylaxis, pulmonary fibrosis	NCPE, DAD, DAH of other causes, including opportunistic pulmonary infection, ILD due to other drugs, TRALI, overload pulmonary edema
	mTOR inhibitors G-CSF, GM-CSF Blood and fractions	ILD, BOOP, DAH Ranges from pulmonary infiltrates to NCPE TRALI	ILD, BOOP, DAH of other causes NCPE of other causes Overload pulmonary edema
Oncology: hematologic malignancies	Chemotherapy agents including TKIs and imatinib	NCPE, DAD, DAH, anaphylaxis, pulmonary fibrosis	NCPE, DAD, ILD, DAH of other causes, including opportunistic pulmonary infections
	ATRA	ATRA syndrome ILD, pleural effusion	NCPE, ARDS, DAH of other causes
	Imatinib	Pleural effusion, chylous effusion	Underlying disease
	Dasatinib	Pleural effusion, chylous effusion	Underlying disease
	Thalidomide, lenalidomide, pomalidomide	ILD	ILD of other causes
Rheumatology	Corticosteroids	Opportunistic infections including *Pneumocystis* pneumonia	Drug-induced ILD
	Methotrexate	Acute methotrexate pneumonitis	Opportunistic pulmonary infection
	Leflunomide	Subacute ILD	Rheumatoid lung, ILD of other causes
	Anti-TNF agents	Accelerated ILD, opportunistic infection including tuberculosis, autoimmune phenomena	Idiopathic ILD
Cardiology	Amiodarone	Insidious or acute ILD	Left ventricular failure, pulmonary edema
	β-Adrenergic receptor blockers	Acute bronchospasm	“Cardiac asthma”
	ACE inhibitors	Coughing	Coincidental lung disease
Dermatology	Minocycline	Pulmonary infiltrates and eosinophilia	PIE of other causes
	Acitretin	Acute ILD	Underlying disease
Endocrinology	Propylthiouracil	Diffuse alveolar hemorrhage, pneumorenal syndrome	ANCA-associated vasculitis (Wegener granulocytosis/microscopic polyangiitis)

one of diffuse or focal pulmonary infiltrates, with or without hypoxemia. This pattern often is referred to as ILD, although histopathologic evidence is rarely available to confirm the diagnosis. Under the influence of cultural differences throughout the world, a given clinical imaging pattern may be named using various descriptor English terms. A recent trend is to ascribe a specific “pathologic diagnosis” to a given pattern on high-resolution computed tomography (HRCT). This should be done with caution, however, because correlation of these two diagnostic modalities can be suboptimal. Drugs can elicit virtually any pattern of naturally occurring ILD, which as noted is a clinical, radiologic, and histopathologic mimic of numerous

Box 17-1 Approach to Diagnosis and Management of Drug-Induced Respiratory Disease

Diagnostic Criteria

- Confirmed exposure to an eligible drug
- Confirmatory literature data
- Pattern of reaction appropriate for the drug
- Appropriate latency period and timing of onset of respiratory symptoms relative to taking the drug
- Supportive BAL and histopathologic findings
- Resolution of symptoms after dechallenge
- Exclusion of any other cause including other drugs
- Relapse after rechallenge, if performed

Checklist for Fine-Tuning Diagnosis and Management

In patients with compatible clinical presentation or supportive imaging or histopathologic findings (summarized on the Pneumotox website):

1. Depending on level of consciousness and presence or level of respiratory distress, take history of exposure to drugs, occupational/environmental agents, chemicals, and toxic substances. Confirm drug history from relatives, friends, or pharmacist when needed.
2. Evaluate risks associated with discontinuance of drug for underlying condition. Substitute when appropriate.
3. Arrange for timely evaluation of drug and metabolites in blood and/or urine (e.g., opiates, amiodarone, aspirin, mTOR inhibitors) and a urine drug screen.
4. List patterns of respiratory involvement attributable to an underlying disease if present. Match with pattern of involvement from the drug or drugs under consideration. Check for overlapping features.
5. Check complete blood count, $CD4^+$ count, autoimmunity (ANA, ANCA), and HIV serostatus whenever appropriate.
6. Retrieve earlier, pretreatment, and baseline imaging studies, respiratory physiology reports, laboratory data, and autoantibody assay results.
7. List exposure to any drug (even if remote), blood transfusion, blood products, radiation therapy, concealed exposure to illicit drugs, substances of abuse, and chemicals used to synthesize drugs in the household.
8. List possible risk factors related to dosing or blood levels (see text).
9. Examine timing of exposure—discontinuation versus latency period, onset, peak, and resolution of pulmonary symptoms and signs on imaging studies.
10. Match clinical presentation, imaging data, and findings on BAL, laboratory testing, ANA and ANCA assays, and histopathologic analysis (if available) with the drug under study. Contribution of KL-6 glycoprotein assay and in vitro tests is limited.
11. Examine other diagnostic possibilities including *Pneumocystis* and viral pneumonia and pulmonary involvement from the underlying disease.
12. Check laboratory findings for involvement of organs other than the lung.
13. If patient has been exposed to more than one drug, assess causality for each specific drug.
14. Examine whether adverse reaction may result from the known pharmacologic effect of the drug
15. Determine pharmacogenetic trait when appropriate.
16. Evaluate whether corticosteroid therapy is indicated in addition to drug withdrawal (as indicated by clinical severity).
17. Schedule follow-up assessment for signs/symptoms and imaging and laboratory abnormalities after drug withdrawal, to confirm positive dechallenge.
18. Ensure proper communication with any health professional so that the patient is not inadvertently rechallenged with the drug.
19. Discuss whether deliberate rechallenge is indicated (reserved for vital drugs for which no substitute is available). This procedure is performed using low doses in a hospital setting close to an ICU. Tolerance can be induced for a limited number of drugs.
20. Report to national/federal drug safety monitoring authorities; plan publication of findings.

ANA, antinuclear antibody; *ANCA*, antineutrophil cytoplasmic antibody; *BAL*, bronchoalveolar lavage; *HIV*, human immunodeficiency virus; *ICU*, intensive care unit; *mTOR*, mammalian target of rapamycin.

entities: nonspecific cellular or fibrotic nonspecific interstitial pneumonia (NSIP), eosinophilic pneumonia, BOOP, desquamative interstitial pneumonia (DIP), ILD with a granulomatous component, interstitial pulmonary fibrosis, or pulmonary alveolar proteinosis. Drugs also may cause NCPE, DAD, and DAH.

Other patterns of respiratory involvement include angioedema, bronchospasm, pleural effusion with or without the lupus syndrome, pulmonary vasculopathy with or without pulmonary arterial hypertension, neuromuscular failure, and methemoglobinemia. Although DIRD generally occurs in isolation, concomitant involvement of the liver has been reported with nitrofurantoin, nilutamide, and amiodarone.

DIRD may at times manifest as a systemic condition with extrapulmonary and pulmonary involvement. Systemic presentations include the drug-induced lupus syndrome, antineutrophil cytoplasmic antibody (ANCA)-positive vasculitis with DAH, and the Churg-Strauss syndrome. In these conditions, involvement of the skin, kidney, heart, and lung occurs in a manner similar to that seen in the idiopathic conditions. The DRESS syndrome includes a distinctive cutaneous rash and involvement of the liver, kidney, central nervous system, fever, and blood eosinophilia; in a fraction of affected patients, pneumonitis is present. Propythiouracil and anticonvulsants epitomize the culprit agents for drug-induced ANCA–related vasculitis and DRESS, respectively (Table 17-5).

PARENCHYMAL PATTERNS

ILD is the most common pattern of DIRD and sometimes is assigned as a “definitive” diagnosis, although lung biopsy is rarely used to confirm this. Severity ranges from the asymptomatic state or mild changes on imaging, to the gas exchange characteristics of acute lung injury (ALI) or adult respiratory distress syndrome (ARDS). If performed, lung biopsy can reveal almost any form of ILD or interstitial and alveolar lung disease including NSIP (the most common reaction), eosinophilic pneumonia, BOOP, DAD, and DAH. Of importance, these patterns may overlap in different areas of a given lung biopsy. The potential for harm versus possible gain with transbronchial or surgical lung biopsy should be weighed in each individual patient, inasmuch as the biopsied tissue may show only nonspecific changes. A state of immunosuppression, severe hypoxemia, and rapidly deteriorating lung function all are contraindications to undertaking an invasive diagnostic procedure.

Nonspecific Interstitial Pneumonia: Cellular Interstitial Pneumonitis

On histopathologic examination, the pattern of NSIP consists of interstitial inflammation with expansion of alveolar septa by a mild to moderate mononuclear cell infiltrate, occasional eosinophils, and interstitial edema. Among the well over 100 drugs that may cause this condition, β-blocking drugs, amiodarone, flecainide, fludarabine, gold salts, imatinib, lenalidomide,

Table 17-5 Systemic Drug-Induced Reactions With Possible Pulmonary Involvement

Systemic Condition	Protypical Drugs(s) or Family	Presentation	Potential for Severity
Lupus syndrome	Lupus-inducing drugs	Pleural/pleuropericardial effusion arthralgias, neutropenia	–
ANCA-positive vasculitis	Propylthiouracil	DAH ± renal failure; pneumorenal syndrome	+++
Churg-Strauss syndrome	Leukotriene receptor antagonists	Eosinophilia, pulmonary infiltrates, mononeuritis multiplex	+
DRESS or anticonvulsant syndrome	Anticonvulsants (e.g., phenytoin), minocycline	Eosinophilia, pneumonitis, hepatitis	+++
Polymyositis	Statins	Diffuse ILD/BOOP and myopathy	+++
Systemic inflammatory response	Aspirin	Temperature disturbances, hyperventilation, tachycardia, leukocytosis or leukopenia, NCPE, acid-base disturbances	++

ANCA, antineutrophil cytoplasmic antibody; *BOOP*, bronchiolitis obliterans organizing pneumonia; *DAH*, diffuse alveolar hemorrhage; *DRESS*, drug rash, eosinophilia, and systemic symptoms [syndrome]; *ILD*, interstitial lung disease; *NCPE*, noncardiac pulmonary edema.

methotrexate, mTOR inhibitors, nilutamide, nitrofurantoin, propylthiouracil, statins, sulfasalazine, thalidomide and its congeners, tocainide, and venlafaxine are cited most often (see under categories Ia and Ib on the Pneumotox website). Methotrexate pneumonitis in rheumatoid arthritis seems to typify acute drug-induced NSIP. Collection of evidence for drug relatedness can be done using the approach set forth in Box 17-1.

Onset of signs and symptoms can be insidious or rapid, with a dry cough, dyspnea, fever, fatigue, and malaise (**Figure 17-1**). In patients who develop this complication with methotrexate and particularly if the drug is continued, the disease may accelerate without notice, causing further shadowing and progressive respiratory failure. The chest radiograph exhibits areas of ground glass attenuation, confluence, or consolidation, which often predominate in the bases, where such changes may extend rather than migrate. In more advanced cases, findings include areas of consolidation with air bronchograms and generalized volume loss, which can be marked. In early or mild cases, HRCT discloses a discrete and diffuse haze, ground glass shadowing, or mosaic attenuation, which may resemble hypersensitivity pneumonitis in appearance. Other signs on imaging include disseminated or diffuse inter- and/or intralobular septal thickening or "crazy paving"; in severe cases, an associated pleural exudate can be present. The BAL fluid typically reveals a CD8$^+$-dominant lymphocytosis, except with bacillus Calmette-Guérin (BCG)-induced pneumonitis, and sometimes an associated increase in neutrophils and/or a modest increase in eosinophil counts. The results of BAL fluid analysis are influenced by timing of the test in the course of the disease and whether the patient has received corticosteroids. BAL has an important exclusionary role: It is used to rule out a coincidental or drug-induced infection, the main competing diagnosis in drug-induced ILD. Particularly important is the use of the most recent nucleic acid–targeted molecular techniques to diagnose *Pneumocystis jiroveci* infection, as opposed to colonization, and viral infections. Nevertheless, BAL is not 100% sensitive for detection of infection. If lung biopsy is performed, the specimen will show uniform expansion of the interstitium by edema and a chronic, inflammatory cellular mononuclear infiltrate composed of lymphocytes and occasional plasma cells. Eosinophils and interstitial fibrosis are inconspicuous. Occasionally scarce and loosely formed granulomas and giant cells may be evident in methotrexate- and sirolimus-induced ILD. Special stains and in situ hybridization studies in the tissue must be used to reliably rule out an infection, which drug-induced ILD can closely resemble.

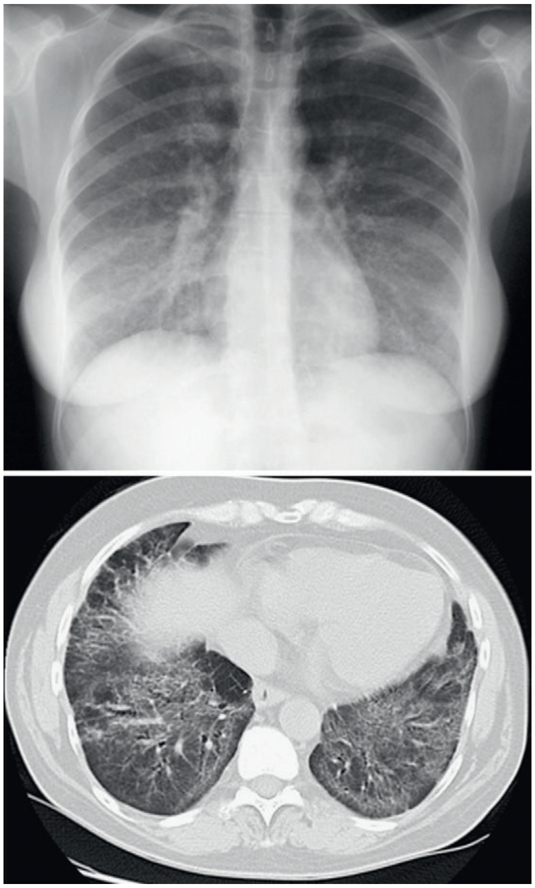

Figure 17-1 Methotrexate lung. Changes include presence of fine interstitial infiltrates in the context of dyspnea, dry cough, and fever. Clinical improvement followed discontinuance of the drug. Although not used in this particular case, corticosteroids are indicated in patients with severe presentations, after an infection has been carefully ruled out. Drug-induced cellular interstitial pneumonitis may manifest with bilateral opacification and transient acute respiratory failure; a list of drugs that may cause this pattern is available on the Pneumotox website, under categories Ia and Ib (www.pneumotox.com).

Outcome with this form of drug-induced ILD is good, with dissipation of signs and symptoms after drug discontinuance. Corticosteroid therapy is reserved for severe presentations or cases in which the disease progresses despite cessation of the drug. Dose and duration of treatment with corticosteroids are adjusted to clinical response; the usual regimen generally is for

2 to 12 weeks, using tapered dosages. The recent trend of administration of methylprednisolone in 1-g boluses has no proven efficacy as compared with conventional dosages. Pneumonitis associated with use of mTOR inhibitors may respond to simple dose reduction. Rechallenge for the purpose of an academic diagnosis is not recommended, because of the risk of life-threatening relapse or death, which would be difficult to justify from a medical-legal standpoint. Reexposure can be contemplated only if use of the specific agent is vital and no substitute drug is available, with administration of small initial doses in a hospital setting. Adequate communication among the patient, primary care provider, specialists, and pharmacist must be established to ensure that the patient is not rechallenged with the drug. Pulmonary fibrosis developing after resolution of this condition is exceedingly rare.

Amiodarone Pulmonary Toxicity

Amiodarone is an antiarrhythmic drug that is widely used to treat supraventricular and ventricular arrhythmias. Amiodarone is an amphiphilic drug, which, like most amphilics, sequesters in tissues, notably the lung, where it causes coarsely foamy changes in resident cells and macrophages of the lung—the so-called amiodarone effect. Such changes are found in the BAL fluid in most asymptomatic nontoxic patients on this medication and do not imply or predict the development of pulmonary toxicity. Amiodarone-induced pulmonary toxicity is a distinctive and potentially devastating pulmonary reaction to the drug and its metabolite. It may affect up to 2% to 5% of patients on the medication, manifesting as new-onset pulmonary infiltrates, and carries a mortality rate of about 10%. Advanced age and a history of ILD may increase the patient's risk for development of this condition. Amiodarone pulmonary toxicity typically develops in older men 6 to 12 months into treatment, which corresponds to an accumulated intake of 100 to 150 g of amiodarone, although a few cases emerged within a few days and a few others after several years. Serial monitoring of imaging and pulmonary function tests (PFTs), even if repeated frequently, generally is not capable of detecting the development of this complication early enough, because changes in PFT variables may develop abruptly. However, a pretherapy chest radiograph and lung function testing are advisable. Most cases of amiodarone pulmonary toxicity take the form of cough, breathlessness, malaise, and moderate fever, with slow and insidious onset over weeks or months. On imaging studies, disseminated, asymmetric parenchymal involvement is present and, in a few cases, pulmonary infiltrates. The liver may exhibit increased attenuation from the iodine in the amiodarone molecule. Other supportive features include a decline of 15% or greater in total lung capacity and vital capacity, or more than 20% from baseline for diffusing capacity. BAL fluid examination discloses foamy-appearing macrophages, with an inconsistent increase in lymphocytes and/or neutrophils. Amiodarone pulmonary toxicity must be distinguished from left ventricular failure using a combination of amino-terminal (N-terminal) pro-B-type natriuretic peptide (NT-pro-BNP) assay and appropriate imaging studies, particularly HRCT, heart ultrasound evaluation, cardiac catheterization, and re-imaging after a few days of induced diuresis.

The various clinical imaging patterns of amiodarone pulmonary toxicity (Figure 17-2) include asymmetric pulmonary infiltrates abutting a thickened pleura, segmental or lobar consolidation, a pattern undistinguishable from that of interstitial pulmonary fibrosis, DAH, multiple ill-defined nodules that may exhibit avid uptake on a fluorodeoxyglucose positron emission tomography (FDG-PET) scan, pleuropericardial effusion, masses with a center of decreased attenuation, or white lungs and an ARDS picture, particularly after thoracic surgery. Thoracic surgery should be considered a triggering factor for serious amiodarone pulmonary toxicity. Histopathologic analysis, if performed, discloses a pattern of NSIP with foamy-appearing or vacuolated alveolar macrophages, giving the lung a desquamative interstitial pneumonia appearance, foamy changes in pneumocytes and endothelial cells, BOOP, acute fibrinous organizing pneumonia (AFOP), lymphocytic agents, and sterile suppurative masses. Eosinophilic pneumonia, DAD, DAH, and pulmonary fibrosis are less common manifestations of amiodarone pulmonary toxicity, and foam cells may accompany these changes, depending on the interval from cessation of amiodarone administration. A noninvasive approach, as opposed to the more invasive biopsy and its attendant risk of complications, is recommended, inasmuch as a risk-benefit evaluation is not available. Accordingly, causality is more often inferred rather than proved.

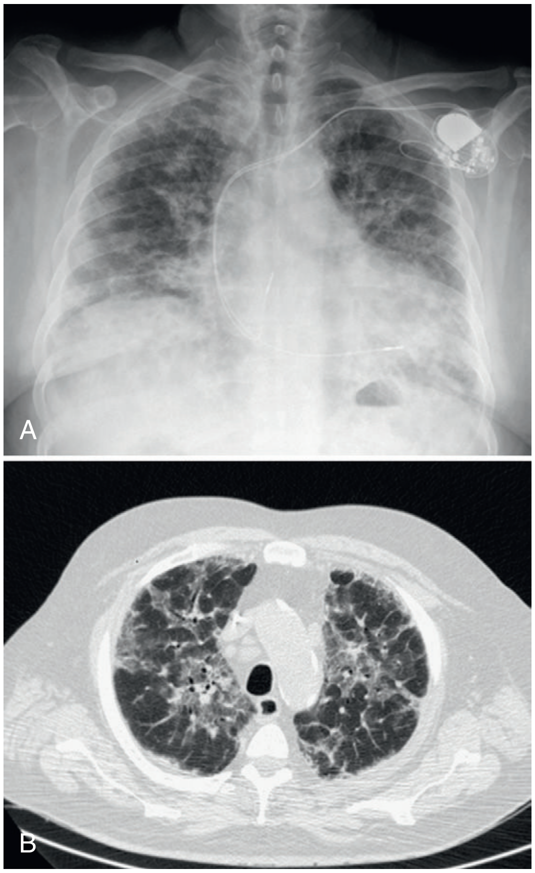

Figure 17-2 Amiodarone pulmonary toxicity (APT). **A,** The chest radiograph shows scattered infiltrates and volume loss. The presence of a pacemaker is a clue to the diagnosis of APT. **B,** Lobular filling is evident on the high-resolution computed tomography (HRCT) scan. Pulmonary involvement in APT is diverse and can be asymmetric or localize in the apices. Other, less common APT patterns include inter/intralobular septal thickening, lobar consolidation, areas of pleural thickening, zonal high attenuation due to the high iodine content of amiodarone, nodules, and masses.

The most important aspect of recommended therapy for amiodarone-induced pulmonary toxicity is curtailing exposure to the drug. Corticosteroids are given if drug discontinuance fails to provide demonstrable benefit and in severe cases are quite efficacious. Because of concern about a flare of toxicity-related symptoms while corticosteroids are tapered, a slow diminution of steroid dose is indicated, and corticosteroids typically are given for at least 6 months. Prolonged treatment with corticosteroids requires that patients be regularly monitored for the possible development of steroid-induced adverse effects, including amyotrophy, osteopenia, and opportunistic infections.

Pulmonary Infiltrates and Eosinophilia: Eosinophilic Pneumonia

Eosinophilic pneumonia is a not uncommon complication of pharmaceutical exposures, with more than 80 distinct drugs and substances including substances of abuse recognized as potentially causative agents. Eosinophilic pneumonia can be divided into several clinically distinct entities, which may have overlapping features:

- Patients with methotrexate or nitrofurantoin lung may exhibit mild to moderate peripheral eosinophilia without displaying significant or predominant eosinophilia in BAL fluid or in tissue. Such cases do not strictly meet the definition for eosinophilic pneumonia.
- Eosinophilic pneumonia, when pulmonary infiltrates and peripheral blood and BAL fluid eosinophilia coexist, is an elective complication of treatment with drug families such as ACE inhibitors, antibiotics (minocycline, sulfa drugs, daptomycin), antidepressants (venlafaxine, sertraline), and NSAIDs. Occasional cases have been reported with the administration of bleomycin, cocaine, heroin, fludarabine, and leukotriene receptor antagonists, but eosinophilic pneumonia is not the primary pattern of pulmonary reaction with these latter drugs. Fever and a skin rash can be present at onset of the condition. On the chest radiograph and HRCT scan (Figure 17-3), pulmonary infiltrates may predominate in the upper lung fields and can be accentuated in the subpleural regions of the lung bilaterally, but this finding is not universal. Eosinophilic pneumonia can be diffuse or migratory and at times may be difficult to separate from other drug-induced ILD on imaging. Blood eosinophil counts can be normal, whereas BAL fluid eosinophils are more specifically increased up to 50% of the total score or more, obviating the need for the lung biopsy. The diagnosis of drug-induced eosinophilic pneumonia rests on the combination of exposure to a compatible drug, consistent temporal relationship, compatible imaging findings, and a confirmatory blood and/or BAL fluid cell count that decreases on drug discontinuance. A lung biopsy was performed in approximately 6% of all cases reported in the literature. Findings included eosinophil-rich interstitial inflammation and, in some cases, a relative abundance of eosinophils perivascularly. Occasional patients present with overlapping imaging features of eosinophilic *and* organizing pneumonia, with migratory opacities and histopathologic evidence of luminal fibrosis. Extrapulmonary signs and symptoms in patients with eosinophilic pneumonia should raise suspicion for the Churg-Strauss syndrome (see further on). Other causes and contexts for eosinophilic pneumonia including parasitic infestation must be carefully excluded. Outcome of this condition is good if the causal drug is withheld. Corticosteroid therapy is indicated in severe cases. Rechallenge has been safely used to confirm the diagnosis and typically results in the early return of fever and blood eosinophilia in a few hours, which is sufficient to confirm the diagnosis, and of the full-blown picture in a few days.
- Acute eosinophilic pneumonia (AEP) is a grave illness manifesting with fever, cough, dyspnea, dense pulmonary infiltrates, blood, and/or BAL fluid eosinophilia and respiratory failure requiring mechanical ventilation. HRCT shows scattered or more diffuse areas of so-called crazy paving, with areas of consolidation and air bronchograms in more advanced cases. A bilateral pleural effusion may be present at the peak of the disease course. Extreme BAL fluid eosinophilia is the rule, but peripheral eosinophilia is not present in every case. Even though AEP can occur in patients exposed to a compatible drug, not all AEP cases are drug-related, because rechallenge with the drug may not lead to relapse in every patient. The list of causal drugs and substances overlaps with that for eosinophilic pneumonia and includes chloroquine, daptomycin, minocycline, venlafaxine, L-tryptophan (a now-recalled dietary supplement), cocaine, heroin, cannabis, and tobacco use with recent onset of smoking. Drug-induced AEP may represent the upper end of the severity spectrum of eosinophilic pneumonia. Early discontinuation of the offending drug and corticosteroid therapy are indicated.

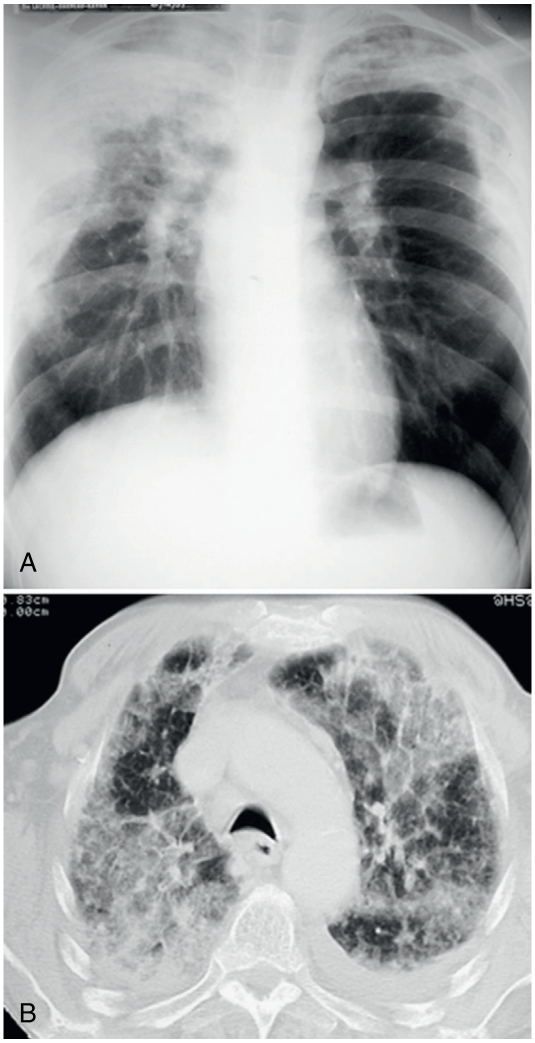

Figure 17-3 **A,** Typically, the opacities of drug-induced eosinophilic pneumonia (caused by minocycline in this case) localize in the apices subpleurally, as seen on this chest radiograph, although they may be more diffuse. **B,** On high-resolution computed tomography (HRCT) scan, lobular ground glass shadowing, interlobular septal thickening, and pleural effusion may be present. See under category Ic on the Pneumotox website (www.pneumotox.com).

- Exposure to minocycline, allopurinol, mexiletine, tricyclic antidepressants, anticonvulsants, ibuprofen, and a few other drugs may induce a systemic reaction characterized by prominent and extensive cutaneous rash, pharyngitis, and involvement of the liver, kidney, heart, and central nervous system; in about 15% to 20% of patients, pulmonary infiltrates or eosinophilic pneumonia also is present. The syndrome is known as *DRESS* (drug rash, eosinophilia, and systemic symptoms) or the *anticonvulsant syndrome*, because cases may follow the administration of carbamazepine, phenobarbital, phenytoin, or lamotrigine. DRESS may occur in 1 of 1000 to 10,000 patients receiving these medications. DRESS seems to be poorly recognized, and delay time to diagnosis often is described as "too long," although early recognition is essential. Reactivation of human herpesvirus type 6 or 7 (HHV6, HHV7) or Epstein-Barr virus (EBV) infection may play a causative role by expanding a pool of activated $CD8^+$ T lymphocytes directed against *Herpesvirus* sequences. Drug withdrawal and corticosteroid therapy are indicated. Although outcomes are considered as good, myocardial involvement may adversely affect prognosis.
- Still other patients, mostly asthmatics, develop the Churg-Strauss syndrome during the course of drug therapy. Most cases (more than 90%) occurred in association with LTRAs, and a minority with a few other drugs. Recent case reports have described the onset of Churg-Strauss syndrome in connection with treatment with omalizumab. With LTRA, a few Churg-Strauss cases developed after the other antiasthma drugs were tapered, suggesting that the disease was suppressed by the non-LTRA antiasthma drugs and had been masked until these were omitted. The current view, however, is in favor of an independent and statistically significant causal relationship of LTRA administration and the development of the syndrome.

Infiltrative Lung Disease with a Granulomatous Component

Drugs causing granulomatous ILD include BCG therapy, interferon alfa or beta, methotrexate, sirolimus, and etanercept. On imaging studies, this condition manifests with diffuse interstitial micronodular or linear infiltrates with or without concomitant hilar or mediastinal lymphadenopathy. In some patients, an abundance of $CD4^+$ or $CD8^+$ lymphocytes in the BAL fluid is seen, whereas in others, lymphocyte numbers are normal. Treatment with interferons and etanercept may induce a clinical-imaging and pathologic picture similar to that in sarcoidosis, sometimes with the typical extrathoracic and laboratory features of the naturally occurring disease. Not all cases of sarcoidosis-like disease in hepatitis C virus infection are related to interferon, however, because in about a quarter of the patients with the association, no antiviral agent was being given at the time of diagnosis. The diagnosis of granulomatous inflammation can be confirmed by transbronchial or open lung biopsy, although biopsy of extrapulmonary sites, preferably the skin, is a desirable means of noninvasively establishing the diagnosis. The granulomas in methotrexate pulmonary toxicity are loosely formed, as opposed to those seen with interferons. Recent evidence suggests that treatment with anti-TNF agents in rheumatoid arthritis, mainly etanercept, may be associated with the development of lymphohistiocytic pulmonary infiltrates and non-necrotizing granulomas showing negative results on cultures and special stains for microorganisms. A blunted response to a yet-to-be identified microorganism, a *forme fruste* of rheumatoid lung nodules, and an authentic pulmonary reaction to etanercept are among the possibilities. With a finding of pulmonary granulomatosis in a patient who is on anti-TNF therapy, it is crucially important to rule out pulmonary tuberculosis using sputum stains and cultures and interferon gamma release assay, even if findings on pretherapy evaluation for latent tuberculosis were negative, because anti-TNF agents predispose to the development of this complication. It also is important that patients on anti-TNF agents be tested for antinuclear and anti–double-stranded DNA (anti–ds-DNA) antibodies, because *drug-induced lupus syndrome* appears to be a common complication of treatments with anti-TNF agents. A few patients have developed both a sarcoid-like reaction and drug-associated lupus with anti-TNF antibody therapy. Drug discontinuance and corticosteroid therapy are associated with improvement in nearly all cases. In published reports, symptomatic patients with granulomatous ILD due to BCG administration were given antituberculosis drugs prophylactically.

Organizing Pneumonia

Organizing pneumonia, or BOOP (see under category Id on the Pneumotox website), is a distinctive but nonspecific pulmonary reaction to several infectious and noninfectious insults including inhalation injury, aspiration, drugs, and radiation therapy. BOOP also can occur in recipients of hematopoietic stem cell transplants and in patients with systemic diseases such as rheumatoid arthritis, lupus erythematosus, inflammatory myopathies, temporal arteritis, and ulcerative colitis. BOOP can also occur idiopathically in patients not exposed to drugs. Thus, the multiplicity of underlying causes or contexts for BOOP makes drug causality assessment in BOOP cases difficult. Reasonable evidence suggests that amiodarone, bleomycin, beta blockers, interferon alfa or beta, nitrofurantoin, rituximab, statins, trastuzumab, and radiation therapy to the breast all may cause BOOP. Regardless of the inciting agent, clinical manifestations will include fever, dyspnea, crackles, and sometimes chest pain. Imaging studies will show focal areas of alveolar consolidation, which can migrate, wander, or levitate on chest films taken serially (**Figure 17-4**). Less common presentations include lung nodules or masses containing air bronchograms or diffuse shadowing and acute respiratory failure. On histopathologic examination (although lung biopsy is rarely performed in typical cases), buds of young connective tissue are seen to populate the distal air spaces, which become solid, and widespread florid interstitial inflammation is typical.

In general, BOOP responds well to drug withdrawal and corticosteroid therapy. Unlike idiopathic BOOP, the drug-related condition may relapse, because corticosteroids are still given at elevated dosages if the culprit drug is inappropriately continued—a clue to the diagnosis of drug-induced BOOP. Statin-induced BOOP can be associated with myalgias and a concomitant increase in creatine kinase levels, indicating statin myopathy. In isolated reports, some patients developed a picture of polymyositis thought to be triggered by statin administration. In a few cases, the recently recognized pattern of AFOP was noted as a possible adverse pulmonary reaction to amiodarone or statins. AFOP shares pathologic features with both BOOP and DAD, and it is characterized by diffuse shadowing on imaging studies and by the gas exchange abnormalities of ALI. Outcome in patients with AFOP is distinctly not as good as in those with BOOP. Some BOOP or AFOP cases diagnosed on histopathologic examination may represent the resolving phase of ALI and DAD (see further on).

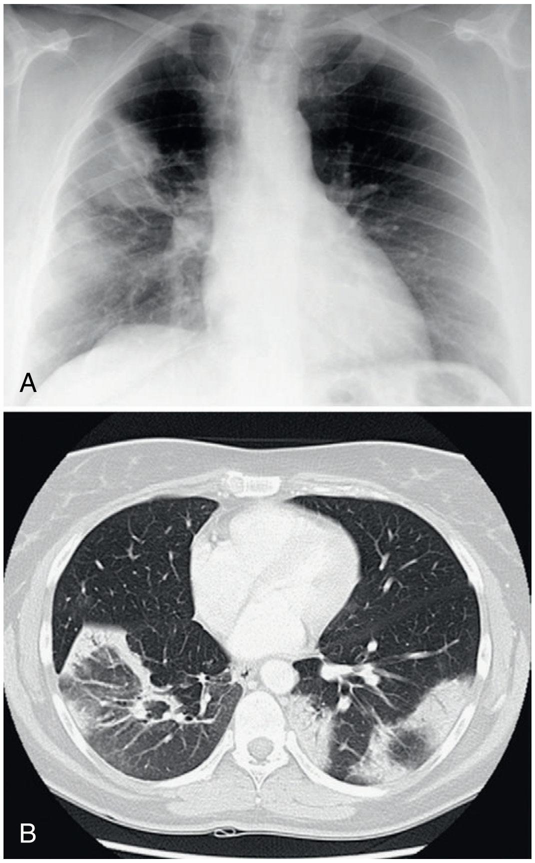

Figure 17-4 Probable organizing pneumonia that developed during treatment with a statin drug. **A** and **B,** Areas of alveolar consolidation and air bronchograms "wandered" from one to another area of the lung on serial chest films, until the drug was eventually withdrawn. See under category Id on the Pneumotox website (www.pneumotox.com). Severe bronchiolitis obliterans organizing pneumonia (BOOP) may overlap with acute fibrinous organizing pneumonia (AFOP).

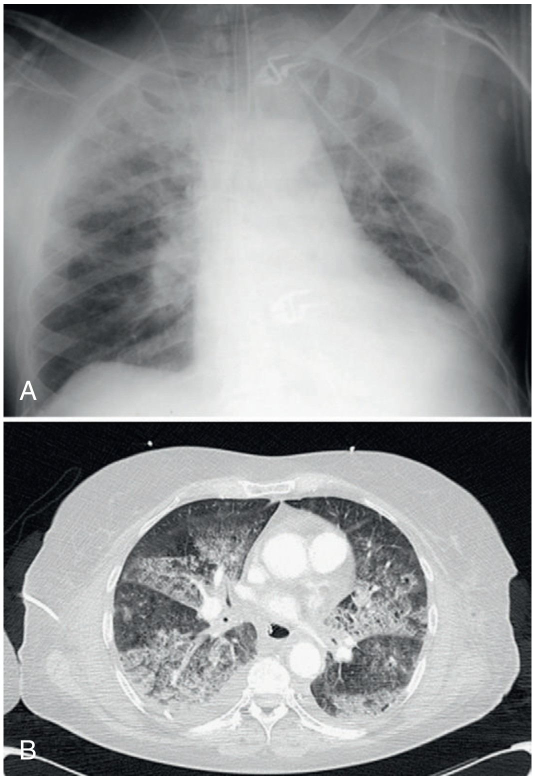

Figure 17-5 Acute noncardiac pulmonary edema (NCPE) after administration of chemotherapeutic drugs in the treatment of solid malignancy. **A** and **B,** Imaging discloses gravity-dependent alveolar opacities, ground glass, interlobular septal thickening, areas of consolidation and moderate pleural effusion. Drug-induced NCPE typically occurs shortly after the administration of chemotherapy or nonchemotherapeutic drugs, or after blood transfusion–related acute lung injury (TRALI). Mechanical ventilation may be necessary in patients with acute respiratory failure. Vigorous inspiration against a closed airway may cause barotrauma and precipitate negative-pressure pulmonary edema. See under category II on the Pneumotox website (www.pneumotox.com).

Acute Pulmonary Edema

Acute pulmonary edema can complicate deliberate or accidental ingestion of large quantities of several drugs and appears to be a nonspecific effect of drug overdose. True drug-induced NCPE is defined by the simultaneous presence of bilateral infiltrates of sudden or rapid onset and severe hypoxemia in a patient with normal pulmonary capillary wedge pressure and absence of changes on heart ultrasound imaging who is receiving a compatible drug at normal dosage, and in whom other causes for NCPE are excluded. The abrupt onset of signs and symptoms after exposure and rapid disappearance on stopping the drug characterize this condition, as opposed to ILD, which runs a more protracted course. Histopathologic confirmation is rarely available, so most cases are suspected rather than proved. In acute, florid cases that came to autopsy after therapy with cytosine arabinoside, methotrexate, gemcitabine, or heroin, alveolar spaces were found to be filled with acellular proteinaceous fluid or fibrin, or there were diffusely distributed hyaline membranes of DAD, a condition with overlapping features, depending on the time frame for diagnosis. Interstitial inflammation is inconspicuous or modest. Interlobular septa may be grossly enlarged by fluid (Figure 17-5).

The mechanisms for NCPE include loss of endothelial cell integrity with consequent extravascular plasma leakage. This is confirmed by the high edema fluid–to–plasma protein ratio. Clinically, NCPE is heralded by the sudden onset of dyspnea and pulmonary opacities sometimes within less than 1 minute after oral, parenteral, or topical administration of a compatible drug, such as epinephrine, all-*trans* retinoic acid (ATRA), arsenic trioxide (As_2O_3), aspirin, hydrochlorothiazide, interleukin-2, nafazoline, narcotics (opiates), propofol, tocolytic agents, antineoplastic chemotherapy (gemcitabine, methotrexate, taxanes), blood and blood products (as in TRALI), or radiocontrast media. In severe cases of NCPE, particularly in drug abusers, a plume of pink frothy sputum is noted at the mouth or in ventilator tubing. Imaging studies disclose the rapid onset of diffuse haze or ground glass shadowing with thickened septal lines and pleural effusion. Typically, there is no cardiomegaly or pedicle enlargement. Notable signs and symptoms include low blood pressure concomitant with the onset of pulmonary infiltrates indicating extravascular fluid loss. In patients with low blood pressure, diuretics are likely to further aggravate the hemodynamic condition and are contraindicated. Epinephrine-induced pulmonary edema can be of the vasoconstrictive type, with marked and transient hypertension concomitant with the onset of pulmonary edema. Hydrochlorothiazide produces a so-called allergic pulmonary edema, characterized by accumulation of pulmonary infiltrates shortly after administration of as little as one tablet of the drug. It may take more than one episode of inadvertent challenge with hydrochlorothiazide before the drug is eventually recognized as a causative agent. Salicylate-induced pulmonary edema can occur in acute and chronic aspirin users, especially in elderly patients with impaired renal function and consequent high plasma drug levels. Patients may present with fever and an impaired level of consciousness, making it difficult to obtain a reliable drug history. Anion gap and metabolic acidosis are characteristic biologic features of salicylate-induced NCPE. Monitoring of drug levels in blood is advised early after hospital admission to confirm the diagnosis, and 30 mg/dL is considered the threshold above which toxicity is likely to occur. Treatment of salicylate-induced pulmonary edema includes serum and urine alkalinization, with hemodialysis reserved for cases with pulmonary edema and other organ damage. Outcomes generally are good if administration of the offending agent is stopped promptly and appropriate supportive care including mechanical ventilation is given. A few cases progress to pulmonary failure or ARDS. The effect of corticosteroid therapy is unclear, but these drugs often are given empirically. The development of pulmonary edema in relation to cardiac dysfunction occasionally has been reported with the administration of doxorubicin and trastuzumab.

Diffuse Alveolar Damage: Chemotherapy Lung

DAD is a pathologic diagnosis that corresponds clinically to acute interstitial pneumonia and the gas exchange characteristics of ALI or ARDS. The condition runs a subacute or acute clinical course and may complicate therapy with numerous antineoplastic agents, particularly when such drugs are given in the form of a multiagent regimen at high dosages, or in conjunction with oxygen and radiation therapy, each of which may cause DAD on its own. Patients treated for solid tumors and hematologic malignancies are at risk for this condition, dubbed "chemotherapy lung" (see under category II on the Pneumotox website). Drugs reported to cause DAD include antineoplastic antibiotics (bleomycin, mitomycin C), alkylating agents (busulfan, cyclophosphamide, chlorambucil, melphalan), antimetabolites (aracytine, azathioprine, gemcitabine, fludarabine, 6-mercaptopurine, methotrexate), nitrosamines (BCNU, chloroethyl-cyclohexyl nitrosourea [CCNU], and novel nitrosoureas), oxaliplatin, podophyllotoxins (etoposide), bortezomib, docetaxel, etoposide, paclitaxel, erlotinib, gefitinib, cetuximab, irinotecan, granulocyte-monocyte colony-stimulating factors (GM-CSFs), and a few nonchemotherapeutic drugs such as amiodarone, carbamazepine, everolimus, opiates, nitrofurantoin, rituximab, salicylate, sertraline, sirolimus, statins, and ticlopidine, as well as blood and blood products used in transfusion. Features of DAD may overlap with those of NCPE, with transition from benign pulmonary infiltrates to noncardiac pulmonary edema or DAD in some patients with inappropriately continued exposure to the causal drug. DAD manifests with cough, dyspnea, disseminated or diffuse haze, ground glass shadowing that may progress to widespread consolidation, lung volume loss, and hypoxemia. HRCT imaging displays linear interlobular and/or intralobular opacities; ground glass attenuation and, on occasion, moderate bilateral pleural effusions are present. Although no study has specifically addressed the contribution of BAL to confirmation of drug-induced DAD, reported series that included a few patients diagnosed with drug-induced DAD showed increased neutrophil counts in their BAL samples; in severe cases, hemosiderin-laden macrophages and bizarre type II cells also were present. It is critical to monitor patients on sequential chemotherapy for the development of subclinical pulmonary infiltrates on imaging studies, because this finding may indicate early NCPE and reflect impending DAD on continued exposure to the drug. PFTs also are often performed serially, and caution is required in the asymptomatic patient when the diffusing capacity for carbon monoxide falls by more than 30% or 40%. A confirmatory lung biopsy is rarely requested, because the procedure often is deemed to have an unacceptable attrition rate, as measured against a modest diagnostic output. On histopathologic examination, depending on stage of the illness, findings may include interstitial edema, alveolar fibrin, hyaline membranes, various stages of resolving or organizing alveolar damage, and an increased prominence of alveolar lining cells, which is a marker of epithelial cell injury. Although DAD certainly is a distinctive pattern of pulmonary involvement, histopathologic analysis is not capable of separating drug-induced from idiopathic DAD, or to pinpoint its cause. DAD has been observed in the setting of infection, after hematopoietic stem cell transplantation (HSCT) or solid organ transplantation, and with exacerbations of preexisting pulmonary fibrosis; in about a fifth of the cases, no cause is found. Thus, drug causality assessment is a difficult task, unless the results of workup for infection are negative and a straightforward drug exposure–symptom relationship is recognized. Empirical corticosteroids often are given, but the results of this form of therapy are unpredictable. Patients treated early in the course of DAD may respond, whereas others may experience progression to an ARDS picture despite high-dose corticosteroids. The overall mortality rate for iatrogenic DAD is 45%.

Diffuse Alveolar Hemorrhage

DAH is a diffuse and synchronous bleeding from the pulmonary capillaries to the alveolar spaces causing shortness of breath, hypoxemia, anemia, and accumulation of pulmonary infiltrates. Before the diagnosis of drug-induced DAH is considered, exposure to inhaled hydrocarbons or cocaine, ingestion of the superwarfarin brodifacoum rodenticide, or subcutaneous injection of fluid silicone should be ruled out, because any of these may cause severe pulmonary bleeding. Bleeding after accidental or deliberate ingestion of brodifacoum can be especially difficult to treat, because the compound has a very long half-life. From 11% to 18% of DAH cases are considered to be due to drugs. On imaging studies, hazy or ground glass opacities of alveolar filling may assume a butterfly or batwing configuration or have a more diffuse appearance, and on HRCT, scattered, loosely demarcated areas of increased attenuation may be seen.

DAH requires emergent management, because clotting may take place in the distal air spaces or major airways, causing respiratory failure or airway blockage. Hemoptysis occurs in less than a third of the patients, even though significant anemia may be present. An increase in the diffusing capacity for carbon monoxide suggesting free hemoglobin in air spaces is an insensitive finding, because it was noted in a quarter of all reported cases of DAH. A hemorrhagic BAL fluid return is the key diagnostic feature in DAH, and most cases are undiagnosed clinically before the test. A progressively bloody return is noted on serial BAL fluid aliquots. Iron-laden macrophages are revealed by Prussian blue staining, and a correlative increase in the Golde score is seen on microscopy. Drug causality assessment necessitates careful exclusion of other causes, because DAH can occur as a manifestation of cytomegalovirus (CMV) pneumonitis, *Strongyloides stercoralis* infestation, coagulation disturbances, thrombocytopenia, or left ventricular dysfunction, or on a background of lupus, ANCA-related vasculitis, or HSCT, or idiopathically. DAH may be an isolated finding (so-called bland DAH), or it may occur in association with features of extrapulmonary involvement such as microscopic hematuria, renal failure, or microscopic vasculitis in the skin. Indications for and benefits of lung biopsy in DAH constitute a matter of debate, because BAL is the key contributor to definitive diagnosis in the presence of compatible imaging. The finding of capillaritis in the form of invasion and permeation of the capillary walls by neutrophils, along with red cells in alveolar spaces, may not change the treatment approach substantially, and the attendant risks are not negligible.

DAH is the main predictable adverse effect of heparin, thrombolytic agents, oral anticoagulants, and a newer class of antiplatelet agents, the glycoprotein IIb-IIIa inhibitors (abciximab, clopidogrel, eptifibatide, ticlopidine, tirofiban). With the last group of drugs, left ventricular dysfunction and smoking are additional risk factors. Platelet counts generally are within the normal range. In the case of DAH and oral anticoagulants, although a high INR is associated with increased risk of bleeding, coagulation studies can be in the normal therapeutic range at the time of clinical onset of DAH. DAH is an occasional adverse effect of amiodarone, ATRA, nitrofurantoin, rituximab, sirolimus, and chemotherapy drugs. Rarely, DAH is secondary to thrombocytopenia occurring with use of abciximab or quinidine.

Distinctive drug-induced DAH contexts have recently attracted attention:

- Antithyroid drugs, mainly propylthiouracil (PTU) and, less often, benzylthiouracil, carbimazole, or methimazole, may induce perinuclear ANCA, with or without clinically demonstrable vasculitis. These antibodies more often exhibit an anti-myeloperoxidase (anti-MPO), antilactoferrin, or antileukocyte elastase staining pattern and, less often, anticathepsin or antiazurocidin reactivity. ANCAs are unusual in untreated Graves' disease and are strongly associated with exposure to antithyroid drugs, and titers are found to be higher than in naturally occurring ANCA vasculitis, which should attract clinical attention. An anti-PR3 specificity similar to that in naturally occurring ANCA-related vasculitis (Wegener) is an unusual finding. Rare patients have exhibited dual anti-MPO and PR3 ANCA specificity. About 25% of patients with PTU-induced ANCA disease present with pulmonary involvement, and pulmonary capillaritis is found in about 20% of those with PTU-related DAH who undergo a lung biopsy. Renal involvement of various stages is a finding in approximately 75% of the patients, ranging from microscopic hematuria to necrotizing and/or crescentic glomerulonephritis. Patients may present with violaceous skin changes related to vasculitis in the skin on the ears or limbs. A few patients will require induction therapy with corticosteroids, cyclophosphamide, and plasma exchange in a manner similar to that for idiopathic DAH or pneumorenal syndromes. Terminal renal failure is reported in about 5%, and death occurs in approximately 15% of the patients, with respiratory death due to uncontrollable DAH. Recognition of the drug-induced disorder as opposed to an idiopathic etiology is important, because all manifestations of the disease including elevation of ANCA titers are likely to fade on discontinuance of PTU. About a third of the patients with Graves' disease who receive PTU, but not those unexposed to the drug, also demonstrate development of ANCA. Monitoring and follow-up but not drug discontinuance are indicated in asymptomatic cases, because only a fraction of the patients who develop ANCA with exposure to PTU will develop overt vasculitis. Only a few cases of ANCA-related or mixed ANCA and ANA-related autoimmune disease have occurred with the use of penicillamine and hydralazine.
- Inhalation of cocaine may be followed in a few days by acute episodes of hemorrhage, and evidence for DAH is a common finding at autopsy in drug addicts. Although anti-basement membrane–related DAH (Goodpasture syndrome) was once considered an idiopathic condition, 9 of 10 patients in a recent study were smokers, and a history of illicit inhaled drug use (cocaine, cannabis, heroin) was elicited in up to a third of the patients. Thus, Goodpasture syndrome may be a form of inhalational lung injury.
- Although not a real drug, fluid silicone is used subcutaneously in cosmetic surgery to augment breast size in women or to feminize body shape in transsexual persons. Fluid silicone can gain access to the venous circulation, potentially causing severe lung injury, DAH, ARDS, and neurologic death. The *silicone embolism syndrome* shares several clinical and imaging features with the fat embolism syndrome: It may develop over a few hours to 2 weeks, typically in a woman or a transsexual person with a history of illegal subcutaneous injections of fluid silicone. Clinical presentation is with any combination of fever, dyspnea, cough, chest pain, hypoxemia, hemoptysis, alveolar hemorrhage, petechiae, and altered consciousness. Imaging findings are remarkably similar across cases and series and include dense, predominantly basilar subpleural shadowing and air bronchograms. On HRCT, these features may resemble those of eosinophilic pneumonia. Specific attention to the breast is required, because breast tissue may show signs of recent subcutaneous injection of silicone on HRCT. Silicone can be found in BAL fluid macrophages, which contain large, pleomorphic, cytoplasmic inclusions, on a background of neutrophils and/or hemorrhage. On histopathologic examination, nonstainable interstitial vacuoles of fluid silicone conform to the shape of pulmonary capillaries, and a foreign body reaction is diagnostic of this condition. The outcome with silicone embolism syndrome is good, except in patients with very early onset of symptoms after the procedure or in those with a neurologic presentation, which is thought to result from transmigration of silicone through the lung or via an atrial septal defect to the brain. Such patients sustain a high mortality.

The management of DAH includes drug therapy withdrawal, supportive care, and, depending on the clinical context, vitamin K, fresh frozen plasma, platelet transfusion, pulmonary lavage with iced saline, activated recombinant factor VII, or corticosteroids. Immunosuppressant regimens or plasma exchange procedures are reserved for refractory or drug-induced DAH in a manner similar to that for DAH or pneumorenal syndrome occurring idiopathically.

Pulmonary Fibrosis

Diagnosing the cause for pulmonary fibrosis in a patient with a history of exposure to drugs is nearly always problematic, in view of the commonness of idiopathic pulmonary fibrosis. Clubbing of the fingers and honeycombing are less common in drug-induced than in idiopathic pulmonary fibrosis. Drug-induced and iatrogenic pulmonary fibrosis can occur as a late complication of antineoplastic combination chemotherapy using bleomycin, busulfan, chlorambucil, cyclophosphamide, melphalan, mitomycin C, or nitrosoureas (BCNU, CCNU). Estimates indicate a 3% to 4% prevalence of clinically detectable pulmonary fibrosis in long-term survivors of Hodgkin disease, and figures are higher if patients with subclinical restrictive lung function are included. The delayed pulmonary toxicity syndrome in hematopoietic stem cell transplant recipients may correspond to radiation- and chemotherapy-induced pulmonary fibrosis. Pulmonary fibrosis may follow an episode of early drug-induced lung injury; it also seems to arise de novo.

Drug-induced pulmonary fibrosis manifests with dyspnea, cough, crackles, and weight loss. Imaging studies disclose predominantly basilar linear or streaky opacities and volume loss. HRCT reveals coarse reticular thickening along with traction bronchiectasis. Histopathologic examination demonstrates mutilating interstitial fibrosis with sparse inflammation. The late changes of nitrosourea- and cyclophosphamide-induced pulmonary fibrosis may have a predilection for the apices. The late changes of cyclophosphamide-induced disease include pleural thickening, which adds to the restrictive lung dysfunction. The thickened pleura is paradoxically liable to spontaneous pneumothorax, which appears to be difficult to treat. Evidence for nonchemotherapy drugs as agents of pulmonary fibrosis is tenuous. Amiodarone has been reported to cause lung fibrosis either after an episode of classic unresolved pulmonary toxicity or unexpectedly during or after the end of therapy with the drug. An association with nitrofurantoin, occasionally with a positive result on ANA testing that reverses on cessation of therapy with the drug, also has been described. Recently, sudden deterioration of previously diagnosed "rheumatoid lung" has been seen in association with administration of various anti-TNF agents. Curtailing exposure to the suspected agent is indicated in all cases of fibrosis thought to be induced or aggravated by a drug. Improvement is inconsistent, as is the response to corticosteroid therapy. Lung transplantation must be considered and has been successfully implemented in a few patients.

Radiation-Induced Injury

The extent, location, and likelihood of radiation-induced changes depend on radiation dose, associated chemotherapy, portals, and irradiation technique. Sporadic radiation pneumonitis typically occurs in the first few months after delivery of therapy. Late radiation-induced lung fibrosis predominates in the mediastinum in patients with lymphoma who received Y-shaped irradiation fields and in the irradiated lung in patients who received oblique radiation therapy for the treatment of lung cancer. This process takes the form of a limited, whorled or convoluted area of fibrosis developing after stereotactic body radiation therapy, or it can be diffuse when occurring after whole-lung or total-body irradiation.

AIRWAY INVOLVEMENT

Upper Airway Obstruction

Angioedema, the most serious upper airway complication of drugs, occurs more often as a complication of ACE inhibitors than with any other drugs, and ACE inhibitors may account for two thirds of all angioedema cases. An underdiagnosed clinical entity, angioedema is poorly identified as drug-induced, and the long delay until diagnosis, during which exposure to the drug continues despite repeated episodes of edema, puts the patient at risk for development of an asphyxiating episode of airway blockage. Incidence of drug-induced angioedema is on the rise, and ACE inhibitor–induced angioedema is seen more often, and in the United States, a disproportionately greater (fourfold) frequency of this disorder has been documented among African Americans or Afro-Caribbeans than among whites. Incidence is greater with enalapril or lisinopril than with captopril. Angioedema tends to occur more frequently in the first few weeks of treatment in dark-skinned people, whereas in whites, angioedema can occur months and up to a few years into treatment. About a quarter of affected patients give a history of previous spontaneously resolving episodes, which failed to be recognized as drug-induced. ACE inhibitor–induced angioedema develops unexpectedly or after manipulation of the airway. It manifests with nonspecific signs and symptoms of sore throat, drooling of saliva, dysphagia, and pruritus, followed by the rapid development of edema of the lips, floor of the mouth, and/or larynx.

Drug-induced angioedema can be classified as type 1, edema limited to the face; type 2, involvement of the floor of the mouth, base of tongue, and uvula; and type 3, involvement of the oropharyngeal, glottic, and supraglottic regions and, rarely, the thoracic trachea. Patients with type 2 and type 3 edema are more liable to experience breathing difficulties and to require admission to an intensive care unit (ICU), or to need intubation. It is crucially important to identify and secure the airway early, using fiberoptic bronchoscopy, because if the edema progresses, complete airway obliteration can occur. Identification of the airway may prove impossible, and emergent tracheostomy may be required. Overall, 40% of patients with angioedema require ICU admission, and mechanical ventilation is indicated in about 10%. Outcome is good with supportive care. Patients need to remain hospitalized for an average of 2 days, because rebound edema has been reported. Autopsy series of asphyxiating ACE inhibitor angioedema point to the need for careful identification and management of this condition.

A similar pattern of acute upper airway obstruction may develop with anaphylaxis. Anaphylaxis is an explosive reaction that may follow the administration of drugs, notably antibiotics or radiocontrast media. Signs and symptoms of the condition include wheezing, bronchospasm, airway obliteration, cramping, cardiovascular collapse, shock, loss of consciousness, seizures, and pulmonary edema. Although outcome is good in most instances, a fraction of affected patients may die from the condition. Drugs and foodstuffs account for most cases of fatal anaphylaxis, with anesthetic agents and antibiotics making up a majority of causal drugs. Time to cardiac or respiratory arrest generally is within 5 minutes of ingestion. Distinction between an asthma attack and anaphylaxis is not made in every patient. Although a fraction of the patients initially are resuscitated, secondary death from hypoxic brain damage may occur. Although epinephrine is administered in most patients, it rarely is given early enough before the arrest.

Less common causes of large airway obstruction include laryngeal hematoma and bleeding around the trachea in patients chronically exposed to oral anticoagulants.

Acute Bronchospasm

Bronchospasm can closely follow exposure to oral or parenteral drugs, with acetylsalicylate, β-blocking agents, analgesics, NSAIDs, antibiotics, and cardiovascular drugs accounting for three fourths of the cases and miscellaneous drugs including corticosteroids accounting for the remainder. About 10% to 15% of cases of acute asthma necessitating ICU admission may be secondary to drugs. Asthma, atopy, and a history of drug allergy are risk factors. A stream of an inhaled drug also can cause bronchospasm.

Although acute bronchospasm may develop with no warning sign or symptom in a subject free from antecedent asthma, most of the time it occurs in patients who have underlying asthma and/or chronic obstructive airway disease. Many of the aforementioned drugs are contraindicated or should be used with caution in patients with asthma or chronic obstructive pulmonary disease (COPD), although novel selective beta blockers may have a favorable risk-benefit ratio in terms of mortality in established COPD.

Aspirin sensitivity and intolerance to NSAIDs do not usually result from acquired sensitization but are intrinsic to the patient, who may exhibit the Widal or Samter triad of recalcitrant sinusitis or nasal polyps and intermittent watery nasal discharge, difficult-to-treat asthma, and intolerance to NSAIDs, including aspirin. Nasal symptoms and severe bronchospasm are precipitated by inadvertent exposure to an NSAID within minutes to a few hours after ingestion of the drug. Although avoidance of any NSAID, including aspirin, is recommended, desensitization using incremental dosages has been successful in patients who need to be treated with these drugs. Continued exposure is required for maintenance of the state of tolerance; otherwise, the drug hypersensitivity will return in a few days. Desensitization also can be undertaken in patients with antibiotic hypersensitivity.

Bronchospasm from beta blockers may be catastrophic and difficult to treat, because the state of beta blockade may blunt the response to β_2-agonists used to reverse the bronchospasm.

A hypersensitivity reaction with pruritus and bronchospasm can occur in patients receiving vinca alkaloids, taxanes, or the novel biologics rituximab, infliximab, etanercept, and cetuximab. The reaction can be quenched or ameliorated in most cases by reducing the perfusion rate and premedicating patients with antihistamines and corticosteroids.

In the recent past, inhaled or insufflated heroin was recognized as a cause for acute bronchospasm necessitating emergency intubation. It is nowadays good clinical practice to raise this possibility in the evaluation of adults presenting with acute asthma attacks, using the urine drug screen performed at the time of admission to identify presumptive cocaine and heroin users.

Solitary Cough

ACE inhibitors can cause a chronic annoying cough in up to 30% of patients taking one of these drugs. Incidence is higher in patients of Asian ancestry. The cough develops for no identifiable reasons and occurs in women more frequently than in men, usually after 1 to 2 months of treatment but occasionally later. All ACE inhibitors can induce chronic cough, although the incidence rate differs among different ACE inhibitors. The direct angiotensin receptor II antagonists appear to induce cough less often. Patients with preexisting asthma are not at increased risk, and no relation of ACE inhibitor cough with ACE inhibitor angioedema has been documented. Of importance, careful pulmonary evaluation is necessary, because the cough that develops during therapy with an ACE inhibitor may reveal lung cancer or other pleuropulmonary conditions.

The exact cause for ACE inhibitor cough is unclear, although the bradykinin catabolic pathway may be involved. Drug discontinuance results in improvement within a few days or weeks, but relapse will follow rechallenge with the drug, another ACE inhibitor, or, rarely, an angiotensin II antagonist. No treatment has proved effective in controlling the cough.

Anesthetic agents such as propofol, fentanyl, and isoflurane can induce violent coughing on induction in the perioperative setting.

Isolated cough can occur during chronic treatment with methotrexate without necessarily indicating impending methotrexate pneumonitis. BAL fluid shows a modest increase in lymphocytes. The cough may abate despite continuation of the drug.

Circumstantial evidence relates chronic cough to the administration of interferon, paroxetine, sirolimus, and topiramate. Generally, a drug holiday is indicated in any patient who complains of chronic, otherwise unexplained coughing during the drug exposure period.

Obliterative Bronchiolitis

The rapid development of obliterative bronchiolitis is a rare complication of therapy with gold or penicillamine in patients with rheumatoid arthritis. Evidence for this association is not strong, because bronchiolitis obliterans is a recognized complication of rheumatoid arthritis. Due to the advent of more efficacious drugs, these drugs have fallen out of favor.

The condition also has been reported in recipients of bone marrow or stem cell transplants, in whom it may represent a form of graft-versus-host reaction, and in recipients of lung transplants.

Patients with obliterative bronchiolitis experience increasing dyspnea and cough. Physical examination findings may be normal, or overinflation squeaks may be auscultated over the lung bases. The chest radiographs may show hyperinflation, and the expiratory HRCT scan may disclose a mosaic pattern, probably related to disseminated air trapping. Histopathologic examination reveals subacute or chronic bronchiolitis and/or *bronchiolitis fibrosa obliterans*.

PLEURAL PATTERNS

Iatrogenic pleural involvement can take the form of unilateral (without predilection for either side) or bilateral, subacute or chronic, free-flowing lymphocyte-rich or eosinophilic exudates (from dantrolene, ergots, or hydralazine or after coronary artery bypass graft surgery), serositis with pleuropericardial inflammatory effusion or constriction (from dantrolene, dasatinib, ergots, or drugs that induce the lupus syndrome), pleural bleeding (from oral anticoagulants, heparin, antiplatelets, or alteplase), pneumothorax (in patients receiving chemotherapy or mTOR inhibitors for the treatment of pulmonary metastases), chylous effusion (from dasatinib), pleural thickening (from ergots), or acute chest pain (from bleomycin or methotrexate or with drug-induced lupus) (Figure 17-6). Drug withdrawal generally is followed by resolution of the effusion. Clinically, pleural disease develops in isolation, concomitant with pericardial involvement or with systemic symptoms and a positive antinuclear antibody test result, which is suggestive of drug-induced lupus. Anti-TNF agents are notable for an increased propensity for causing anti–ds-DNA antibodies similar to that in naturally occurring lupus. Patients may be asymptomatic or present with dyspnea, restrictive lung function, chest pain, compression of the contralateral lung, respiratory distress, anemia, pericardial tamponade, or pericardial constriction. Patients with massive effusion, especially if bilateral or hemorrhagic, or with tension pneumothorax need expeditious therapeutic intervention.

A serous or, less often, serosanguineous pleural exudate may accompany the florid phase of amiodarone, methotrexate, and nitrofurantoin pneumonitis in up to 30%, 10%, and 16% of the cases, respectively. Pleural effusion can develop as a manifestation of fluid retention, capillary leak, and hyperpermeability during treatment with interleukin-2, GM-CSF, cytosine arabinoside, dasatinib, gemcitabine, ATRA, glitazones, gonadotropins, or imatinib. By contrast, pleural effusion is rare in drug-induced pulmonary edema.

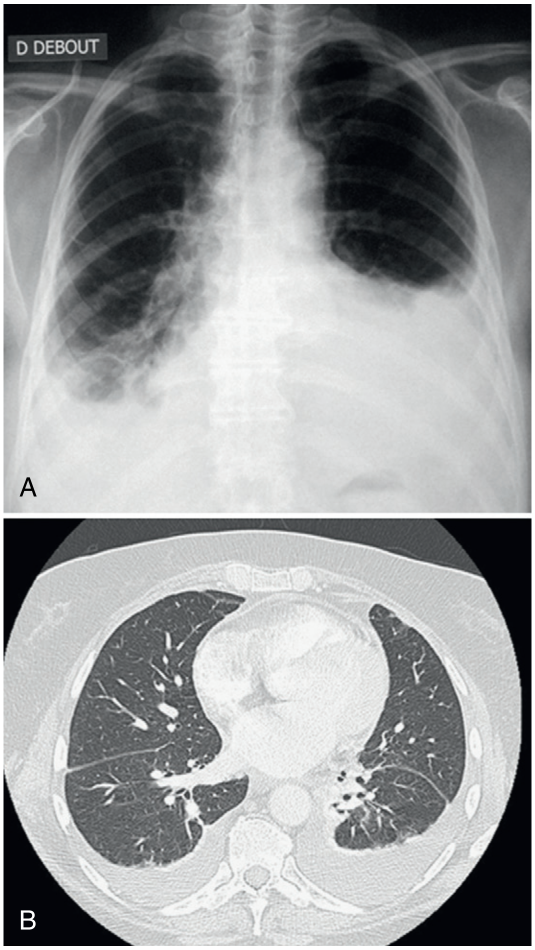

Figure 17-6 Eosinophilic or lymphocytic pleural effusion is visible on chest radiograph **(A)** and/or HRCT **(B)**. The free-flowing effusion is usually an exudate, or pleural thickening may develop during treatments with ergots, dantrolene, or dasatinib, and after chest radiation therapy. In a few cases, pleural effusion and chest pain are the expression of drug-induced lupus, which is diagnosed by the presence of circulating antinuclear and/or anti-DNA antibodies in a patient exposed to a compatible lupus inducer including anti-TNF agents. See under category V on the Pneumotox website (www.pneumotox.com).

The novel orally available multitargeted tyrosine kinase inhibitors imatinib and dasatinib can produce lymphocyte-rich pleural effusions in up to about a third of patients suffering with leukemia who take the drug, and effusions can be chylous in patients on dasatinib. Chylothorax is a rare iatrogenic complication of radiation therapy and coronary artery bypass graft surgery.

Chronic therapy with ergots (e.g., bromocriptine, cabergoline, ergotamine, methysergide, nicergoline) can be complicated by bilateral pleural effusion and thickening, resulting in so-called fibrothorax, manifesting with marked lung restriction and chronic respiratory insufficiency. Previous exposure to asbestos is an additional risk factor. Patients complain of dyspnea, pleuritic chest pain, or a dull sensation in the chest, or they may present with systemic symptoms and congestive heart failure. Muffled breath sounds and a friction rub synchronous with breathing are evident on auscultation, and the noise has been compared by nautically versed patients to that of a mooring rope on a gunwale. Ergot-induced pleural changes develop insidiously over months. Imaging reveals diffuse pleural thickening, areas of folded lung or rounded atelectasis, and loculated or free pleural fluid, but no pleural plaques. These changes are best seen on HRCT, which also may provide evidence of pericardial thickening or pericardial effusion. Restriction, hypoxemia, and sometimes hypercapnia are seen as measures of abnormal pulmonary physiology. ANA assay results are negative. Drug withdrawal is followed by slow and often incomplete resolution of the pleural changes, leaving residual pleural thickening and a restrictive lung function defect. Heart ultrasound examination is advised, because ergots may produce valvular heart disease.

PULMONARY VASCULOPATHY

Pulmonary vasculopathy is a well-documented adverse effect of various drugs. Also included in this category are DAD and the silicone embolism syndrome, described earlier.

A few drugs are associated with an increased specific risk for venous thromboembolism and pulmonary embolism. Important examples are thalidomide, intravenous immunoglobulins, GM-CSF, and antipsychotic agents.

Several amphetamine-like anorectic agents (aminorex, benfluorex, fenfluramine, dexfenfluramine) can produce pulmonary arterial hypertension, and this is one reason why these drugs were recalled in the past. These drugs also can induce valvular heart disease. Illicit amphetamines also may produce pulmonary hypertension in abusers.

Severe pulmonary hypertension, usually progressive, is a recognized complication of intravenous injection of crushed pharmaceutical tablets by drug abusers. Micronodular infiltrates can be present on imaging studies. Examination of lung tissue discloses foreign body reaction around pulmonary arterioles, with drug additives such as talc, cornstarch, microcrystalline cellulose, and crospovidone discernible within granulomas with use of polarized light and appropriate staining.

Lipiodol-laden acrylate used to treat brain arteriovenous fistulas may spill, with consequent access to the distal pulmonary circulation, causing chest pain and transient opacities on the chest radiograph. Similarly, methacrylate cement used in vertebroplasty procedures also may enter the pulmonary circulation, causing formation of micro- or massive pulmonary emboli of radiopaque cement, which may be evident on contrast unenhanced computed tomography (CT) scans.

Pulmonary venoocclusive disease is characterized by occlusion of pulmonary venules, causing interstitial opacities, subclinical hemorrhage, and pulmonary hypertension. The usual presenting manifestation is dyspnea of insidious onset. Chest radiographs may show Kerley B lines in the absence of left ventricular enlargement. Venoocclusive disease has been reported to occur in the aftermath of chemotherapy with cytotoxic agents or radiation therapy for malignant lymphoma or solid tumors, and after bone marrow, stem cell, or cord blood transplantation. Evidence for a causal relationship is not strong.

MEDIASTINAL PATTERNS

Long-term corticosteroid therapy can lead to mediastinal lipomatosis—a radiographic curiosity in most patients and a cause for cough or mediastinal hemorrhage in a few.

Patients with drug-induced granulomatosis resulting from administration of interferons, etanercept, or infliximab, or patients with the DRESS or anticonvulsant syndrome may present with mediastinal lymphadenopathy.

Oral anticoagulants may on occasion be associated with formation of a mediastinal hematoma, which may compress the trachea, causing respiratory distress.

Drugs and enteral nutrition may desiccate in the esophagus, leading to bezoar formation. Bezoars may protrude anteriorly, causing tracheal narrowing and respiratory discomfort. Esophagoscopy with fragmentation and lavage of the condensed material is indicated to rectify the problem.

METHEMOGLOBINEMIA

Oxidizing agents, dapsone, benzocaine, inhaled "poppers" (alkyl nitrites), nitrates, and nitric oxide may convert hemoglobin from its normal ferrous (Fe^{2+}) to the oxidized ferric (Fe^{3+}) state. Methemoglobin is a poor oxygen carrier, and its bluish chocolate-brown color confers a slate-gray, cyanotic appearance to the skin and also results in interference with pulse oximetry, unless the oximeter has a four-wavelength emitter. Newborns are at risk for this disorder owing to their immature reductase system. Patients with methemoglobinemia present with dyspnea, oxygen-resistant cyanosis, and a normal measured PaO_2. Pulse oximetry gives oxygen saturation values in the 60% to 80% range. Measured arterial blood oxygen content is subnormal. The diagnosis is confirmed by actual measurement of methemoglobin. Normal levels are less than 1% to 2%. Levels greater than 50% are life threatening and can be associated with neurologic symptoms and pulmonary edema, which can be life-threatening. Oxygen therapy is indicated. Methylene blue is the therapeutic agent of choice, should drug withdrawal not suffice to correct the problem.

CONTROVERSIES AND PITFALLS

In any patient with new, otherwise unexplained respiratory signs and symptoms, the possibility of a drug reaction (whatever the route of administration) must be sought. Early recognition, careful exclusion of an infection, and drug withdrawal are paramount and may be lifesaving.

Although a few drugs are associated with a distinctive pattern of reaction, most produce nonspecific changes. The clue to diagnosis is development of such changes in conjunction with exposure to the drug, with abatement on withdrawal of the agent. Exposure to abused drugs must be looked for carefully.

The diagnosis of drug-induced respiratory involvement is more often suspected or probable, rather than definite or proved. A lung biopsy may not resolve the issue, and a risk-versus-benefit analysis in terms of diagnosis input and/or exclusion of other causes often is not available. Rechallenge, although providing strong evidence for causality if followed by relapse, is hazardous. It is possible, however, to induce a state of tolerance in hypersensitive patients by rechallenging them with small incremental doses of such drugs as antibiotics or NSAIDs.

Drug-induced involvement may mimic the pulmonary and extrapulmonary features of idiopathic autoimmune conditions such as the lupus syndrome, ANCA-related vasculitis, Churg-Strauss syndrome, antiglomerular basement membrane antibody–related disease, and myositis. Antithyroid drugs, statins, and anti-TNF antibody therapy are under scrutiny at this time. It is important to test patients receiving such agents for autoantibodies, which may be found in high titers, and to relate drug discontinuance with abatement of signs and symptoms, imaging abnormalities, and autoantibodies.

Novel biologic agents when given to patients with systemic conditions capable of involving the lung may be temporally associated with lung injury that is difficult to separate from underlying disease-related pulmonary involvement. Also, anti-TNF blockers increase the likelihood of infection, and excluding an opportunistic infection is vital. Whether biologics cause acute progression or exacerbation of incipient pulmonary involvement from the underlying systemic condition is unclear as yet.

BAL is a powerful test for excluding infection. The finding of a lymphocyte- or eosinophil-rich BAL fluid supports but does not prove a drug etiology. Foamy macrophages point to the diagnosis of amiodarone-associated pulmonary toxicity. The merit of a lung biopsy versus a more conservative approach is not established in the management of this drug toxicity. Amiodarone pulmonary toxicity may be associated with some degree of interstitial cardiac pulmonary edema. The two conditions must be separated with use of measurements of NT-pro-BNP and diuresis.

Evaluation of respiratory physiology and a baseline chest radiograph (against which any further change can be compared) are indicated before initiation of treatment with amiodarone, DMARDs, or a chemotherapy regimen, particularly if bleomycin is to be given. Serial follow-up chest radiographs are indicated in patients exposed to amiodarone and in those receiving bleomycin. Serial respiratory physiology testing is indicated in patients on bleomycin, although a drop in carbon monoxide diffusing capacity does not equate to toxicity in all patients.

The following *risk reduction strategies* are recommended:

- Maintain cognizance of all aspects of drug-induced respiratory disease.
- Use recommended dosages of drugs.
- Adjust dosages if renal failure is present.
- Consult Pneumotox website if needed.
- Relate exposure to drug to onset and nature of signs and symptoms.
- Discontinue the suspected drug and substitute with another active agent.
- Use corticosteroids sparingly, and taper them slowly.

Preventive treatment with corticosteroids is rarely indicated.

Section 4
AN APPROACH TO RESPIRATORY SYMPTOMS

Chapter 18
Cough

Surinder S. Birring • Ian D. Pavord

COUGH IN HEALTH AND DISEASE

Cough is an important defense mechanism that clears the airways of secretions and prevents entry of foreign bodies and irritants to the lower respiratory tract. It is a universal experience in health but also a nonspecific presenting feature of most respiratory conditions and a number of nonrespiratory conditions. Acute cough is one of the most common presenting symptoms in the patient population encountered by the general practitioner. In most cases, cough results from viral and bacterial upper respiratory tract infection, is a self-limiting problem, and does not require further evaluation, but a small proportion of patients will have persistent cough that necessitates specialist opinion.

Chronic cough is arbitrarily defined as presence of cough for longer than 8 weeks. It affects 3% to 10% of the general population and is responsible for between 10% and 20% of respiratory outpatient referrals. Chronic cough with significant sputum production (i.e., more than a tablespoonful per day) is likely to be due to intrapulmonary disease such as chronic bronchitis or bronchiectasis. A chronic dry or minimally productive cough may be related to extrapulmonary factors; the cough is likely to be the result of abnormal sensitization of the cough reflex secondary to the effects of local inflammation on sensory nerve endings or an intrinsic abnormality of airway nerves. Most patients complain of an abnormal sensation in the laryngeal area such as a tickle in the throat (laryngeal paresthesia). Chronic cough often is perceived as a trivial annoyance but can be a disabling problem responsible for impairment of quality of life and associated with distressing symptoms such as musculoskeletal chest pains, syncope, incontinence, disturbed sleep, and social embarrassment.

The key to successful management is establishing a clear diagnosis and applying effective treatment for long enough to reset the activity of cough receptors at a more physiologic level. Important pitfalls include atypical presentations, the presence of multiple pathologic conditions, and inadequate therapy of the underlying disorder. Further difficulty arises from the fact that evidence for the efficacy of specific therapies in chronic cough is largely based on expert opinion or uncontrolled trials, as well as the paucity of randomized controlled trials with well-validated outcome measures to guide the clinician. Nevertheless, a systematic approach based on the so-called *anatomic diagnostic protocol*, which focuses on disease processes within the anatomic distribution of vagal afferent nerves, seems to be successful, and various studies have reported a high rate of treatment success even in tertiary referral populations. The general consensus is that in most cases of chronic cough in patients with no other respiratory symptoms or signs and normal findings on spirometry and chest radiography, the underlying cause is asthma, eosinophilic bronchitis, gastroesophageal reflux, or rhinitis, or a combination of these. Many of these conditions can be recognized clinically, and successful diagnosis and management often are possible without recourse to expensive or invasive investigations.

This chapter focuses primarily on isolated chronic cough, because it is a common condition not dealt with elsewhere in this book. In addition, an isolated chronic cough often is a difficult diagnostic problem for both primary and secondary care physicians. This category of cough is thought to involve a primary abnormality of the cough reflex leading to a heightened response to known tussive stimuli.

THE COUGH REFLEX

Cough is a reflex that occurs when afferent nerve receptors are stimulated by inhaled, aspirated, or endogenous substances. The most sensitive sites for initiating cough are the larynx, the carina, and the points of bronchial branching. Cough receptors also are present in extrapulmonary structures, including the esophagus, diaphragm, and stomach. A broad group of rapidly adapting "irritant" receptors (RARs) found in the larynx and tracheobronchial tree can be stimulated by a wide range of stimuli, including cigarette smoke, ammonia, ether vapor, acid and alkaline solutions, hypotonic and hypertonic saline, and mechanical stimulation by direct contact, mucus, or dust; all such stimuli can provoke cough. Another closely related fiber is the slowly adapting stretch receptor (SAR), which terminates inspiration and initiates expiration when the lungs are at an adequate level of inflation. SARs also may influence cough. C-fiber receptors, which have thin, nonmyelinated vagal afferent fibers, are found in the laryngeal, bronchial, and alveolar walls. They are relatively insensitive to mechanical stimulation and lung inflation but are exquisitely sensitive to chemicals such as bradykinin, capsaicin, prostaglandins, and acid pH. Stimuli that are known to cause cough in human subjects such as capsaicin, bradykinin, and citric acid activate C-fiber afferents, particularly those located in the bronchi. Afferent nerve fibers pass to a central cough receptor in the medulla, triggering a forced expiratory maneuver against a closed glottis, followed by glottal opening and high-velocity expiration (Figure 18-1).

DIFFERENTIAL DIAGNOSIS OF COUGH

The causes of cough can be conveniently divided into acute and chronic (Box 18-1 and Table 18-1). An *acute* cough is arbitrarily defined as a cough of less than 3 weeks' duration. Infectious and allergic conditions are by far the most common

Figure 18-1 Representative scheme of afferent and efferent pathways that regulate cough, and of the pathophysiology of the enhanced cough reflex. Laryngeal and pulmonary receptors, such as rapidly adapting receptors (RARs), C-fibers, and slowly adapting fibers (SARs), and putative cough receptors provide input to the brain stem medullary central cough generator through the intermediary of the relay neurons in the nucleus tractus solitarius (nTS). The central cough generator then decides and coordinates the efferent output to the muscles that causes the cough effort. Also present is an efferent output to airway smooth muscle and mucosal glands (*not shown*). The cerebral cortex may control the motor output of cough volitionally or influence the "urge-to-cough" sensation. Potential factors involved in the enhancement of the cough reflex both in the upper airways and at the brain stem level are illustrated. Inflammatory responses with expression of mediators, neuropeptides, and vanilloid receptors (e.g., TRPV1) may influence the cough response and brain stem modulation of the afferent pathways. *CGRP*, calcitonin gene–related peptide; *LTD_4*, leukotriene D_4; *PGE_2*, prostaglandin E_2; *TNF-α*, tumor necrosis factor-α; *TRPV1*, transient receptor potential cation channel subfamily V member 1 [i.e., vanilloid receptor 1 or capsaicin receptor].

etiologic disorders. Most acute coughs related to viral upper respiratory tract infection resolve by 3 weeks, but a small proportion become persistent and require further evaluation.

Most pulmonary conditions implicated in causing chronic cough, such as chronic obstructive pulmonary disease, lung cancer, an inhaled foreign body, pulmonary tuberculosis, sarcoidosis, idiopathic pulmonary fibrosis, and heart failure, will be obvious on clinical assessment, spirometry, and chest radiography. Assessment and management of these conditions are dealt with elsewhere in this book. Thus, a majority of patients referred for investigation of chronic cough are nonsmokers with normal findings on physical examination and chest radiography. Most present with a nonproductive or minimally productive cough, and 60% to 75% are female. A recognized tendency is for cough to manifest initially around the time of menopause. The most common conditions implicated in aggravating or causing chronic cough in these patients are listed in Table 18-1.

Table 18-1 Common Conditions Implicated in Causing Chronic Cough

CLINICAL ASSESSMENT

An initial assessment of a patient with chronic cough is directed at finding a specific cause, assessing severity, and initiating trials of treatment. A careful history and physical examination are paramount in the evaluation of a patient with chronic cough (Table 18-2). Details of the factors surrounding the onset of

Table 18-2 Initial Evaluation of the Patient with Chronic Cough

Evaluation Component	Assessment Factors
History	Cough: onset, duration, character, triggers, laryngeal paresthesia
	Sputum: volume, character
	Smoking, occupation
	Upper respiratory tract infection
	Drug history (ACE inhibitors)
	Asthma: breathlessness, wheeze, nocturnal symptoms, atopy
	Gastroesophageal reflux: reflux-associated symptoms
	Rhinitis: postnasal drip, sinusitis, throat clearing, nasal congestion
	Adverse quality of life: musculoskeletal chest pains, incontinence, syncope, social embarrassment, anxiety, disturbed sleep
	Snoring
Examination	Clubbing
	External nasal: polyps
	External ears: excessive wax
	Oropharyngeal: signs of postnasal drip, tonsillar enlargement
	Chest: signs of airflow obstruction, crackles
Investigations	Chest radiograph
	Spirometry ± bronchodilator reversibility
	Serial peak expiratory flow
	Complete blood count and eosinophil differential cell count
Optional investigations	Bronchoprovocation challenge test, induced sputum, allergen skin tests
	Exhaled nitric oxide test
	Sinus radiography/sinus CT study
	24-hour esophageal pH and manometry
	Chest CT/bronchoscopy in selected patients

cough and associated symptoms and a careful assessment of the upper airways and the respiratory system are particularly important. Basic initial investigations should include up-to-date chest radiography, spirometry, and tests of bronchodilator reversibility, if appropriate. An abrupt onset of coughing while eating or chewing should raise the possibility of an inhaled foreign body, and the onset of cough shortly after introduction of angiotensin-converting enzyme (ACE) inhibitor therapy suggests ACE inhibitor associated cough. The presence of significant quantities of sputum, hemoptysis, systemic symptoms, prominent breathlessness, wheeze, or abnormal physical signs increases the probability of intrinsic lung disease and should trigger appropriate investigations, which may include a CT scan of the chest and bronchoscopy even in the absence of suggestive findings with more simple investigations. The onset of cough with symptoms suggesting an upper or lower respiratory tract infection raises the possibility of a postinfectious cough; prominent whoops, a very troublesome nocturnal cough, and cough associated with vomiting all are associated with pertussis, a condition that is increasingly recognized in both school-age children and adults. Otherwise, little evidence is available to suggest that information on the timing, nature, complications, and potential aggravating factors is predictive of the underlying cause of the cough.

Findings on history and physical examination often are unremarkable, in which case the patient evaluation should focus on the recognition of corticosteroid-responsive conditions (i.e., asthma and eosinophilic bronchitis) and extrapulmonary factors that may be aggravating the cough, such as rhinitis and gastroesophageal reflux. One approach to the assessment of patients with chronic cough is outlined in Figure 18-2. The emphasis is on early recognition of corticosteroid-responsive cough, which can be detected easily in most cases with appropriate investigations or treatment trials. By contrast, the management of patients with nonasthmatic cough can be complex, time-consuming, and expensive, often with disappointing response to specific therapy. Far from clear, however, is whether extrapulmonary factors implicated in the pathogenesis of cough are aggravating a preexisting tendency or represent the underlying cause. Several factors point to the former, including the tendency for nonasthmatic chronic cough to affect middle-aged women and the frequent clinical observation that interventions against potential causes of chronic cough often help, but rarely cure the cough. It is best to have no preconceptions about the underlying causative factors in nonasthmatic cough and to view extrapulmonary factors such as rhinitis and gastroesophageal reflux as potential aggravating factors rather than as causes of the problem. This model has the advantage of providing a basis for the incomplete response to the treatment of these conditions seen in many patients; it also should stimulate research into the cause and treatment of the underlying heightened cough reflex sensitivity.

A further difficulty in evaluating patients with nonasthmatic chronic cough is the poor correlation between the presence of symptoms or abnormalities on investigation of the potential aggravating factor and the success of treatment directed against that factor. Thus, the diagnosis is secured largely by demonstrating clinical improvement as indicated by decrease in frequency or severity of cough after a suitable trial of treatment. Spontaneous improvement is common, and multiple potential aggravating factors typically are present; these factors add another layer of complexity to the clinical encounter. Results of treatment trials are more easily interpreted when combined with attempts to assess cough severity objectively before and after treatment. Suitable methods for such assessment include use of a simple cough visual analogue (with scores of 0 to 100 mm) (Figure 18-3), cough-specific health-related quality of life questionnaires, and evaluation of cough reflex sensitivity. A 15-mm change in visual analogue score, a 2-point change in Leicester Cough Questionnaire quality of life score, and a 2–doubling dose change in C2 (concentration of capsaicin that causes 2 coughs) can be regarded as evidence of a significant response to treatment. The remainder of this section focuses on the evaluation of the commoner conditions implicated in causing chronic cough.

COUGH VARIANT ASTHMA/EOSINOPHILIC BRONCHITIS

Asthma is a condition characterized by airway hyperresponsiveness and inflammation that manifests with variable symptoms of cough, dyspnea, and wheeze. A subgroup of patients can present with an isolated chronic cough known as *cough variant asthma*. Heightened cough reflex sensitivity is a common finding in cough variant asthma but not in non–cough-predominant asthma. The airway inflammation in cough variant asthma is essentially similar to that seen in classic

asthma. The cough typically is dry or minimally productive; it may occur nocturnally, or after exercise or allergen and occupational exposure, although clinical clues often are lacking. The key to diagnosing asthma is demonstrating variable airflow obstruction. Serial peak flow recordings and spirometry with bronchodilator response are routine first-line investigations, but findings often are normal in cough variant asthma. Demonstration of airway hyperresponsiveness by bronchoprovocation testing is a more sensitive and specific index of variable airflow obstruction, and the hyperresponsiveness may be the only abnormality found. Blood or sputum eosinophilia, a raised exhaled nitric oxide concentration, the presence of atopy, and a positive result on allergen skin prick testing or allergen-specific IgE assay provide supportive evidence for the presence of asthma.

The diagnosis of so-called cough variant asthma usually is confirmed by observation of clinical improvement with therapy. Although originally described as manifesting with a bronchodilator-responsive cough, cough variant asthma is much more commonly associated with a corticosteroid-responsive cough, and inhaled corticosteroids are the mainstay of treatment. A blood eosinophil count above 0.4×10^9/L, a sputum eosinophil count more than 3%, and an exhaled nitric oxide concentration above 50 parts per billion (ppb) at an exhalation flow of 50 L/minute are strongly associated with a positive response to corticosteroid therapy in patients with cough. These tests are arguably more fruitful and clinically informative than tests of airway dysfunction. A 2-week trial of oral corticosteroids may be a useful alternative if these tests are unavailable.

Eosinophilic bronchitis is an increasingly recognized entity that presents with a corticosteroid responsive cough and is characterized by sputum eosinophilia (Figure 18-4), heightened cough reflex sensitivity, but no evidence of variable airflow obstruction or airway hyperresponsiveness. Most patients also have a raised exhaled nitric oxide concentration, and blood eosinophilia often is present. Studies suggest that eosinophilic bronchitis is responsible for 10% to 15% of cases of chronic cough. The airway inflammation is similar to that seen in asthma although available evidence indicates that differences in the pattern of airway dysfunction are due to differences in the site of mast cell localization within the airway, with infiltration of the epithelium occurring in eosinophilic bronchitis and infiltration of the airway wall smooth muscle occurring in asthma. Recognition of eosinophilic bronchitis is important, because like cough variant asthma, it responds well to inhaled corticosteroids. This is best achieved by assessing airway inflammation using induced sputum or exhaled nitric oxide; if these techniques are not available, a trial of corticosteroid therapy is indicated irrespective of the presence of airway hyperresponsiveness.

ANGIOTENSIN-CONVERTING ENZYME INHIBITOR–ASSOCIATED COUGH

ACE inhibitors increase cough reflex sensitivity and cough frequency in patients and healthy research volunteers. Around 8% of patients develop a persistent troublesome cough. This is a class effect that is not obviously dose-related. The cough often is triggered by a viral upper respiratory tract infection or an obvious environmental insult, but it persists long after these stimuli are removed. Thus, there may not be a close temporal relationship between starting treatment and the onset of cough. ACE inhibitor–associated cough occurs more commonly in

females and in patients of South East Asian ancestry. Excess cough is not seen with use of ACE receptor antagonists. Increased airway concentrations of antitussive mediators such as bradykinins and prostaglandins are thought to be responsible for heightened cough reflex sensitivity and increased cough in patients with ACE inhibitor cough. The cough usually resolves within 2 months of withdrawal. Persistence may suggest asthma, the onset of which has been linked to the use of ACE inhibitors.

COUGH DUE TO UPPER AIRWAY DISEASE

Rhinitis, often associated with sinusitis and postnasal drip, is one of the most common conditions implicated as an aggravating factor in chronic cough. Allergy and infection are common causes of rhinitis and are thought to result in cough by mechanical stimulation from a postnasal drip and extension of local inflammation to the pharyngeal and laryngeal area where the cough receptors are most concentrated. Patients may report nasal congestion, nasal discharge, and facial pain; they may be aware of a postnasal drip and the frequent need to clear the throat. Careful examination of upper airways may reveal a nasal quality to the voice, nasal polyps, sinus tenderness, and inflammation of the posterior pharyngeal wall, with evidence of draining secretions. Investigations for rhinitis include nasal endoscopy and radiography or CT scan of the sinuses, which may reveal mucosal thickening and fluid levels.

A causal link between upper airway inflammation and cough has not been clearly established. No evidence has established that upper airway symptoms are more common in patients with chronic cough than in control subjects, or that specific findings on investigations are predictive of successful resolution of cough developing after treatment directed against rhinitis, nor is there good-quality evidence from double blind studies that interventions against rhinitis are associated with a reduction in cough frequency in a general cough population. Thus, rhinitis may represent an epiphenomenon not directly causally linked to cough.

Other upper airway conditions including viral upper respiratory tract infection, chronic tonsillar enlargement, disease of the external auditory canal, obstructive sleep apnea, and chronic snoring have been associated with chronic cough, supporting the concept that structural and inflammatory conditions of the upper airway disease can aggravate coughing. Therefore, it seems reasonable to suppose that structural abnormalities and chronic inflammation of the upper airway are potential albeit unproven aggravating factors for chronic cough, and to offer appropriate treatment in patients with suggestive symptoms or clinical findings.

GASTROESOPHAGEAL REFLUX–ASSOCIATED COUGH

Signs and symptoms suggesting gastroesophageal reflux and abnormalities of esophageal function are common in patients with chronic cough, and effective treatment of gastroesophageal reflux has been associated with decreased frequency and severity of cough, supporting a causal association. Potential mechanisms include microaspiration of esophageal contents to the tracheobronchial tree and stimulation of a neural esophageal-tracheobronchial reflex. Gastroesophageal reflux is associated with the relaxation of the lower esophageal sphincter and often occurs during eating and talking and on waking; also of note, many patients with chronic cough report increased cough during these activities. The presence of symptoms such as heartburn, dysphagia, sore throat, globus, and dysphonia may not be a good guide to the success of antireflux treatment, because some evidence suggests that cough can be the sole clinical manifestation of gastroesophageal reflux in up to 75% of patients.

Many of the aforementioned problems with cough due to rhinitis also apply for cough associated with gastroesophageal reflux. Good evidence indicates that reflux symptoms and abnormalities of esophageal function occur more commonly in patients with cough than control subjects, but this is also the case for other airway diseases such as asthma and chronic obstructive pulmonary disease (COPD), so it is difficult to make a case for a specific link between cough and gastroesophageal reflux. Moreover, it has not been possible to identify particular features on investigation that are predictive of the success of treatment directed against gastroesophageal reflux, and randomized trials of acid suppression therapy in gastroesophageal reflux associated cough have been disappointing. Potentially the link between reflux and cough is more dependent on the volume of reflux than on acid reflux, and therapeutic strategies that reduce reflux volume by addressing gastro-esophageal sphincter function may be more effective. Another possibility, however, is that the occurrence of excess gastroesophageal reflux in cough is a function of coughing itself, or else a manifestation of a global abnormality of upper aerodigestive reflexes, with no direct causal link between one and the other. The current state of knowledge is such that a reasonable approach is to offer a trial of treatment with acid suppression therapy with a proton pump inhibitor and an alginate for 2 to 3 months in patients with otherwise unexplained cough even when there are no suggestive upper gastrointestinal symptoms. More work is needed before more invasive treatments with a potentially greater effect on the volume of reflux, such as Nissen fundoplication, can be recommended in patients with suspected gastroesophageal reflux–associated cough if the sole motive is to relieve cough.

OTHER CAUSES OF COUGH

Community surveys suggest that most coughs related to upper respiratory tract infections resolve within 3 weeks. In such instances, however, the cough can take several months to resolve in a small proportion of subjects. The infection in most cases remains unidentified, but respiratory viruses, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, basidiomycetous fungi, and *Bordetella pertussis* have been implicated in adults. Chronic bronchitis is a common cause of cough in smokers and may occur in nonsmokers with dusty occupations or living in polluted environments. These patients typically have a productive morning cough. Other conditions reported to be associated with isolated chronic cough include Holmes-Adie syndrome, premature ventricular complexes, and familial peripheral neuropathy.

Diffuse panbronchiolitis is a well-recognized cause of corticosteroid-resistant adult-onset chronic productive cough in Japan and other parts of Southeast Asia. This is an important diagnosis to consider, because treatment with low-dose macrolide antibiotics is associated with a striking improvement that appears to be independent of the antimicrobial effects of these drugs. Patients with diffuse panbronchiolitis typically exhibit sinusitis and prominent small airway changes on imaging studies. Significant airflow obstruction and respiratory failure can occur. Whether less clinically overt cases occur in a general cough population is unclear, but this is certainly a possibility.

FURTHER INVESTIGATIONS

The use of fiberoptic bronchoscopy and high-resolution CT scanning should be reserved for evaluation of patients suspected of inhaling a foreign body; for those with suggestive symptoms, signs, or chest radiograph findings; and for patients with no objective evidence of more common causes of cough, because the investigations are invasive and expensive, with low diagnostic yield. Cough reflex sensitivity measurement has limited value in the validation of the presence of chronic cough in clinical practice because of the wide overlap of cough sensitivity between health and respiratory disease causing cough. Ambulatory cough monitors have the advantage of providing objective evidence of the presence and frequency of cough, but their routine use is hampered by automation difficulty of analysis of the recordings. Recent advances in recording devices and improved battery life have led to a renewed interest in cough monitor development, and they should be available for clinical use in the near future.

TREATMENT

Treatment directed at the specific cause of chronic cough is summarized in Table 18-3. With use of the anatomic diagnostic protocol, success rates of up to 95% in the management of chronic cough have been reported. The success rate goes down to 60% to 80% in specialist cough clinics, possibly owing to the

Table 18-3 Specific Therapy for Chronic Cough

Cause	Treatment
Rhinitis	Nasal corticosteroids Selected patients: topical ipratropium, topical decongestants, oral antihistamines, surgery
Asthma	Inhaled corticosteroids Leukotriene antagonists
Eosinophilic bronchitis	Inhaled corticosteroids, oral corticosteroids in selected cases
GER-associated cough	Self-help measures: weight loss, smoking cessation, reduce alcohol intake, elevate head of bed, avoid eating within 2 hours of bedtime Acid suppression: proton pump inhibitors Prokinetic agents: metoclopramide or domperidone in selected patients Surgery: laparoscopic fundoplication in selected patients
Chronic bronchitis	Smoking cessation
ACE cough	Drug withdrawal; substitution of alternative if appropriate
Post–viral infection cough	Observation
Bronchiectasis	Chest physiotherapy and postural drainage, antibiotics
Idiopathic chronic cough	Antitussives (dextromethorphan, codeine); nebulized lidocaine; speech and language therapy or physiotherapy

ACE, angiotensin-converting enzyme; *GER*, gastroesophageal reflux.

complexity of cases referred. Reassessment of the patient after treatment with exclusion of additional aggravating factors or causes forms an integral part of management for chronic cough. A common dilemma faced by physicians managing these patients is that the diagnosis of cough often depends on successful trials of treatment, which if unsuccessful leads to the difficult question of whether the underlying condition has not responded or is not responsible for the cough. In some situations, the use of objective tests to make a diagnosis and careful validation of the effect of therapy for the underlying condition should minimize this problem. Therapeutic interventions for common causes of chronic cough are discussed next.

COUGH VARIANT ASTHMA/EOSINOPHILIC BRONCHITIS

Cough due to asthma responds well to inhaled corticosteroids. A response typically occurs within 1 to 2 weeks of starting therapy and reaches a maximum after 8 to 10 weeks. Leukotriene antagonists also are helpful in cough variant asthma. The duration of asthma therapy remains unclear, but return of the cough on gradual withdrawal of therapy suggests the need for long-term therapy. Patients with cough variant asthma often have coexisting rhinitis or postnasal drip, and a complete response may not be seen until all potential aggravating factors are treated. Treatment of cough due to eosinophilic bronchitis is with inhaled corticosteroids. Rarely, oral corticosteroids are required to suppress eosinophilic airway inflammation and cough.

RHINITIS

Topical corticosteroids are the mainstay of treatment for cough due to rhinitis. Antihistamines, particularly first-generation agents, are frequently used. When nasal obstruction is prominent, initial additional treatment with topical decongestant sprays may be necessary, and antibiotics should be administered if infection is suspected. Topical ipratropium bromide often is helpful if rhinorrhea is prominent, and antihistamines are useful when sneeze and nasal itch are prominent and in cases with coexisting atopy. Surgical treatment may be necessary to correct obvious anatomic abnormalities.

GASTROESOPHAGEAL REFLUX–ASSOCIATED COUGH

Gastroesophageal reflux–associated cough is managed with self-help measures such as weight reduction, avoidance of tight clothing, elevation of headrest during sleep, reduced alcohol and tobacco intake, and drug therapy for acid suppression. Use of proton pump inhibitors is the most effective treatment for heartburn associated with gastroesophageal reflux, but the effect of these agents in cough thought to be associated with reflux has been mixed. Anecdotal evidence suggests that high-dose therapy for at least 3 months often is required before clinical improvement is seen. In patients who appear to respond to proton pump inhibitors, confirmation of a link between cough and gastroesophageal reflux may be sought by withdrawal and rechallenge. Prokinetic agents such as metoclopramide and domperidone may have a role in some cases. The role of antireflux surgery is unclear.

ANTITUSSIVE THERAPIES

Treatments directed against potential aggravating factors often do not achieve perfect results, and antitussive therapies that target the heightened cough reflex directly are needed as well. Codeine and the non-narcotic antitussive dextromethorphan have been demonstrated to have some effect on cough associated with upper respiratory tract infections, although the effect on cough frequency is small and of uncertain clinical relevance. The use of morphine and diamorphine has been restricted to patients with the severe cough of malignant disease, which often is associated with pain and distress. Lidocaine delivered by aerosol or nebulizer has been used to treat chronic cough, although good evidence of the efficacy and safety of this approach is lacking.

A recent study has shown clinical improvement in patients with chronic cough in a randomized placebo-controlled trial of a speech therapy intervention; similar benefits have been shown with an outpatient physiotherapy approach. The key components of these interventions are unclear, but an important component of the latter approach is training in voluntary cough suppression, suggesting that excess coughing may be partly due to the continuation of a vicious circle whereby coughing leads to airway trauma and activation of the cough reflex.

There are no other well-established antitussive agents, and the value of much of the existing work evaluating the pharmacologic manipulation of the cough reflex is limited, because it has been carried out in animal models that are poorly predictive of effects in humans. Moreover, those agents that have been investigated in humans have been tested against models of questionable relevance for the at-need population. Early evidence points to a role for drugs that modulate nerves, such as amitriptyline and gabapentin, but further investigation is necessary. More relevant basic science is needed, and there is an urgent need for better treatments and clinical trials.

Box 18-2 Common Pitfalls in the Management of Chronic Cough

- Incorrect diagnosis
- Failure to recognize multiple causes of cough
- Lack of objective evidence for the diagnosis of asthma
- Prolonged and aggressive treatment may be required before cough improves.
- Poor treatment compliance
- Post-viral infection and gastroesophageal reflux-associated cough may take many months to resolve.
- Inappropriate labeling of psychogenic cough
- Failure to assess the impact of cough on quality of life

UNEXPLAINED CHRONIC COUGH

Cough remains unexplained after extensive investigations and treatment trials in up to 40% of patients. These patients are predominantly middle-aged females with objective evidence of airway abnormalities, including increased cough reflex sensitivity and airway inflammation. Organ-specific autoimmune diseases are common, suggesting that the airway abnormalities may have an autoimmune basis.

Unexplained cough is responsible for considerable physical and psychological morbidity. Many patients with unexplained chronic cough are labeled with a diagnosis of psychogenic cough, although little evidence is available to support this view, and it is perhaps more likely that any abnormal illness behavior is secondary to the adverse impact of cough on psychosocial aspects of quality of life. In evaluating a patient with unexplained cough, it is important to recognize common pitfalls in managing chronic cough (Box 18-2). Therapy for idiopathic chronic cough is disappointing, and there is therefore a large unmet need for better antitussive treatment in these patients. Referral to a respiratory physiotherapist or speech therapist for cough management coaching may be of some help.

CONCLUSION

All pulmonary and many nonpulmonary conditions can manifest with cough. Most will be evident after a simple clinical assessment that includes a careful history, physical examination, plain chest radiography, and spirometry. Cough that remains unexplained after such an assessment is a common reason for referral to a specialist. Potential causes include asthma, eosinophilic bronchitis, rhinitis, and gastroesophageal reflux. Satisfactory outcomes can be achieved in a majority of patients with a management strategy that includes targeted investigations and carefully controlled treatment trials. Complete cure is not always possible, however, particularly in patients with cough thought to be due to extrapulmonary factors, and a significant minority of predominantly middle-aged women have unexplained chronic cough. Whether this reflects failure to identify important causes or represents inadequate treatment of established factors is unclear.

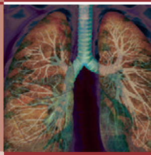
Section 4

AN APPROACH TO RESPIRATORY SYMPTOMS



Chapter 19

Dyspnea

Alex H. Gifford • Donald A. Mahler

WHAT IS DYSPNEA?

In healthy people, breathing is an unconscious activity that is regulated by automatic command by groups of neurons in the brain stem to control cyclic contraction and relaxation of the respiratory muscles. With a perturbation of this process, the affected person may experience breathing difficulty or discomfort. This sensation is considered a symptom and typically is referred to as *dyspnea*, which literally means "disordered breathing" (*dys-* + *-pnea*). In 1999, the American Thoracic Society defined dyspnea as "a subjective experience of breathing discomfort that consists of qualitatively distinct sensations that vary in intensity." Patients typically cite such discomfort when describing their symptoms: "I am short of breath." "I can't get enough air." "It's hard to breathe."

A majority of studies investigating dyspnea have focused on patients with chronic obstructive pulmonary disease (COPD), for two reasons: (1) COPD is the most prevalent respiratory disease, and (2) exertional breathlessness is the major symptom of this condition. Thus, the accumulated knowledge of clinical features of dyspnea and current understanding of the relevant mechanisms and qualities derive in large part from studies involving patients with COPD.

An interesting point is that dyspnea shares many features with pain. Both symptoms are complex neurophysiologic processes that are influenced by physiologic, psychologic, social, and environmental factors. These sensations function as warning signals of potential harm that usually lead the affected individual to reduce activities in order to minimize the complaint and/or to seek medical attention. Like pain, dyspnea can be perceived only by the affected person and has both sensory (how bad is it?) and affective (how does it feel?) components. Because both dyspnea and pain are under behavioral control, any emotional state may worsen these experiences to a degree that may be out of proportion to the magnitude of physiologic impairment. For example, high levels of anxiety and panic attacks are associated with increased breathlessness and more intense pain.

Dyspnea is an important problem in the elderly population, often with a major impact on quality of life. It is estimated that more than 30% of those 65 years of age or older without known cardiorespiratory disease report breathlessness with various activities of daily living, including walking on a level surface or up an incline. An analysis of 124 patients over 70 years of age who were randomly selected from a large family medicine practice revealed that up to 37% had moderate to severe dyspnea, and that dyspnea was associated with poor perceived health, more anxiety and depression, and impaired daily functioning. With any physical activity, including exercise, older people exhibit higher levels of ventilation than those typical for younger persons performing the same amount of physical work. Not clear, however, is whether this increased ventilatory demand in older people is a direct result of the aging process in the respiratory system (secondary to a decrease in lung elasticity, increase in chest wall stiffness, and decrease in respiratory muscle strength) or a consequence of sedentary life style, deconditioning, and possible weight gain, which frequently occur with advancing age in populations of developed countries.

Gender differences in the prevalence and severity of dyspnea among patients with COPD have been documented. For example, women are more likely to report severe dyspnea compared with men despite significantly fewer pack-years of smoking cigarettes and similar frequencies of coughing. In the National Emphysema Treatment Trial involving 1053 patients with severe COPD (emphysema phenotype), women reported greater dyspnea than that described by men when findings were controlled for lung function, age, pack-years of smoking, and proportion of the lung affected by emphysema. Whether this gender difference in dyspnea relates to physiologic differences (compared with men, women have smaller airway lumina, with disproportionately thicker airway walls) is uncertain.

MECHANISMS OF DYSPNEA

The neurophysiologic pathways that mediate the control of breathing (to supply oxygen, to eliminate carbon dioxide, and to maintain acid-base balance) also are relevant to the mechanisms of dyspnea (Figure 19-1). In simple terms, nerve fibers (sensory receptors) send electrical signals (afferent impulses) to the spinal cord, which in turn transmits these signals to the brain.

The brain interprets these signals as a sensation (dyspnea). Outgoing commands from the brain may then elicit an appropriate response—the affected person may stop the offending activity, for example, or may use a rescue inhaler in an attempt to relieve the breathing difficulty.

Presented next is an overview of the neurophysiology of dyspnea, with details of the important components of the relevant pathways.

SENSORY RECEPTORS

Activation of sensory receptors provides afferent information to several brain areas that are perceived as respiratory sensations. Blood gas abnormalities (hypoxemia and hypercapnia), mechanical respiratory loads (increased airway resistance and elastance), disturbances in airway epithelium (e.g., edema,

inflammation), and hyperinflation are stimuli that activate sensory receptors. For example, neurons in the carotid bodies (peripheral chemoreceptors) are more sensitive to arterial hypoxemia than are neurons in the aortic bodies, although both contribute to hypoxemic ventilatory responsiveness. Central chemoreceptors located in the ventral medulla respond to changes in bloodstream H^+-CO_2 equilibrium.

Mechanoreceptors are distributed throughout the lung and the chest wall. Parenchymal stretch receptors transmit information about airway caliber and lung volume to the somatosensory cortex through unmyelinated vagal nerve fibers. C-fibers relay information about airway irritation, which can be demonstrated using various chemical mediators. J-fibers are stimulated by interstitial pressure increases, especially pulmonary edema. The chest wall muscles are innervated by Golgi tendon organs and spindle fibers that project to anterior horn cells of spinal neurons. These structures transduce information on length-tension and spatial relationships to the somatosensory cortex.

AFFERENT IMPULSES

Afferent information from sensory receptors are transmitted to brain stem respiratory centers that automatically adjust breathing and also may project to higher brain areas for direct assessment of the status of various stimuli. Well-characterized examples include the following: The glossopharyngeal nerve transmits impulses for peripheral chemoreceptors; the vagus nerve transmits information for rapidly adapting, slowly adapting, and C-fiber lung mechanoreceptors; and cervical spinal nerves 3 to 5 (C3 to C5) transmit sensory information accrued by mechanoreceptors from the diaphragm.

Two different pathways have been proposed to process respiratory sensations to the cerebral cortex. One pathway reflects *discriminative processing*—that is, awareness of the spatial, temporal, and intensity components (e.g., how bad is it?). With activation of respiratory muscle receptors, afferent information is relayed into the brain stem medulla and is then projected to the ventroposterior thalamus area; from here, projections ascend to the primary and secondary somatosensory cortex. These structures are thought to process the intensity component of dyspnea.

A second pathway reflects *affective processing* (e.g., how does it feel?). With activation of airway and lung receptors, afferent information is relayed by the vagal nerve to the brain stem medulla and is then projected to the amygdala and medial dorsal areas of the thalamus; from here, projections ascend to the insular and cingulate cortex. These structures are part of the limbic system, which forms the inner border of the cortex and contains rich interconnections among the cerebral cortex, thalamus, and brain stem, and are thought to process the affective component of dyspnea.

CENTRAL NERVOUS SYSTEM

The central nervous system integrates and processes the sensory information into a combined output carried by the phrenic nerve to the respiratory muscles. Neuroimaging studies demonstrate that the anterior cingulate cortex, amygdala, and thalamus are consistently activated in response to various respiratory perturbations. Activation of cortical neural processes appears to require a gating mechanism that can receive changes in respiratory afferent neural activity and distribute this sensory information to specific cortical areas for cognitive processing. It is believed that the thalamus and hippocampus are critical neural areas for the gating of respiratory sensory input to the cerebral cortex.

The experience of dyspnea is thought to result from a mismatch between incoming afferent information (from one or more activated sensory receptors) and the outgoing central respiratory motor activity.

NEUROMODULATION BY ENDOGENOUS OPIOIDS

Endogenous opioids and their receptors are expressed broadly throughout the peripheral and central nervous systems, as well as the respiratory system. Beta-endorphins are one of five groups of naturally occurring opioid peptides that modulate pain and dyspnea. In response to noxious and stressful stimuli, the pituitary gland releases beta-endorphins into the circulation, whereas the brain elaborates endogenous opioids into the cerebrospinal fluid.

Naloxone, an opioid antagonist that readily crosses the blood-brain barrier, has been used to uncover the putative effects of endogenous opioids on modulating dyspnea. Studies using methacholine-induced bronchoconstriction, high-intensity treadmill exercise, and inspiratory resistive breathing (as stimuli to provoke breathlessness) have shown that patients with asthma or COPD report higher ratings of dyspnea after receiving naloxone than after receiving normal saline. These observations support the role of endogenous opioids as neuromodulators of the perception of dyspnea.

THE LANGUAGE OF DYSPNEA

To help dyspneic patients describe their experience more accurately, questionnaires have been developed that allow for the selection of specific descriptors of breathlessness. It appears that the descriptors selected by patients relate in part to the underlying mechanisms contributing to dyspnea. For example, *chest tightness* is relatively specific to bronchoconstriction in patients with asthma but is not typically reported by patients

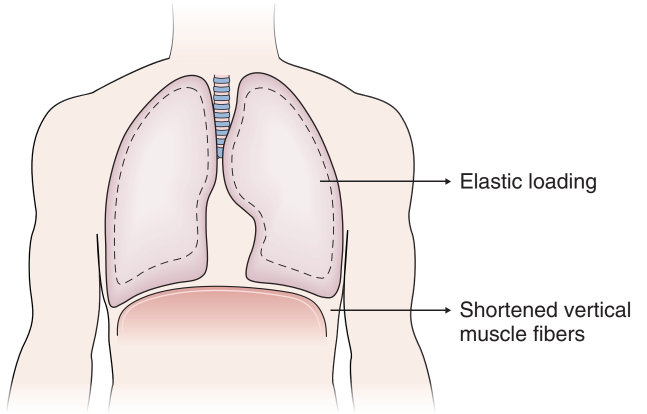

Figure 19-2 Mechanical consequences of dynamic hyperinflation.

with COPD. This perception of tightness presumably is due to activation of sensory receptors located in large airways and can be relieved with use of bronchodilator therapy.

The sense of respiratory *work* or *effort* commonly is reported by patients with various conditions including asthma, COPD, interstitial lung disease, and neuromuscular disease. The descriptor "work/effort" of breathing difficulty probably is related to activation of respiratory muscle afferents imposed by mechanical loads (airway narrowing → added resistance; parenchymal edema/infiltrates → added elastance) imposed by certain diseases as well as respiratory muscle weakness. For example, in patients with COPD, the lungs typically hyperinflate during the performance of physical tasks. This dynamic hyperinflation results in two major consequences that contribute to dyspnea: (1) an added elastic load and (2) functional weakening of the diaphragm by shortening of the vertical muscle fibers (Figure 19-2). Although patients with acute asthma initially may experience chest tightness, they typically report that the increased work or effort of breathing develops as airway narrowing progresses as a result of subsequent lung hyperinflation.

A perception of not being able to take in enough air has been described as *air hunger*, or "unsatisfied inspiration." This experience is not specific to any particular disease or stimulus. A consistent finding is that patients with various cardiorespiratory conditions generally report greater breathing difficulty during inspiration than with expiration. A clustering of reported sensations such as smothering, suffocating, and air hunger has been documented in patients with panic disorder and idiopathic hyperventilation syndrome who do not have any cardiopulmonary or neuromuscular disease. These findings are consistent with an increase in ventilatory drive.

The three qualities of dyspneic sensations, as described, do not explain all clinical features of breathlessness. Moreover, multiple pathways may combine to contribute to dyspnea in an individual patient. For example, in a patient with cardiogenic pulmonary edema, bilateral pleural effusions, cardiac cachexia, and arterial hypoxemia, dyspnea may be due to activation of carotid body neurons (hypoxemia), stretch receptors (interstitial edema), and Golgi tendon organs and spindle fibers (muscle weakness).

ACUTE DYSPNEA

INITIAL EVALUATION

The rapidity with which dyspnea develops is clinically important. Although a standard definition of acute dyspnea does not exist, potentially life-threatening cardiopulmonary processes often are heralded by unprecedented, severe dyspnea minutes to hours in duration. Whenever possible, details should be sought about the circumstances under which dyspnea began, whether it is associated with other symptoms, and how it has progressed. Knowledge of medications and comorbid conditions also is helpful. Dyspnea in the prehospital environment independently predicts a nearly seven-fold likelihood of hospital admission from the emergency department. Studies have shown that delays in seeking clinical attention for acute exacerbations of asthma, COPD, and congestive heart failure (CHF) are associated with a higher frequency of hospital admissions and worse outcomes.

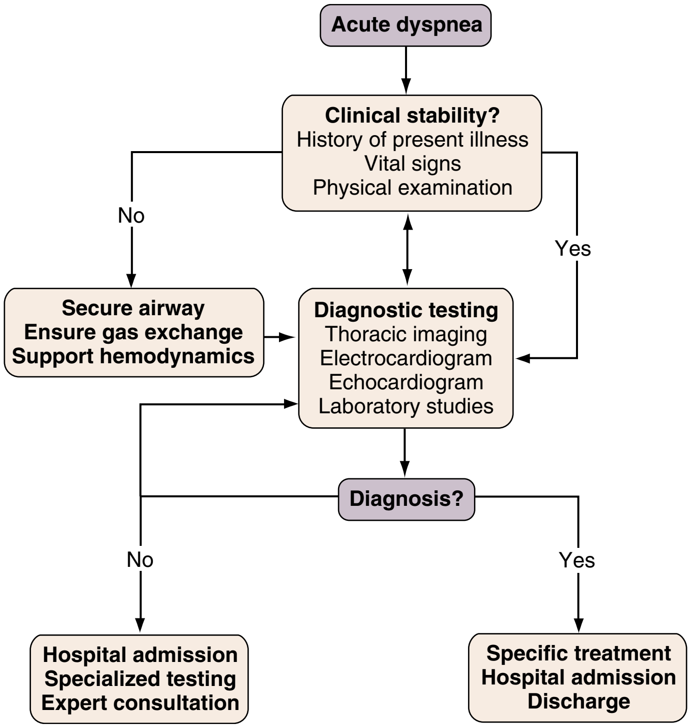

Figure 19-3 Initial evaluation of acute dyspnea.

With any clinical encounter, the focus of the initial assessment is on whether or not the patient is stable (Figure 19-3). If this evaluation reveals evidence of hemodynamic insult or lability, hypotension may need to be treated promptly with intravenous fluids, vasopressors, and/or vasodilators. Airway patency and adequacy may be threatened by a depressed level of consciousness, aspiration, or trauma. Endotracheal intubation may become necessary in such instances and when gas exchange derangements cannot be rectified by supplemental oxygen or noninvasive positive-pressure ventilation. Once these basic support elements are addressed, diagnostic testing can safely proceed.

DIFFERENTIAL DIAGNOSIS

One approach to the differential diagnosis for acute dyspnea is to consider how processes in certain anatomic regions contribute to this symptom (Table 19-1). Obstruction is the most common mechanism for dyspnea arising from upper airway problems. Stridor, a variably high-pitched, harsh inspiratory noise caused by turbulent airflow, often can be heard in the context of an aspirated foreign body and edema of the epiglottis and laryngeal soft tissues. Prompt evaluation and management of upper airway blockage are critical, because the airway is

Table 19-1 Differential Diagnosis of Acute Dyspnea

Anatomic Region/ Structure	Relevant Pathologic Process(es)	Related Signs/Symptoms	Physical Findings
Upper airway	Obstruction	Impaired phonation Cough Wheeze	Commonly child or infant Cyanosis Altered mental status Stridor
	Anaphylaxis/angioedema	Pruritus Flushing Throat/chest tightness Cough Nausea	Facial swelling Urticaria Stridor Hypotension Wheeze on auscultation
	Epiglottitis (E) Peritonsillar abscess (PTA) Retropharyngeal abscess (RPA)	Sore throat (E/PTA/RPA) Fever (E/PTA/RPA) Altered voice (E/PTA/RPA) Cervicalgia (RPA) Dysphagia (E/PTA/RPA)	Stridor (E) Drooling (E) Tripod posture (E) Fever (E/PTA/RPA) Uvula deviation (PTA) Trismus (PTA/RPA)
Lungs	Asthma exacerbation	Chest tightness Cough Wheeze	Wheeze on auscultation Prolonged expiratory phase Accessory muscle use
	COPD exacerbation	Increased cough frequency Wheeze Change in sputum production	Wheeze on auscultation Pursed-lip breathing Barrel chest Cyanosis
	Pulmonary embolism	Lateral chest pain Presyncope/syncope Palpitations Hemoptysis	Hypoxemia Hypotension Asymmetric extremity size
	Pneumonia	Cough ± sputum production Fever ± chills Pleurisy Hemoptysis	Altered mental status Rales on auscultation Sepsis
	Pneumothorax	Chest pain (anterior/superior) Anxiety	Tachypnea Hypotension Distant breath sounds
Heart	Congestive heart failure	Paroxysmal nocturnal dyspnea Orthopnea Weight gain Wheeze	Jugular venous distention Crackles on auscultation S3 gallop Lower extremity edema
	Acute coronary syndrome	Chest pain ± arm radiation Diaphoresis Nausea ± emesis	Hemodynamic instability S4 gallop Hypoxemia
Muscles	Acute idiopathic demyelinating polyneuropathy	Acral paresthesias Progressive global weakness Dysphagia	Autonomic dysregulation Symmetric weakness Areflexia
Other	Hyperventilation syndrome	Chest discomfort Complaint of "can't get enough air in"	Frequently normal findings on examination

endangered. Exacerbations of asthma and COPD typically are manifested as bronchospasm, wheeze, and cough. Sputum production is common to exacerbations of COPD associated with acute bronchitis and pneumonia, but its physical characteristics alone are not useful in predicting a causative pathogen. Pleuritic chest pain is sharp, incisive, breath-taking discomfort caused by irritation of the parietal pleural nerve supply along the thoracic cavity. This type of pain can accompany pulmonary embolism, pneumonia with or without pleural effusion, and pneumothorax.

In an acute coronary syndrome (ACS) or CHF, dyspnea is caused by pulmonary venous hypertension and interstitial fluid accumulation. Sudden dyspnea without chest discomfort is the presenting feature of myocardial infarction in 4% to 14% of events. Papillary muscle rupture with mitral valve incompetence, florid pulmonary edema, and shock complicates myocardial infarction in approximately 7% of affected patients. Neuromuscular diseases more commonly cause chronic, progressive dyspnea, but ventilatory failure can develop over just a few hours in acute idiopathic demyelinating polyneuropathy

(AIDP). Dyspnea is a frequent consequence of severe abdominal distention, such as that seen with bowel obstruction. The increased pressure of the abdominal cavity restricts diaphragm excursion, thereby decreasing functional residual capacity. Abdominal pain restricts ventilation as a consequence of muscle splinting, which also can cause atelectasis.

PHYSICAL EXAMINATION

Inspection of the patient in respiratory distress may be quite revealing. Stigmata of adrenergic excess commonly are present, including hypervigilance, diaphoresis, and tachycardia. The breathing pattern frequently is rapid and shallow, which foreshortens responses to clinical questioning. An exception is the deep and sometimes bradypneic pattern of Kussmaul respirations seen with severe metabolic acidosis, typical of diabetic ketoacidosis. Engagement of accessory inspiratory muscles (e.g., scalenes, intercostals, and sternocleidomastoids) often signals respiratory failure. This finding alone is associated with a nearly three-fold risk of death and a roughly doubled requirement for posthospital care in patients admitted through the emergency department for COPD exacerbation. Among adult asthmatics who were noted to use accessory breathing muscles at the time of hospitalization, percent-predicted FEV_1 values were lower than in patients who were not activating these muscles. Pursed-lip breathing (exhaling against partially occluded lips) can be seen in persons with airflow obstruction. In patients with moderate to severe COPD, pursed-lip breathing facilitates the recruitment of accessory muscles, decreases the electromyographic propensity for diaphragm fatigue, and improves tidal volume and arterial oxyhemoglobin saturation. Dyspnea observed in the context of altered mental status and cyanosis is worrisome, because taken together, these findings attest to profound gas exchange problems.

BIOMARKERS

Brain Natriuretic Peptides

Peripheral blood concentrations of brain-type natriuretic peptides (BNPs) commonly are used in emergency medicine to distinguish CHF from other causes of acute dyspnea. BNP is one of the natriuretic peptides released from cardiac myocytes with ventricular stretching and pressure overload. A prospective, multicenter study published in 2002 called the Breathing Not Properly trial evaluated the test characteristics and diagnostic accuracy of BNP for CHF in 1586 patients who presented for urgent evaluation of acute dyspnea. The clinical diagnosis of CHF was adjudicated by two cardiologists who were blinded to BNP results. At a cutoff value of 100 pg/mL, the diagnostic accuracy for CHF was 83%. Patients with BNP levels of 100 pg/mL or higher were nearly 30 times more likely than those with lower values to have CHF. Other clinical correlates of CHF, such as cephalization of pulmonary vessels on chest radiograph (odds ratio, 10.7), crackles on chest auscultation (odds ratio, 2.2), and jugular venous distention (odds ratio, 1.8), also were helpful.

A related natriuretic peptide called amino-terminal pro-BNP (NT-proBNP) also has been shown in the emergency department setting to strongly suggest CHF as the correct diagnosis for acute dyspnea. Nonetheless, elevated natriuretic peptide measurements do not independently secure a CHF diagnosis. Atrial arrhythmias, cardiomyopathies, regurgitant valvular disease, pulmonary arterial hypertension, obstructive sleep apnea, pulmonary embolism, and even sepsis can cause abnormal results on BNP assays. An echocardiogram can be beneficial when BNP levels return to within an indeterminate range.

Troponin Isoforms

Dyspnea is a common feature of ACS, affecting roughly 35% to 55% of patients. Although chest discomfort and diaphoresis are encountered more frequently, dyspnea alone can herald myocardial infarction, particularly in women. Troponin isoforms are cardiac myocyte proteins that leak into the circulation due to ischemic damage. Modern troponin assays are exquisitely sensitive such that positive results are obtained in many conditions other than ACS and MI. Patients are likely to experience dyspnea in a number of these conditions: aortic dissection, acute respiratory distress syndrome, pulmonary embolism, sepsis, and blunt chest trauma. Troponin elevation in the setting of nonmassive, symptomatic pulmonary embolism is associated with a four-fold increase in short-term mortality (i.e., risk of death in the immediate post–embolic event period). Unlike BNP and NT-proBNP, troponin isoforms are not sufficiently specific to distinguish cardiac from noncardiac causes of acute dyspnea in the emergency department setting.

D-Dimer

In the three largest investigations of diagnostic imaging modalities for acute pulmonary embolism, dyspnea as an isolated symptom was reported by only 22% to 46% of patients. Because dyspnea is not a completely reliable indicator of pulmonary embolism, which carries a mortality rate of about 30% without treatment, the aim of any workup is to confidently exclude this diagnosis. To this end, the D-dimer assay has found a place in the evaluation of acute dyspnea. D-dimer is a fibrin degradation product detectable in venous blood as a result of clot breakdown. Of utmost importance in clinical decision-making, the use of D-dimer results requires understanding that pretest probability and test characteristics of a given assay strongly influence diagnostic accuracy.

Prediction scores can help the clinician settle on a pretest probability of venous thromboembolism. The incidence of venous thromboembolism at 3 months is 1% or less when the clinical pretest suspicion is low and the D-dimer test result is normal (and anticoagulation therapy is withheld). When venous thromboembolism is more strongly suspected or D-dimer assay results are positive, more definitive testing using computed tomography (CT) pulmonary angiography should be considered.

THORACIC IMAGING

Chest Radiograph

Plain chest radiography is perhaps the most widely utilized imaging modality for the evaluation of acute dyspnea. Depending on patient stability and mobility, adequate views in anteroposterior or standing posteroanterior projections can be obtained using portable techniques. The chest radiograph complements the workup for an airway foreign body but has some limitations. Retrospective studies involving children have shown that the chest radiograph has a sensitivity of 73% to 85% and a specificity of 9% to 45% for foreign body, suggesting that direct visualization is warranted in most instances.

Certain technical caveats apply to the use of the chest radiograph to diagnose pneumothorax. The air collection appears as a lucent region between the chest wall and the line of the visceral pleura. This interface can be difficult to visualize in the supine patient, because air accumulates in subpulmonic regions. This pattern of localization causes the so-called deep sulcus sign. Chest radiography cannot be used to estimate the size of a pneumothorax, and there is no difference between expiratory and inspiratory views in terms of diagnostic yield.

The chest radiograph is insensitive for the diagnosis of pulmonary embolism. For example, a wedge-shaped peripheral opacity (Hampton's hump) and abrupt pulmonary arterial cut-off (Westermark's sign) were observed on the chest radiograph in only 22% and 14%, respectively, of pulmonary embolism cases confirmed by angiography.

Computed Tomography

Chest CT has become the most sensitive and specific chest imaging technique to evaluate acute dyspnea, especially when it is associated with pain or trauma. In the latter circumstance, CT elucidates pneumothorax, pulmonary contusion, and aortic injury very well. Sensitivity and specificity of CT pulmonary angiography (CTPA) for pulmonary embolism range from 57% to 100% and 78% to 100%, respectively, mostly because of technologic variability. A cross-sectional investigation of CTPA in 589 emergency department patients with suspected pulmonary embolism demonstrated a two-fold greater likelihood of discovering pulmonary nodules and lymphadenopathy than an embolism. A key implication of this finding is that using a CT scan for work up of acute dyspnea often begets further diagnostic studies. Nonetheless, CTPA may play a more important diagnostic role during COPD exacerbation because some data suggest that pulmonary embolism complicates up to 25% of hospitalized cases. Multidetector row CT scan is highly sensitive (95%) and specific (90%) for detection of obstructive coronary artery disease, but its utility in diagnosing acute myocardial infarction is not well defined.

TREATMENT

Further details on the treatment of acute dyspnea caused by the aforementioned processes are presented elsewhere in this book. Two interventions, oxygen therapy and noninvasive positive-pressure ventilation (NIPPV), merit a brief discussion here because of their application to several of these processes. Table 19-2 presents a list of processes that cause acute dyspnea and their specific therapies.

Oxygen

Supplemental oxygen commonly is administered for acute dyspnea, regardless of hypoxemia, with perceived benefit. The mechanisms by which oxygen relieves dyspnea are surprisingly not well characterized. In a dose-dependent fashion, oxygen has been shown to relieve dyspnea and improve endurance in patients with COPD but without exercise-induced hypoxemia, potentially by slowing breathing rate and reducing dynamic lung hyperinflation. Similar physiologic effects may explain its utility during a COPD exacerbation. Alternatively, it could reduce dyspnea by rectifying oxygen debt of respiratory muscles already mechanically disadvantaged in COPD or by decreasing chemoreceptor output. Supplemental oxygen can overcome ventilation-perfusion mismatch, a process shared by other reasons for acute dyspnea such as CHF, pulmonary embolism, pneumonia, atelectasis, and asthma exacerbation.

Noninvasive Positive-Pressure Ventilation

NIPPV is a form of mechanical ventilation provided by mask or cannula that obviates the need for an invasive endotracheal airway. It has found particular utility in the management of acute ventilatory failure due to exacerbations of COPD and CHF. A bilevel airflow pattern can be established through the circuit such that inspiration is augmented by a higher pressure than that set during exhalation. NIPPV has been shown to help correct acute respiratory acidosis in COPD exacerbation, thereby avoiding the need for endotracheal intubation. Bilevel and continuous positive airway pressure delivered noninvasively can improve hypoxemia caused by cardiogenic pulmonary edema and atelectasis in the postoperative period. NIPPV

Table 19-2 Specific Therapies for Acute Dyspnea by Etiologic Condition

Etiologic Condition	Therapeutic Intervention(s)/Agent(s)
Aspirated foreign body	Endotracheal intubation Fiberoptic or rigid bronchoscopy with removal
Anaphylaxis/ angioedema	Antihistamines Subcutaneous epinephrine Systemic corticosteroids
Epiglottitis (E) Peritonsillar abscess (PTA) Retropharyngeal abscess (RPA)	Endotracheal intubation (PTA/RPA) Broad-spectrum antibiotics (PTA/RPA) Incision and drainage (PTA/RPA)
Asthma exacerbation	Supplemental oxygen Inhaled β_2-adrenergic agonists by nebulizer or MDI Systemic corticosteroids
COPD exacerbation	Supplemental oxygen Inhaled β_2-adrenergic agonists by nebulizer or MDI Inhaled anticholinergic agents by nebulizer or MDI Systemic corticosteroids Antibiotics for purulent sputum Noninvasive positive-pressure ventilation
Pulmonary embolism	Systemic anticoagulation Catheter-based thromboembolectomy
Pneumonia	Supplemental oxygen Antibiotics Airway clearance techniques Immunization
Pneumothorax	Thoracostomy tube placement Supplemental oxygen
Congestive heart failure	Supplemental oxygen Diuretics Systemic vasodilators Inotropic agents
Acute coronary syndrome	Percutaneous transluminal coronary angioplasty ± stent Antiplatelet agents Lipid-lowering therapies Diuretics
Acute idiopathic demyelinating polyneuropathy	Mechanical ventilatory support Intravenous immunoglobulin infusion Systemic corticosteroids
Hyperventilation syndrome	Anxiolytic medications Psychiatric evaluation

COPD, chronic obstructive pulmonary disease; *MDI*, metered dose inhaler.

is not appropriate for patients who are hemodynamically unstable, unable to protect their airway, and agitated to the point of not tolerating the apparatus.

CHRONIC DYSPNEA

Chronic dyspnea has been defined as lasting longer than 1 month. Prevalence statistics for chronic dyspnea vary by setting and population. In a cross-sectional survey from Australia, 8.9% of the nearly 5500 respondents acknowledged exertional breathlessness. Environmental tobacco smoke exposure independently increased the likelihood of dyspnea by a factor of 1.45 among 4197 Swiss never-smokers. In 2009, dyspnea was the most common symptom or reason for referral encountered by European hospital-based internists, constituting 19% of admissions. Chronic dyspnea accounts for 3% to 25% of general ambulatory practice visits and has a significant impact among the elderly.

Patients with chronic dyspnea can be disproportionately burdened with comorbid conditions. A 2006 telephone survey of 1003 patients with COPD, 61% of whom reported moderate or severe dyspnea, identified coexistent hypertension (55%), hypercholesterolemia (52%), depression (37%), cataracts (31%), and osteoporosis (28%). Retrospective and prospective data suggest that patients with COPD have a tendency to sustain falls. Idiopathic pulmonary fibrosis, a disease in which the vast majority of patients experience breathlessness, is associated with an excessive risk of cardiac ischemia, venous thromboembolism, and obstructive sleep apnea. From the U.S. Third National Health and Nutrition Examination Survey (NHANES III), researchers interested in asthma and obesity found that the proportion of subjects citing dyspnea during hill climbing rose as obesity worsened. The prevalence of airflow obstruction fell as body mass index increased, yet the most severely obese subjects were using bronchodilators more frequently. These observations led investigators to conclude that asthma may be overdiagnosed in severely obese patients.

DIFFERENTIAL DIAGNOSIS

Causes of chronic dyspnea are listed in **Table 19-3**. Conditions such as COPD and CHF (see Table 19-1) may have both acute and chronic phases. Relatively few studies have tried to identify those diseases that most commonly underlie chronic dyspnea in the outpatient setting. A prospective evaluation of 85 patients at a university-based pulmonary clinic showed that asthma (29%), COPD (14%), interstitial lung disease (14%), and cardiomyopathy (10%) explained two thirds of cases. Although the study investigators emphasized a rational diagnostic approach that incorporated the responses to disease-specific therapies, an average of 6.2 tests were conducted per patient, and no participants had pulmonary vascular disease or muscle weakness. Another investigation of 72 consecutive patients with chronic dyspnea and unrevealing history, physical examination, chest radiograph, and spirometry data found that 36% had pulmonary disease, 14% had cardiac disease, and 19% had primary hyperventilation. Only 3% had an extrathoracic reason for their breathlessness.

Dyspnea often affects patients without obvious heart or lung disease; therefore, the clinician must consider various etiologic conditions. Some of these processes, listed in Table 19-3, warrant further discussion, because dyspnea could be overlooked as a presenting symptom. Moderate to severe anemia can limit tissue oxygen delivery but does not lead to oxyhemoglobin desaturation. Thus, the mechanism by which a low hemoglobin concentration provokes dyspnea probably is related to impaired muscle energetics and a compensatory increase in ventilation and cardiac output. Patients with many forms of advanced cancer indeed experience significant, albeit temporary, dyspnea relief from blood transfusions and erythropoietic growth factor support. Respiratory muscle weakness has been implicated as the cause of chronic dyspnea in patients with hypothyroidism and thyrotoxicosis, on the basis of responses to specific medical therapy. Limited data are available regarding the prevalence of dyspnea among patients with selected neuromuscular diseases. Roughly 40% of patients with amyotrophic lateral sclerosis, 23% of patients with postpoliomyelitis, and 12% of patients with multiple sclerosis complain of dyspnea. Both weight gain and a sedentary lifestyle are common causes of exertional dyspnea in those residing in developed countries.

MEDICAL HISTORY

Processes that cause chronic breathlessness are likely to have evolved to some extent before a patient presents for evaluation. Accordingly, it is incumbent on the clinician to ask about the ways in which the patient's dyspnea has changed. Questions might focus on how frequently dyspnea occurs, how long each episode lasts, how intense each episode is, and defining factors that both trigger and relieve it. Eliciting which activities of daily living provoke dyspnea can facilitate longitudinal assessment. This determination also sheds light on whether the patient is modifying behaviors as dyspnea worsens. Unless the clinician specifically asks about activities that the patient has stopped because of breathing difficulty, it can appear that breathlessness only modestly affects that patient's functional status. Perspectives on the patient's dyspnea from spouses, relatives, and friends frequently are useful and should be sought.

As discussed earlier, the correct diagnosis may be suggested by patient-selected descriptors of dyspnea, but it also can be substantiated by the presence or absence of associated symptoms. For example, asthmatic persons generally experience episodes of wheezing, chest tightness, and dyspnea with or without antecedent exposure to a discrete trigger such as an aeroallergen or cold air. A report of wheezing is nonspecific for asthma, however, because it can signify COPD, upper airway obstruction, or CHF. Many asthmatics also cough during bronchospasm periods, but asthma explains a chronic cough only about 25% of the time. The elderly asthmatic patient may describe exertional dyspnea and no other respiratory symptoms—a possible correlate of nonreversible airflow obstruction.

Paroxysmal nocturnal dyspnea and orthopnea may suggest CHF. A systematic review of studies investigating emergency department diagnosis of CHF found that a history of paroxysmal nocturnal dyspnea increased the pretest probability of CHF in the dyspneic patient by a factor of 2.6. Data from the Cardiovascular Health Study suggest that orthopnea and paroxysmal nocturnal dyspnea are relatively specific (87.5% and 89.8%, respectively) but somewhat insensitive (42.8% and 37.6%, respectively) indicators of CHF. Orthopnea also may be due to respiratory muscle weakness and abdominal "loading," as with ascites and obesity.

PHYSICAL EXAMINATION

A focused physical examination frequently yields sufficient clues about the origin of chronic breathlessness. The

Table 19-3 **Differential Diagnosis of Chronic Dyspnea**

Anatomy	Processes	Risk Factors
Upper airway	Vocal cord dysfunction	Head, neck, and lung cancer Neck surgery Head trauma Endotracheal intubation Viral infection Psychiatric disorder
	Subglottic stenosis	Endotracheal intubation ANCA-positive vasculitis
	Partially obstructing lesion(s)	Cancer Granulomatous inflammation
Thyroid	Thyrotoxicosis Hypothyroidism	Autoimmunity Viral infection
Blood	Anemia	Chemotherapy Chronic kidney disease Chronic gastrointestinal blood loss
Heart	Systolic heart failure	Myocardial infarction
	Diastolic heart failure	Hypertension, obesity
	Pericardial disease	Pericarditis
	Valvular disease	Mitral and aortic insufficiency
	Intracardiac shunt	Patent foramen ovale, ventricular septal defect
Lungs		
Airways	COPD	Tobacco abuse, α_1-antitrypsin deficiency
	Asthma	Atopy, genetic predisposition
	Cystic fibrosis	Heritable genetic defect
Parenchyma	Interstitial lung disease	Idiopathic interstitial pneumonia Pneumotoxic drug reaction Connective tissue disease
Vasculature	Pulmonary arterial hypertension	Idiopathic pulmonary arterial hypertension Chronic venous thromboembolism Vasculitis Obesity-hypoventilation syndrome
	Arteriovenous malformation	
Pleura	Pleural effusion	Systolic heart failure Cancer Infection Hepatic hydrothorax
Thorax	Kyphoscoliosis	Congenital Osteoporosis
Respiratory muscles	Mechanical loading	Morbid obesity Pregnancy
	Dyskinesia/dystonia Neurodegenerative disease	
Integrated	Deconditioning	Sedentary lifestyle Nutritional deficiency Obesity
Other	Hyperventilation syndrome	Anxiety

ANCA, antineutrophil cytoplasmic antibodies; *COPD*, chronic obstructive pulmonary disease.

investigation should begin with an appraisal of the patient's voice. Someone with "breathy" dysphonia whose voice tends to wane during prolonged speech could have vocal cord dysfunction. In the setting of chronic dyspnea, stridor most commonly is caused by the development of benign or malignant lesions or focal stenoses. The diagnostic utility of jugular venous pressure elevation for detection of decompensated CHF has been extensively studied. The sensitivity and specificity of this finding for high pulmonary capillary occlusion pressure (i.e., pulmonary venous hypertension) are 70% and 79%, respectively. The jugular venous pressure can be difficult to measure in persons with an obese habitus and can be elevated as a consequence of pulmonary arterial hypertension, tricuspid regurgitation, pericardial constriction, or occlusion of the superior vena cava.

Examination of the neck also should involve palpation for thyroidomegaly and lymphadenopathy, because dyspnea can result from tracheal compression.

Inspection of the spine and thorax can provide a clear reason for why a patient experiences persistent dyspnea. Severe kyphosis reduces total lung capacity, limits alveolar ventilation, and eventually impairs gas exchange. The anteroposterior dimension of the thorax can be exaggerated in patients with COPD, but this adaptation to lung hyperinflation lacks sensitivity for this diagnosis. Central adiposity in the morbidly obese patient reduces functional residual capacity (FRC) and reserve volume, thereby increasing resistance to airflow and decreasing lung compliance. Collapse of small peripheral airways in the lung bases of obese patients can lead to ventilation-perfusion mismatch and breathlessness.

Crackles on lung auscultation can reflect several pathologic processes, all of which should be considered along with other aspects of the examination. The negative predictive value of crackles for interstitial lung disease and CHF has been reported as 98% and 89%, respectively, indicating that a majority of patients without crackles will not have these conditions. The sensitivity of crackles for CHF can be as low as 29%, even when echocardiography is used to affirm or refute presence of left ventricular dysfunction. In one study of 57 patients with pleural effusions, 49 of whom were dyspneic, dullness to percussion and decreased breath sounds were individually more suggestive of pleural fluid than crackles. Wheezes similarly are useful in diagnosing asthma and COPD, but their absence cannot exclude airflow obstruction. Emphysema is suggested by diminished breath sounds in the upper lung fields, sometimes associated with indistinct heart tones. The S3 gallop on heart auscultation is highly specific for elevated left ventricular end-diastolic pressure.

DIAGNOSTIC TESTING

Details from the history and physical examination should inform the selection of diagnostic tests that further refine decision-making. One approach involves categorizing these modalities according to their ability to investigate relevant anatomy and physiology (Table 19-4). Various guidelines on management of COPD recommend that the diagnosis be determined by a value of 70% or less for the ratio of postbronchodilator forced expiratory volume in 1 second (FEV_1) to forced vital capacity (FVC). However, the FEV_1/FVC ratio declines with aging, and the use of a “fixed” ratio may lead to overdiagnosis of COPD among patients older than 60 years of age. We concur with the American Thoracic Society–European Respiratory Society recommendation that airflow obstruction be diagnosed by a FEV_1/FVC value below the lower limit of normal for the specific patient.

A low FVC may be due to air trapping in a patient with airflow obstruction or may point to a restrictive lung process that can be confirmed by measurement of lung volumes. Analysis of the flow-volume loop can demonstrate evidence of upper airway obstruction (Figure 19-4). In cases of suspected asthma, a negative result on direct bronchoprovocation testing essentially rules out this diagnosis. However, false-positive results can be seen in normal persons as well as those with sarcoidosis or vocal cord dysfunction. Measurement of maximal inspiratory mouth pressure is sensitive for detection of respiratory muscle weakness.

Many cardiac causes of chronic breathlessness can be identified by echocardiography. In addition to quantifying left

Table 19-4 Diagnostic Testing for Chronic Dyspnea

Test	Diagnostic Utility
Spirometry	Diagnose and quantify airflow obstruction and restriction
Flow-volume loop	Diagnose upper airway obstruction
Single-breath diffusion capacity for carbon monoxide (DLCO)	Reduced in emphysema, interstitial lung disease, and pulmonary hypertension Can be reduced in anemia Can be increased in alveolar hemorrhage, asthma
Lung volume determination	Confirms restrictive lung diseases
Bronchoprovocation testing	Diagnose airway hyperreactivity
Maximal inspiratory and expiratory mouth pressures	Evaluate neuromuscular weakness
Chest computed tomography	Interstitial lung disease Airway caliber well delineated; can identify endobronchial lesions Excellent characterization of pleural space and mediastinum
Echocardiography	Diagnose and quantify ventricular function Evaluate valvular incompetence, pericardium
Cardiopulmonary exercise testing	Diagnose cardiac dysfunction, ventilatory limitation, oxygen desaturation, deconditioning, psychogenic dyspnea
Complete blood count	Diagnose anemia

	Pre-drug measured (L)	Predicted	Pre-drug predicted (%)
FVC	4.08	3.88	105
FEV_1	*0.91	3.24	28
FEV_1/FVC	*22.17	83.80	26
$FEF_{25–75\%}$	*0.59	3.42	17
$FEF_{50\%}$	0.61	4.70	13
FEF_{max}	*1.45	7.17	20
FEF_{50}/FIF_{50}	24.12		
FIF_{max}	2.63

Table 19-5 **Cardiopulmonary Exercise Testing and Chronic Dyspnea**

Measured Parameter	Deconditioning	Cardiac Process	Pulmonary Process
$V\text{O}_2\text{max}$	↓	↓	↓
Anaerobic threshold (AT)	Normal	↓	↓ or normal
O_2 pulse (mL/beat)	Normal	↓	Normal
Heart rate reserve (normal ≤15%)	Normal	Normal	>15%
$V\text{O}_2$/power slope (mL/min/W)	Normal	↓	Normal
Breathing reserve (normal ≥30%)	Normal	Normal	<30%
SaO_2 (rest to exercise)	No change	No change	Possible ↓
Usual exercise-limiting symptom	Leg discomfort	Chest discomfort	Dyspnea

ventricular systolic function, this procedure provides information about peak systolic pulmonary artery pressure, pericardial structure, and valvular function. Intravenous administration of agitated saline solution coupled with echocardiography (i.e., contrast echocardiography) is more than 98% sensitive for detecting pulmonary arteriovenous malformations. In a study of nearly 18,000 patients without established coronary artery disease who were referred for radionuclide myocardial perfusion testing, evidence of inducible ischemia was similar for patients with self-reported dyspnea and for those with typical angina pectoris, prompting the investigators to conclude that a more systematic appraisal of dyspnea should occur at the time of stress testing referral.

The etiology of chronic dyspnea will sometimes remain elusive despite a careful history and physical examination and multiple diagnostic endeavors. Then, cardiopulmonary exercise testing should be considered to provoke the patient's dyspnea with comprehensive assessment of the oxygen transport system on an integrated level. Pulmonary gas exchange, cardiac function, and metabolic activity can be measured noninvasively (Table 19-5). Patients also are asked to rate dyspnea and leg discomfort throughout the exercise test. The results of cardiopulmonary exercise testing usually are able to distinguish cardiac dysfunction and ventilatory limitation but cannot always discriminate between cardiac disease and deconditioning.

TREATMENT

Disease-specific therapies generally are successful in mitigating chronic dyspnea, although this may not be the case with multiple concurrent processes or disease progression. Dyspnea is a prominent feature of CHF, yet most studies of various interventions for CHF consider death or utilization of health care resources as outcome metrics. Good-quality evidence supports exercise training to improve functional status in patients with CHF. Diuretics, inotropes, and vasodilators are mainstays of a management strategy of regulating volume status and controlling symptoms in CHF.

For patients with COPD, the combination of an inhaled corticosteroid and a long-acting β-agonist has been shown to improve lung function, relieve respiratory symptoms, and modestly reduce risk of death. Large trials of inhaled long-acting anticholinergic drugs also show a positive impact on dyspnea associated with COPD. Supplemental oxygen is indicated for patients with COPD who have resting hypoxemia, although its effect on mortality and symptoms in patients who display only exertional oxyhemoglobin desaturation is currently being investigated. Specific criteria to select patients with emphysema who could benefit from lung volume reduction surgery are well established. Pulmonary rehabilitation has been shown to have multiple benefits, including decreasing the severity of dyspnea, enhancing exercise tolerance, reducing the frequency of exacerbations, and improving quality of life. Interstitial lung disease is a broad category of infiltrative pulmonary disorders for which disease-modifying and symptom-relieving treatments are needed.

PALLIATION OF DYSPNEA

A recent consensus statement addresses management of dyspnea in advanced heart and lung disease. Its authors emphasize that dyspnea should be regularly assessed and documented, with a goal of determining whether this symptom is being adequately addressed. The statement affirms the potential for oxygen to palliate dyspnea in patients who are hypoxemic at rest or with modest physical activity. Recommended nonpharmacologic approaches to the management of dyspnea include pursed-lip breathing, relaxation, guided imagery, and NIPPV.

Systemic opioids are effective for palliating refractory dyspnea; the dose and frequency of opioid medications should account for altered pharmacokinetics due to liver or kidney disease. The consensus statement affirms that concerns about addiction or dependence should not curtail the effective palliation of dyspnea. Moreover, the principle of double effect provides an ethical basis for treating with a class of drugs that can hasten death by respiratory depression, so long as the primary intent is to relieve the disabling and distressing experience of dyspnea.

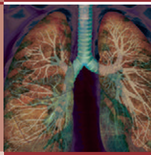
Section 4

AN APPROACH TO RESPIRATORY SYMPTOMS



Chapter 20

Hemoptysis

John W. Kreit

Hemoptysis is defined as the expectoration of blood that results from hemorrhage into the lower respiratory tract. It can be caused by a wide variety of disorders and constitutes a common reason for referral to a pulmonary specialist. The amount of blood expectorated can range from minimal streaking of the sputum to large volumes of pure blood and depends not only on the rate of bleeding but also on its location. For example, hemorrhage into the lung parenchyma or a distal airway may be accompanied by little or no hemoptysis, whereas even a relatively small amount of bleeding from a central airway may lead to a significant volume of expectorated blood.

Hemoptysis, by itself, does not usually lead to significant morbidity or death. Rather, it typically is important only as a sign of an underlying and often unrecognized disorder. Thus, hemoptysis is an extremely important symptom, and its cause must be determined by means of a thorough and orderly evaluation.

Massive hemoptysis is an uncommon but potentially life-threatening event, in that flooding of the airways and alveoli may quickly lead to respiratory failure. It requires rapid evaluation and emergent and specific therapy, so massive hemoptysis usually is considered to represent a distinct clinical entity and is discussed separately in a later section of this chapter.

DIFFERENTIAL DIAGNOSIS

A large number of disorders have been reported to cause hemoptysis, and the most important are listed in Box 20-1. Of these, bronchogenic carcinoma, bronchiectasis, bronchitis, and bacterial pneumonia are responsible for most cases. Table 20-1 shows the relative frequency of disorders causing hemoptysis in major series published since 1980. The significant variability, especially in the frequency of bronchiectasis, bronchitis, and tuberculosis, probably reflects differences in the time of publication, the patient population studied, and the diagnostic tests and criteria used. Figure 20-1 illustrates the percentage of patients with each diagnosis on the basis of pooled data from these studies.

NEOPLASMS

Malignancy is one of the most common causes of hemoptysis, and bronchogenic carcinoma accounts for most of these cases. In patients with hemoptysis, the tumor typically involves a central airway (i.e., a main, lobar, or segmental bronchus) and most commonly is a squamous cell carcinoma. Much less commonly, hemoptysis is caused by a peripherally located carcinoma or by other primary pulmonary neoplasms, such as carcinoid tumor or hamartoma. Extrathoracic malignancies, especially melanoma and carcinoma of the breast, colon, and kidney, also may cause hemoptysis because of their propensity to metastasize to endobronchial locations in the tracheobronchial tree.

BRONCHIECTASIS

In studies published before the early 1960s, bronchiectasis often was the most common cause of hemoptysis and frequently accounted for 25% to 35% of cases. In the subsequent decades, this number dropped dramatically to less than 5%. Although this decline was correctly attributed to the greater availability and effectiveness of antibacterial and antituberculosis therapy, it probably was also caused by a marked decrease in the use of bronchography, the principal diagnostic modality of that era. Since the advent of high-resolution computed tomography (HRCT), bronchiectasis has been diagnosed with increasing frequency, and recent studies indicate that it remains a very important cause of hemoptysis.

ACUTE BRONCHITIS

Hemoptysis often is attributed to an acute infectious bronchitis on the basis of compatible clinical or bronchoscopic findings, and this is a common final diagnosis in most series. Although acute bronchitis undoubtedly may cause hemoptysis, the symptoms, signs, and bronchoscopic findings in this disorder are neither sensitive nor specific. In fact, several studies have demonstrated that the diagnosis of acute bronchitis often is made in patients with another source of bleeding. Thus, acute bronchitis must be considered to represent a diagnosis of exclusion, and great care must be taken to search for other causes of hemoptysis.

TUBERCULOSIS

Although tuberculosis remains relatively common in certain patient populations and geographic regions, successful methods of treatment and prevention have markedly reduced both its incidence and its importance as a cause of hemoptysis. Hemoptysis most commonly results from active disease, but it also may be caused by the sequelae of infection, particularly bronchiectasis, parenchymal cavitation, and mycetoma formation.

BACTERIAL PNEUMONIA

Hemoptysis may result from virtually any type of bacterial pneumonia but most often accompanies infection with *Streptococcus pneumoniae*. Other commonly implicated pathogens

Box 20-1 Causes of Hemoptysis

Common (≥5% each)
- Bronchogenic carcinoma
- Bronchiectasis
- Bronchitis
- Bacterial pneumonia
- Tuberculosis

Uncommon (1-4% each)
- Pulmonary embolism
- Left ventricular failure
- Mycetoma
- Nontuberculous mycobacterial infection
- Traumatic or iatrogenic lung injury

Rare (<1% each)
- Other primary lung neoplasms
- Metastatic neoplasms
- Nonbacterial pneumonia
- Broncholithiasis
- Foreign body aspiration
- Mitral stenosis
- Amyloidosis
- Pulmonary arteriovenous malformation
- Pulmonary artery aneurysm
- Endometriosis
- Pulmonary sequestration
- Alveolar hemorrhage syndromes
  - Goodpasture syndrome
  - Wegener granulomatosis
  - Microscopic polyarteritis
  - Systemic lupus erythematosus

include *Klebsiella pneumoniae, Staphylococcus aureus, Pseudomonas aeruginosa,* and anaerobic organisms.

CRYPTOGENIC HEMOPTYSIS

In almost all reported series, the cause of hemoptysis remains unknown in a significant percentage of patients. As shown in Table 20-1, the frequency of cryptogenic hemoptysis has varied widely, and this variability presumably is due to differences in diagnostic criteria and the extent of evaluation.

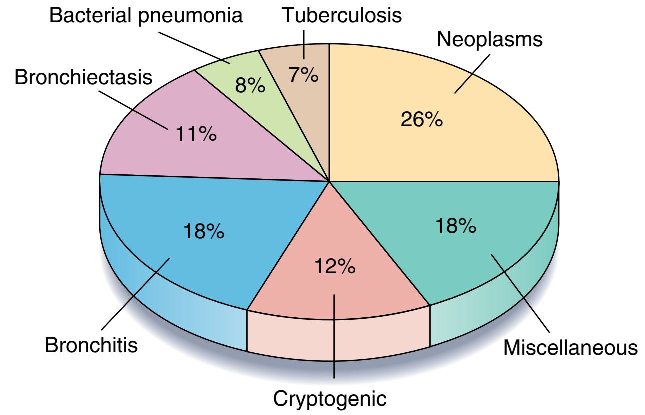

Figure 20-1 Final diagnosis in patients presenting with hemoptysis. The approximate percentage of cases attributed to each diagnosis is shown.

PATIENT EVALUATION

When the patient reports a history of expectorating blood, the first step must be to determine whether hemoptysis has actually occurred. That is, bleeding must be localized to the lower respiratory tract, and alternative sites, such as the nose, mouth, pharynx, larynx, and gastrointestinal tract, must be excluded. Few patients have difficulty distinguishing between vomiting and expectorating blood, although specific questions may be required to elicit a report of nausea and retching. Distinguishing between an upper and a lower airway source of bleeding occasionally is more difficult, although this usually can be accomplished by a directed history and physical examination. Patients with hemoptysis almost always report that the expectoration of blood follows an episode of coughing; in those with an upper airway source, it typically is preceded by a feeling of blood pooling in the mouth or the need to “clear the throat.” A history of epistaxis also is an important indicator of upper airway hemorrhage. Routine examination of the nose, mouth, and pharynx is important to rule out an obvious site of bleeding. A thorough examination that includes rhinoscopy and laryngoscopy is indicated when an upper airway source cannot be reliably excluded.

Table 20-2 Important Clinical Features in Patients with Hemoptysis

Category	Feature(s)	Disorder(s)
Historical	Cigarette smoking	Bronchogenic carcinoma
	Previously diagnosed malignancy	Metastatic malignancy
	Previously diagnosed pulmonary, cardiac, pulmonary vascular, or systemic disease	
	Recent chest trauma or procedure	Traumatic/iatrogenic lung injury
	Risk factors for aspiration	Lung abscess, foreign body aspiration
Symptom	Purulent-appearing sputum	Bronchiectasis, bronchitis, pneumonia, lung abscess
	Pleuritic pain	Pneumonia, pulmonary embolism
	Paroxysmal nocturnal dyspnea, orthopnea	Left ventricular failure, mitral stenosis
	Fever	Pneumonia, lung abscess
	Weight loss	Bronchogenic carcinoma, other malignancy, tuberculosis, lung abscess
Sign	Bronchial breath sounds, egophony	Pneumonia
	Localized decrease in breath sounds, localized wheezing	Bronchogenic carcinoma, broncholithiasis, foreign body
	Coarse crackles, rhonchi	Bronchiectasis, bronchitis
	Pleural rub	Pneumonia, pulmonary embolism
	S3 gallop	Left ventricular failure
	Diastolic murmur	Mitral stenosis

Table 20-3 Important Radiographic Findings in Patients with Hemoptysis

Radiographic Finding	Associated Disorder(s)
Nodule(s) or mass(es)	Bronchogenic carcinoma or other neoplasm, lung abscess, fungal infection, vasculitis
Atelectasis	Bronchogenic carcinoma or other endobronchial neoplasm, broncholithiasis, foreign body
Hilar/mediastinal adenopathy	Bronchogenic carcinoma or other neoplasm, mycobacterial or fungal infection, sarcoidosis
Dilated peripheral airways	Bronchiectasis
Air space consolidation	Pneumonia, alveolar hemorrhage, pulmonary contusion
Reticulonodular densities	Sarcoidosis, lymphangitic carcinoma
Cavity—single or multiple	Mycobacterial or fungal infection, mycetoma, lung abscess, bronchogenic carcinoma
Hilar/mediastinal calcification	Previous mycobacterial or fungal infection, broncholithiasis

INITIAL EVALUATION

Once hemoptysis has been confirmed, a search must be made for its cause. This process begins with an initial evaluation that consists of a complete history and physical examination and a chest radiograph.

Important symptoms, signs, and historical details that suggest one or more disorders are listed in Table 20-2. In some patients, such as those with pulmonary embolism, left ventricular failure, mitral stenosis, and traumatic or iatrogenic lung injury, the history and physical examination may provide the most important clues to the diagnosis.

As shown in Table 20-3, the chest radiograph also may yield important information about the underlying cause of hemoptysis. The chest film, however, is "localizing"—that is, it demonstrates a mass, cavity, infiltrate, lobar atelectasis, or other finding that is likely to be directly related to the cause of hemoptysis—in less than 40% of patients. In the remainder, the chest radiograph is either normal in appearance or demonstrates abnormal but nonspecific findings such as emphysema, interstitial fibrosis, minor atelectasis, or pleural thickening—a category referred to as "nonlocalizing." This radiographic classification has important diagnostic and prognostic implications. Malignancy is found in almost 40% of patients with hemoptysis associated with localizing findings on the chest radiograph. On the other hand, cancer is diagnosed in only 6% to 10% of patients with normal-appearing or nonlocalizing chest radiographs.

ADDITIONAL TESTING

The history, physical examination, and plain chest radiography are essential to reduce the number of possible causes of hemoptysis, and findings often point toward specific disorders. This initial evaluation, however, yields a definitive diagnosis in only a small percentage of patients. In most cases, additional testing is required, which most commonly consists of computed tomography (CT) and fiberoptic bronchoscopy (FOB).

COMPUTED TOMOGRAPHY

Compared with conventional chest radiography, CT is clearly superior for imaging the peripheral and central airways, mediastinum, and lung parenchyma. Thus, it is not surprising that CT has been shown to be very useful in the evaluation of patients with hemoptysis. In the presence of a normal-appearing or nonlocalizing chest radiograph, CT reveals an unsuspected cause of hemoptysis, most commonly bronchiectasis, in approximately one third of patients (Figure 20-2). CT also may demonstrate an endobronchial lesion (Figure 20-3) or an unsuspected

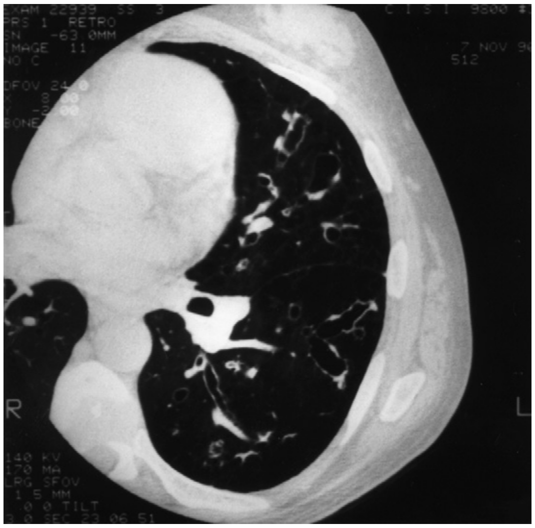

Figure 20-2 Computed tomography (CT) appearance of bronchiectasis. Dilated peripheral airways are clearly seen on this high-resolution CT image.

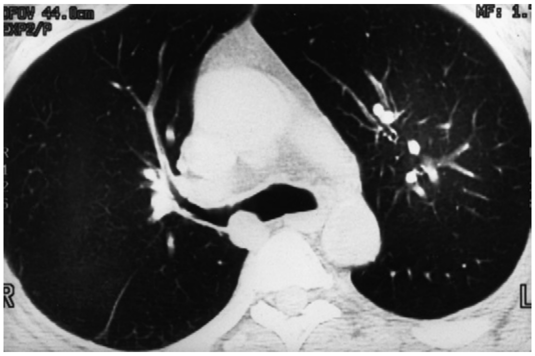

Figure 20-3 Computed tomography (CT) scan showing an endobronchial mass. The lesion, which proved to be a bronchogenic carcinoma, is clearly visible in the right main bronchus.

parenchymal mass, nodule, or cavity (Figure 20-4). CT also is useful in more than half of all patients whose chest radiograph is localizing, either by revealing a new source of hemoptysis or by providing additional information about a previously recognized abnormality.

FIBEROPTIC BRONCHOSCOPY

Since becoming widely available in the early 1970s, fiberoptic bronchoscopy (FOB) has been used almost routinely in the evaluation of patients with hemoptysis. By combining endoscopic examination with brushings, washings, endobronchial and transbronchial biopsy techniques, and transtracheal needle aspiration, FOB may be used both to identify the site of bleeding and to obtain a definitive diagnosis. FOB is most useful for diagnosing bronchogenic carcinoma and other endobronchial neoplasms (Figure 20-5); it is far less effective at detecting other causes of hemoptysis. The most common non-neoplastic diagnosis made by FOB is acute bronchitis, which is based on the presence of mucosal hyperemia and edema and purulent-appearing secretions. As previously discussed, however, these findings are nonspecific and often are unrelated to the actual cause of hemoptysis. When this diagnosis is excluded, a specific, non-neoplastic cause of hemoptysis is found by FOB in less than 10% of cases.

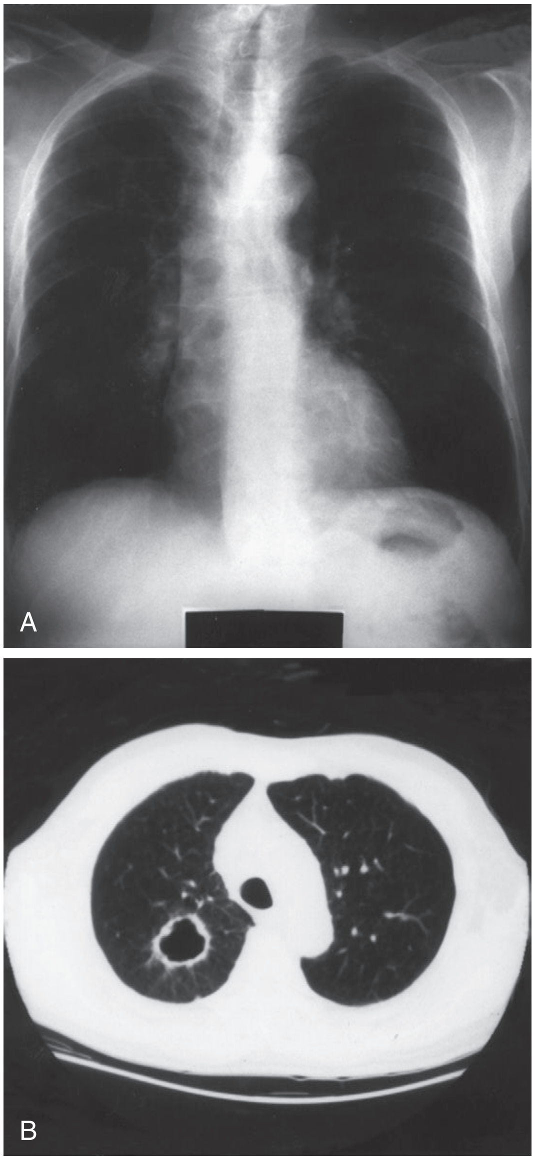

Figure 20-4 Chest radiograph and computed tomography (CT) scan obtained in a patient with a cavitary squamous cell carcinoma. **A,** The lesion cannot be seen on the chest radiograph but is clearly demonstrated on the CT scan, shown in **B.**

COMPUTED TOMOGRAPHY VERSUS BRONCHOSCOPY

Six studies have compared the sensitivity rates for CT and FOB for detection of bronchogenic carcinomas and other lung neoplasms in patients with hemoptysis. Five of these studies were published between 1990 and 1999 and used nonhelical, single-detector scanners. In most cases, images were acquired at 10-mm intervals, although additional sections usually were obtained through the central airways. A total of 296 patients were included in these studies, in whom the chest radiograph typically was either normal-appearing or nonlocalizing, and 83 were diagnosed with a pulmonary malignancy. CT demonstrated all but 1 tumor found by FOB and identified 12 cancers that were not detected by FOB.

Since that time, of course, a dramatic evolution has occurred in CT technology. The advent of continuous, helical scanning using multiple detectors has led to tremendous improvement in image quality and resolution. In a recently published retrospective comparison of FOB and CT in 270 patients with

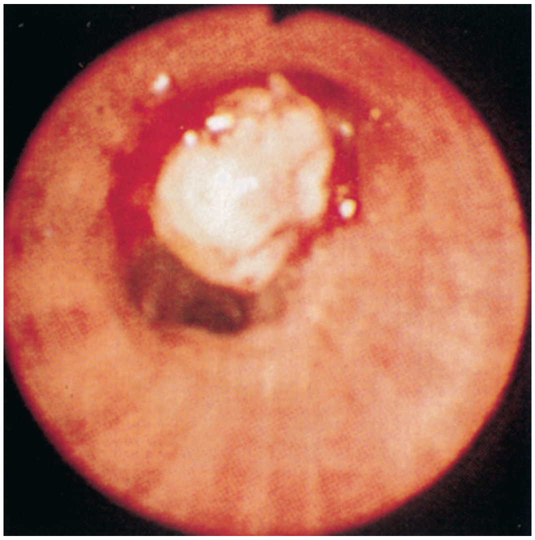

Figure 20-5 Bronchogenic carcinoma visualized through the fiberoptic bronchoscope. The tumor occludes the left upper lobe and is actively bleeding.

hemoptysis and a normal-appearing chest radiograph, FOB and CT detected 14 and 25 of 26 lung malignancies, respectively. The 1 tumor missed by CT was found by FOB.

These studies clearly show that CT is much better than FOB at detecting and excluding malignancy. However, because CT can still miss small, endobronchial lesions and FOB can establish a definitive tissue diagnosis, both of these tests are recommended, to provide important complementary information in the evaluation of patients with hemoptysis.

Still more recent advances in CT technology have further improved imaging of the airways. Manipulation of CT data allows the creation of two-dimensional multiplanar images as well as three-dimensional internal views of the airways; the relevant technology often is referred to as "virtual bronchoscopy." Although these advancements would be expected to make CT an even more powerful tool, no studies have evaluated their efficacy in patients with hemoptysis.

DIAGNOSTIC ALGORITHM

A suggested approach to the patient with hemoptysis that is based on the preceding information is shown in Figure 20-6. If the initial evaluation yields a firm diagnosis, such as bacterial pneumonia or iatrogenic or traumatic lung injury, appropriate therapy is instituted. Alternatively, the initial evaluation may suggest a cause of hemoptysis that requires investigation using one or more specific tests. For example, an echocardiogram may confirm the presence of left ventricular failure or mitral stenosis, pulmonary embolism may be diagnosed by means of a CT angiogram, and sputum cultures may be diagnostic in patients with tuberculosis. In all other patients, CT is the most appropriate next step in the diagnostic evaluation. As discussed previously, CT often identifies an unsuspected cause of hemoptysis, even in patients whose chest radiograph is normal in appearance or nonlocalizing, and may provide important information in patients who already have a presumptive diagnosis. For example, in patients with suspected bronchogenic carcinoma, CT adds vital information for staging and also provides a "road map" for bronchoscopy by defining the exact location of a parenchymal mass and enlarged mediastinal lymph nodes.

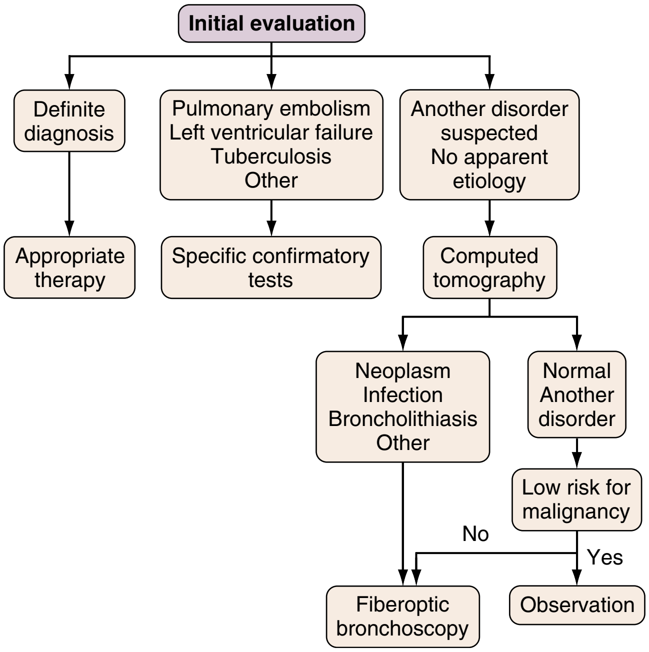

Figure 20-6 Diagnostic algorithm for patients presenting with hemoptysis.

If CT suggests a disorder that is amenable to bronchoscopic diagnosis, such as neoplasm or infection, FOB is performed next in the diagnostic evaluation. Additional studies such as mediastinoscopy or surgical lung biopsy may be required if FOB is nondiagnostic. When CT either yields normal findings or demonstrates another cause of hemoptysis, such as bronchiectasis, the role of FOB is less clearly defined. The absence of an endobronchial lesion on the CT scan is associated with a low risk of malignancy, and available data suggest that FOB may be safely omitted in never-smokers younger than 40 years. Because CT occasionally fails to detect small endobronchial lesions, however, FOB should be performed in all other patients.

MASSIVE HEMOPTYSIS

No generally accepted definition of *massive hemoptysis* has emerged, although the most commonly used criteria require the expectoration of between 200 and 600 mL of blood over 24 hours. Any definition based on the amount of expectorated blood is, of course, arbitrary, especially because the volume often is difficult to quantify.

From a clinical standpoint, it is more appropriate to define massive hemoptysis simply as bleeding that impairs ventilation and gas exchange. Because this effect depends not only on the volume of expectorated blood but also on the rate of bleeding, the ability of the patient to clear blood from the airways, and the extent and severity of any underlying lung disease, it is evident that the amount of bleeding needed to be considered "massive" will vary significantly from patient to patient.

Massive hemoptysis is relatively uncommon and occurs in fewer than 5% of patients with lower respiratory tract bleeding. Although any of the disorders listed in Box 20-1 may potentially give rise to life-threatening hemorrhage, massive hemoptysis most commonly is caused by bronchiectasis, bronchogenic carcinoma, mycetoma, lung abscess, and tuberculosis (active or inactive). Overall, the risk of death from massive hemoptysis is approximately 20%, although reported mortality rates vary widely, ranging between 0 and 75%.

The lungs have a dual blood supply. The pulmonary circulation has low pressure and resistance, carries the entire output of the right ventricle, and is responsible for the exchange of oxygen and carbon dioxide. The bronchial arteries are very small systemic arteries with high pressure and resistance. They usually arise from the aorta and normally contribute less than 1% of the blood flow entering the lung vasculature. The bronchial circulation provides oxygen and nutrients to the conducting airways, the pulmonary arteries and veins, the visceral pleura, and the esophagus. Chronic inflammatory disease or neoplasms within the lungs causes enlargement and proliferation of the bronchial arteries as well as recruitment of collateral vessels from extrapulmonary systemic arteries. These vessels tend to have thin walls and are more likely to rupture when exposed to systemic arterial pressure. Massive hemoptysis originates from a bronchial artery in about 90% of cases and from a nonbronchial systemic artery or a pulmonary artery in the remainder. Occasionally, bleeding comes from more than one type of artery.

Because of its associated morbidity and mortality, massive hemoptysis constitutes a respiratory emergency and necessitates rapid evaluation and therapy. Unlike in patients with small amounts of bleeding, in whom the emphasis is on determining the underlying cause, in patients with massive hemoptysis the goals are to maintain a patent airway and to localize and control the bleeding. Patients should be closely monitored in an intensive care unit, and intubation and mechanical ventilation are indicated if ventilation and gas exchange become sufficiently compromised.

Bronchoscopy should be performed immediately in an effort to identify the cause of bleeding or at least to localize the bleeding to a specific segment or lobe. Either rigid bronchoscopy or FOB may be used, depending largely on the clinical circumstances. Rigid bronchoscopy, with its large lumen, affords excellent airway control and suctioning capability, and is ideally suited to management of patients with very brisk bleeding. Disadvantages include poor visualization of the segmental and lobar bronchi and the need for general anesthesia. In most patients, FOB is the procedure of choice, because it can be performed rapidly and allows visualization of airways down to the subsegmental level. All patients with massive hemoptysis should be intubated before FOB. Implementation of this precaution optimizes airway control, allows effective suctioning should the rate of bleeding increase, and permits the bronchoscope to be easily removed and reinserted if the suction channel becomes occluded.

CT also is very effective in identifying both the cause and the site of bleeding in patients experiencing massive hemoptysis. In addition, CT angiography usually can provide images of the bronchial circulation that increase the ease and effectiveness of bronchial artery embolization (see later on) and identify patients who have a nonbronchial systemic arterial source of bleeding.

Localization of the bleeding site is important for two reasons. First, it provides a guide for embolization therapy to control ongoing hemorrhage (see further on). Second, in the setting of persistent, severe hemoptysis, it allows isolation of the bleeding site to prevent the spread of blood throughout the tracheobronchial tree. This potentially lifesaving intervention is performed by placing a bronchoscopically guided balloon catheter in a segmental or lobar airway. When bleeding can be localized only to one lung, a larger balloon may be inflated in a main bronchus, or the fiberoptic bronchoscope can be used to selectively intubate and ventilate the nonbleeding lung.

Once the bleeding site has been localized and a stable airway has been achieved, ongoing hemorrhage must be controlled. Guided by the results of bronchoscopy and CT angiography, bronchial or other intrathoracic arteries may be visualized by use of selective arteriography and occluded with embolized, nonabsorbable material. Arterial embolization is successful in rapidly controlling hemorrhage in 73% to 98% of attempted procedures. Emergent surgical resection is accompanied by a mortality rate that approaches 30% and usually is reserved for patients in whom arterial embolization is unsuccessful.

Once bleeding has resolved, either spontaneously or after embolization therapy, its cause, if not already identified, must be determined (see Figure 20-6). Specific treatment, such as antibacterial or antituberculosis therapy, often prevents further episodes of hemoptysis. When effective therapy is not available, recurrent and often life-threatening hemorrhage occurs with a frequency as high as 50%. Recurrent bleeding is especially likely in patients with bronchiectasis, a mycetoma, or pulmonary malignancy, and surgical resection should be considered in these cases. For patients who are not surgical candidates, repeat embolization therapy often is successful if bleeding recurs.

SUMMARY

Hemoptysis is a commonly encountered sign of extreme clinical importance in that it often signifies the presence of an underlying and sometimes unrecognized lung disease. Adherence to a thorough and orderly diagnostic approach to determine its cause is essential. Massive hemoptysis constitutes a life-threatening emergency, and therapy must focus on maintaining a patent airway and on identification and occlusion of the bleeding artery by means of selective arteriography and embolization.

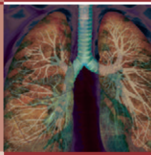
Section 4

AN APPROACH TO RESPIRATORY SYMPTOMS



Chapter 21

Chest Pain

Richard K. Albert • Stephen G. Spiro

Chest pain is a very common symptom, and its severity and etiology will depend, to a large extent, on the clinical circumstances in which it occurs. Chest pain is the most frequent new symptom reported by patients seen in outpatient clinics. Although it is an extremely nonspecific symptom (Box 21-1), it may be the presenting manifestation of a number of conditions, most of which will be relatively benign. Also, in many patients with such pain, a firm diagnosis may never be established. When chest pain is a presenting symptom in the emergency department setting, however, more serious, acute, and potentially life-threatening causes need to be considered. Accordingly, a complaint of chest pain requires thorough and careful investigation.

DIFFERENTIAL DIAGNOSIS

The pathophysiology of chest pain is understood for many but not all of the conditions with which it is associated. The most common form of chest pain is musculoskeletal pain. The causes of this form of chest pain are legion—in some instances involving an organic process, often due just to excessive coughing, as discussed later on. Of note, however, possible psychiatric or psychogenic reasons for chest pain need to be kept in mind. Cardiac disease is the most important cause of chest pain overall, so this entity is first in the overview of potential causes.

MYOCARDIAL ISCHEMIA

The chest pain associated with myocardial ischemia is attributed to an imbalance between myocardial oxygen (O_2) supply and demand. Most tissues can increase O_2 supply by increasing O_2 delivery, increasing O_2 extraction, or both. O_2 extraction by the myocardium is much greater than that occurring in other tissues, manifested by the O_2 content of coronary venous blood normally being much lower than that of blood coming from other muscles. Because the ability of the myocardium to increase O_2 extraction is limited, the primary mechanism by which the heart increases O_2 delivery in response to increased demands is to increase coronary blood flow.

Coronary blood flow is determined by the driving pressure (i.e., the aortic pressure minus the left ventricular end-diastolic pressure) and the resistance in the coronary arteries. Chest pain can therefore be caused by conditions that increase myocardial O_2 demand (e.g., hypertension, hyperthyroidism, exercise) in the setting of a limited ability to increase O_2 supply, decrease mean aortic pressure (e.g., aortic stenosis), decrease O_2 delivery (e.g., anemia, hypoxemia), or increase the downstream pressure for coronary arterial flow (e.g., aortic and mitral valve disease, left or right ventricular hypertrophy, or dilatation). The importance of coronary arterial diameter is apparent in Poiseuille's law, which states that resistance is inversely related to the vessel radius taken to the fourth power, explaining why anything that might result in even a small change in coronary arterial diameter (e.g., coronary arterial spasm, thrombosis, atherosclerosis) can result in chest pain.

A wide range of disorders other than angina may be the cause of chest pain. These potential alternative diagnoses are summarized in Box 21-2.

PERICARDIAL PAIN

The visceral pericardium has no pain fibers, and the pain fibers in the parietal pericardium are localized to the caudal (i.e., diaphragmatic) region. This sparse, localized distribution of pericardial pain fibers may explain why most noninflammatory causes of pericardial effusions (e.g., myocardial infarction, uremia) are not associated with chest pain and why inflammatory problems may cause pain only when the inflammation spreads to the visceral pleura.

PULMONARY PAIN

The lung parenchyma and the visceral pleura are insensitive to most painful stimuli, and interference with stretch fibers tends to cause most intrapulmonary symptoms. Pain can arise from the parietal pleura, the major airways, the chest wall, the diaphragm, and the mediastinal structures. Inflammatory conditions affecting the lung periphery or the peripheral portions of either hemidiaphragm cause chest wall pain when the process extends to the parietal pleura and stimulates the intercostal nerves. Inflammation of the parietal pleura that lines the more central portions of the diaphragm stimulates the phrenic nerves, with the result that the pain is referred to the ipsilateral neck or shoulder. The augmentation of pulmonary pain during inhalation is attributable to the stretching of the inflamed pleura. Airway pain can be described as a burning pain, whereas mediastinal pain is a dull, central type of discomfort. For example, about 50% of patients with mediastinal metastatic disease describe this type of symptom.

PULMONARY EMBOLUS

Most cases of pulmonary embolism do not exhibit chest pain. If the embolism is big, chest tightness can be present, but most of the symptoms are related to circulatory disturbances. If pain is associated with acute pulmonary embolism, it is thought to result from distention of the central pulmonary artery or

Box 21-1 Causes of Chest Pain

Cardiac System
- Myocardial infarction
- Myocardial ischemia
  - Angina pectoris
  - Variant angina
  - Syndrome X: microvascular angina in setting of non–insulin-dependent diabetes mellitus, dyslipidemia, and central obesity
  - Myocarditis
- Aortic dissection
- Pericarditis (infections, Dressler syndrome)
- Aortic stenosis
- Syphilitic aortitis
- Takayasu aortitis
- Myocarditis
- Hypertrophic cardiomyopathy

Pulmonary System
- Pleurisy
- Tracheobronchitis
- Tumor
- Pneumothorax
- Pulmonary embolus (with or without infarction)
- Pulmonary hypertension

Gastrointestinal System
- Esophageal reflux
- Esophageal dysmotility (e.g., spasm, achalasia, hyperactive lower sphincter)
- Esophageal rupture
- Peptic ulcer disease
- Biliary colic
- Pancreatitis
- Splenic or hepatic flexure syndrome

Musculoskeletal Conditions
- Costochondritis
- Subacromial bursitis
- Biceps, supraspinatus, or deltoid tendinitis
- Shoulder or spinal arthritis
- Intercostal muscle cramps
- Hyperabduction or strain of the anterior scalene or rectus abdominis muscles
- Fibromyalgia
- Slipping rib syndrome (pain at the costochondral junction, generally affecting the eighth, ninth, or tenth rib; may be posttraumatic)
- Rib fractures
- Sternal marrow pain (with acute leukemia)

Neurologic Conditions
- Neuritis-radiculitis (cervical compression, herpes zoster infection)
- Brachial plexus involvement (cervical rib, spasm of the scalenus anterior, Pancoast tumors)

Others
- Breast inflammation
- Chest wall tumors
- Mondor syndrome (thrombophlebitis of the superficial thoracic veins)
- Diaphragm spasm
- Mediastinal emphysema
- Mediastinitis
- Panic attacks
- Hyperventilation syndrome

Box 21-2 Potential Causes of Chest Pain Other Than Angina

Cardiovascular
Aortic dissection; pericarditis

Pulmonary
Pulmonary embolism or infarction, pneumothorax, pneumonia, pleuritic pain

Gastroesophageal
Esophageal spasm and/or reflux, esophageal rupture, biliary inflammatory conditions, pancreatitis, peptic ulceration

Chest Wall
Costochondritis, fractured rib, rib/spinal metastases, herpes zoster, fibrositis, muscular strain

Pericardial
Inflammatory, neoplasia, post–myocardial infarction (Dressler syndrome), postirradiation, drug-induced, connective tissue disorders

Psychiatric
Anxiety disorders (panic, hyperventilation), depression, thought disorders and fixations

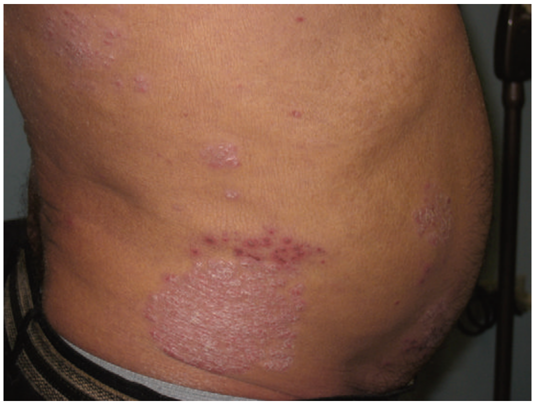


Figure 21-1 Herpes zoster infection affecting an intercostal nerve.

arteries. Pain occurring later in the illness is attributable to infarction of a peripheral segment of lung and occurs with concomitant inflammation of the adjacent pleura.

PULMONARY HYPERTENSION

The pain of chronic pulmonary hypertension is attributed to the disparity between right ventricular myocardial O_2 supply and demand, although vascular distention also may play a part.

MUSCULOSKELETAL PAIN

Costochondral and chondrosternal articulations are common sites of anterior and anterolateral chest pain. The articulations of the second, third, and fourth ribs are most commonly involved. When accompanied by swelling, redness, and heat, the condition is referred to as Tietze syndrome. Coughing or trauma can dislocate the costochondral junctions (most commonly those of ribs 10 to 12). The pain resulting from intercostal neuritis most frequently results from cervical osteoarthritis. Intercostal neuritis also is seen with herpes zoster infection, in which the onset of pain may precede the typical rash by 1 or 2 days (Figure 21-1). Thoracic roots most commonly are involved.

Subacromial bursitis, biceps or deltoid tendinitis, and arthritis of the shoulder can manifest as chest pain with extension to the shoulder and arm. The brachial plexus and subclavian artery can be compressed by a cervical rib, or by spasm of the scalenus anticus muscle. In the Pancoast syndrome (most commonly but not exclusively caused by bronchogenic carcinoma), invasion of the C8, T1, and T2 nerve roots by tumor may be the cause of considerable pain and other symptoms such as muscular weakness (**Figure 21-2**).

ESOPHAGEAL REFLUX OR DYSMOTILITY

The chest pain resulting from esophageal reflux or dysmotility (e.g., esophageal spasm, achalasia, hyperactive lower sphincter) results from acid irritation of the esophageal mucosa. Esophageal reflux or dysmotility accounts for the chest pain that occurs in as many as 30% of patients with normal findings on a coronary arteriogram.

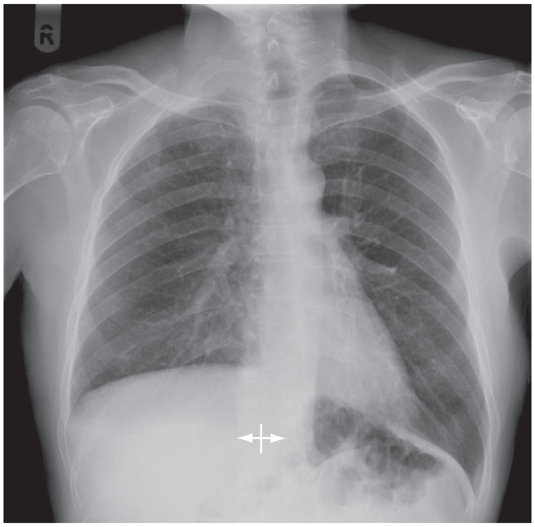

Figure 21-2 Chest radiograph showing a right apical lesion destroying the posterior parts of the first and second rib, with a soft tissue mass extending into the neck.

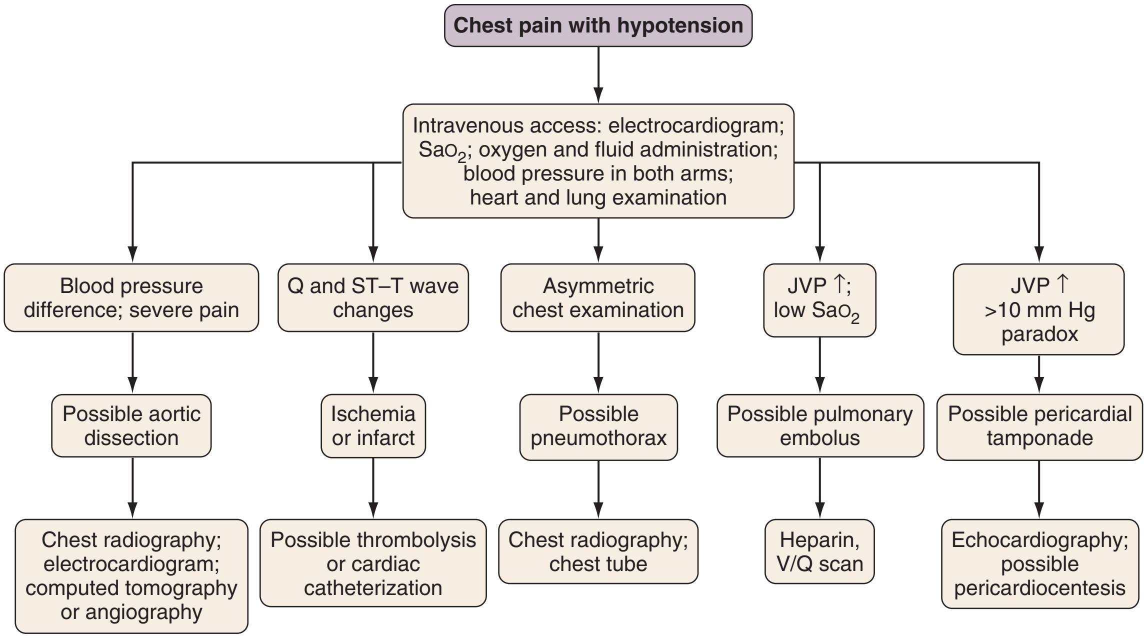
PATIENT EVALUATION

The approach to patients complaining of chest pain should focus initially on the potentially lethal causes of the symptom, especially in the emergency department or similar setting (**Figure 21-3**). Severe pain is more commonly associated with life-threatening causes, but any of these conditions may occur with minimal symptoms. Accordingly, patients frequently are treated as if the chest pain were life-threatening until these more serious conditions can be excluded by studies that yield more specific information than that obtainable at the time of the initial presentation.

CLINICAL PRESENTATION

If the pain is acute (and therefore generally of short duration) and the patient is hypotensive, myocardial infarction, pulmonary embolism, pericardial tamponade, dissecting aneurysm, and tension pneumothorax should be considered first (see Figure 21-3). Less commonly, this clinical syndrome can result from a ruptured esophagus, which not infrequently is missed because it is rare and the emergency physician may be reassured by normal findings on cardiac evaluation. In other patients, the approach is governed primarily by the findings on history and physical examination, which are interpreted on the basis of actual or estimated previous probabilities for each of the conditions listed in Box 21-1. For example, a middle-aged man with one or more risk factors for coronary artery disease (e.g., hypercholesterolemia, diabetes, hypertension, obesity, smoking) who experiences exertional chest pain typical for coronary artery disease that abates with rest has a greater than 90% probability of having myocardial ischemia as the cause of his symptoms. By contrast, a 20-year-old pregnant woman with a chest infection, cough, and localized chest pain is far more likely to have a spontaneous rib fracture.



Chest pain with hypotension
Intravenous access: electrocardiogram; Sao_2; oxygen and fluid administration; blood pressure in both arms; heart and lung examination
Blood pressure difference; severe pain
Q and ST–T wave changes
Asymmetric chest examination
JVP ↑; low Sao_2
JVP ↑ >10 mm Hg paradox
Possible aortic dissection
Ischemia or infarct
Possible pneumothorax
Possible pulmonary embolus
Possible pericardial tamponade
Chest radiography; electrocardiogram; computed tomography or angiography
Possible thrombolysis or cardiac catheterization
Chest radiography; chest tube
Heparin, V/Q scan
Echocardiography; possible pericardiocentesis

Figure 21-3 Evaluation algorithm for management of the severely ill patient with chest pain. Therapeutic approach is determined by blood pressure and findings on brief examination of the neck, chest, and head. *JVP*, jugular venous pressure; *SaO_2*, arterial oxygen pressure; *V/Q*, ventilation-perfusion.

HISTORY

The onset, duration, location, radiation pattern, character, and intensity of the pain should be ascertained, as should the factors that precipitate or diminish it. Unfortunately, both the sensitivity and specificity of the history are low for many of the conditions that must be considered in the differential diagnosis. For example, most episodes of electrocardiographically documented ischemia in patients with stable angina are asymptomatic. A history of cocaine, crack, or other stimulating drug use should be sought.

Cardiovascular Disorders

The pain of *myocardial ischemia* frequently is described as a dull pain accompanied by a sensation of tightness, pressure, squeezing, or heaviness in the chest. It characteristically radiates down the ulnar aspect of the left arm, but radiation to the neck or jaw also occurs. The pain develops gradually; occurs in association with exertion, emotional distress, or large meals; and abates within 2 to 10 minutes after the stressful activity is curtailed or within 5 minutes of administration of nitroglycerin.

The pain associated with *myocardial infarction* is of greater intensity and lasts longer. In addition, it can be associated with nausea (particularly with inferior infarctions), diaphoresis, hypotension, or arrhythmias and is not relieved by nitroglycerin.

Variant or *Prinzmetal angina* occurs in the early morning and at rest, rather than during stress, and results from coronary artery spasm. Patients with this type of angina frequently have other vasomotor symptoms such as migraine headaches or Raynaud phenomenon. Angina that occurs with a progressively lesser degree of exertion is considered unstable and is thought to be secondary to rupture of an atherosclerotic plaque with thrombin formation and coronary vasospasm.

Pericardial pain may be pleuritic in nature but more commonly is steady, worsens when the patient is recumbent or lying on the left side, and lessens when the patient sits up and leans forward. The pain often is centrally situated and radiates symmetrically to the upper portion of the trapezius muscles. The pain can be pleuritic if the adjacent parietal pleura is involved in the inflammatory process. Pericardial pain can radiate to the shoulder, neck, flank, or epigastrium. Because inflammatory causes are common, the history may include viral infection–type symptoms—myalgia, fever, and malaise. Similarly, in patients with known malignant disease, the main considerations in the differential diagnosis should be pericardial effusion and tamponade due to dissemination of an adenocarcinoma. Connective tissue disorders—rheumatoid arthritis, systemic lupus erythematosus, polymyositis, dermatomyositis, and scleroderma—also can be associated with pericardial pain.

The pain of a *dissecting aortic aneurysm* begins abruptly, becomes extremely severe within seconds or minutes, and radiates to the back, abdomen, neck, flank, and legs. It commonly is described as "tearing" and may be associated with an acute cerebrovascular event; a cold, pulseless extremity; and aortic insufficiency. Unusually large amounts of analgesic agents generally are needed to provide relief.

Pulmonary Inflammation and Chest Wall Problems

Many adjectives have been used by afflicted persons to describe the pain resulting from conditions that cause pulmonary inflammation or chest wall problems, but the pain is almost always pleuritic in nature in that it increases with forced inhalation or exhalation (e.g., during coughing or sneezing), during spontaneous breathing, and when pressure is applied to the chest wall by bending or lying down. In response to the pleuritic or positional character of the pain, patients frequently limit their depth of inhalation and, accordingly, may complain of dyspnea, rather than or in addition to pain.

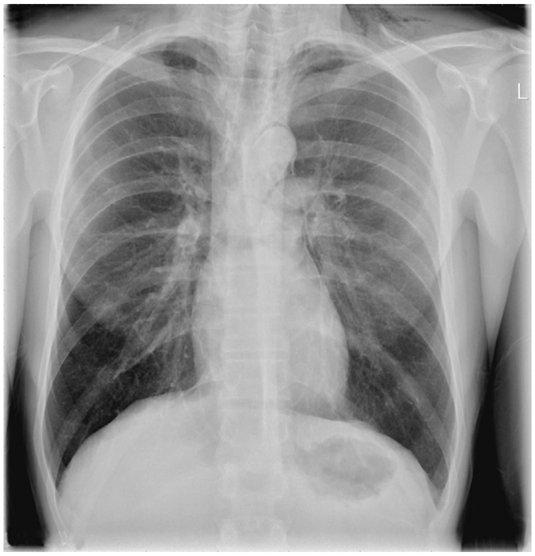


Figure 21-4 Chest radiograph obtained in patient with retrosternal pain of sudden onset. The image shows a pneumomediastinum, with air at the left heart border and around the aortic knuckle.

An abrupt onset suggests a rib fracture, pneumothorax, or pneumomediastinum (Figure 21-4). A more gradual onset over a few minutes or hours is seen with bacterial pneumonia and pulmonary emboli, and a gradual onset (e.g., days or weeks) is more compatible with chronic infections (e.g., tuberculosis, fungal infections) or tumor.

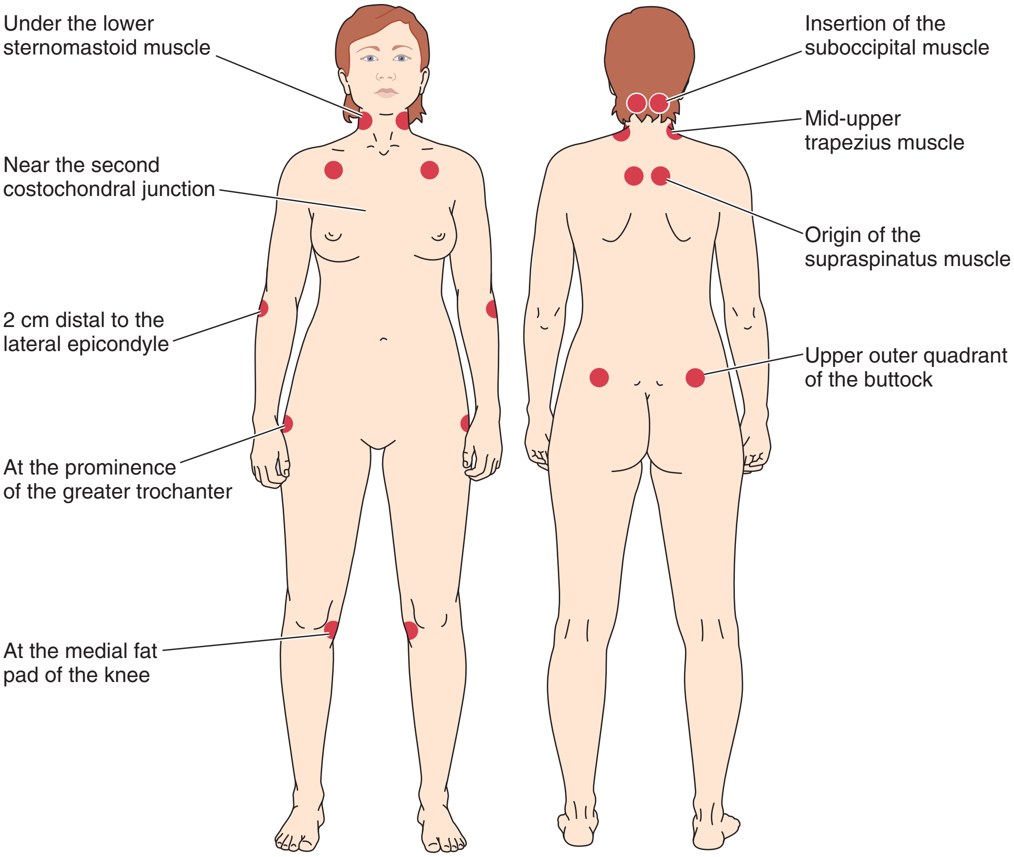
Patients with chronic obstructive pulmonary disease who experience an acute exacerbation of bronchitis frequently describe a burning type of chest pain that localizes to the substernal region. A similar symptom can occur in otherwise normal subjects in the setting of tracheobronchitis or during the hyperventilation that accompanies heavy exercise, particularly if the exercise is done in a cold environment.

In many instances, patients with costochondral pain or pain that results from muscle strains describe an episode of chest trauma or unusual upper extremity exercise (e.g., gardening, digging, scraping) that can result in an overuse syndrome. More commonly, no specific inciting event can be determined. The costosternal articulations are common "trigger sites" for the pain of fibromyalgia. Patients with this syndrome also have trigger sites in other locations (Figure 21-5). Musculoskeletal conditions generally are exacerbated by deep breathing and frequently are overlooked as causes of pleuritic or exercise-induced chest pain. The patient often can localize the painful area, where tenderness or muscular spasm may be elicited by palpation.

Intercostal neuritis commonly is described as being pleuritic. One potentially distinguishing characteristic is that patients may describe abrupt, electric shock–like sensations occurring in the same distribution as for the pleuritic pain.

Bursitis, Tendinitis, and Arthritis

Subacromial bursitis, biceps and deltoid tendinitis, and arthritis of the shoulder can manifest as chest pain with extension to



Under the lower sternomastoid muscle
Near the second costochondral junction
2 cm distal to the lateral epicondyle
At the prominence of the greater trochanter
At the medial fat pad of the knee
Insertion of the suboccipital muscle
Mid-upper trapezius muscle
Origin of the supraspinatus muscle
Upper outer quadrant of the buttock

Figure 21-5 Tender points in fibromyalgia.

the shoulder and arm. In these conditions, the pain is worse with neck or shoulder movement but is not exercise-related.

Gastrointestinal Disorders

Like angina, the pain of esophageal reflux or dysmotility is located substernally; can radiate to the throat, neck, or left arm; and may be relieved by nitroglycerin. Unlike angina, however, the pain is rarely associated with exertion. Rather, it is exacerbated by bending, stooping, drinking alcohol, or lying supine and frequently is worse in the early morning, in association with acidic gastric secretions. Chest pain from esophageal reflux or spasm typically lasts for 1 hour or longer and may be relieved to a variable degree by sitting upright or by ingesting antacids or food. The history also may be positive for odynophagia, dysphagia, or regurgitation of undigested food.

Esophageal rupture is a life-threatening condition if not recognized rapidly and repaired. It can occur in otherwise healthy persons, in whom it may follow an episode of choking while swallowing, or violent or prolonged vomiting. It usually is accompanied by a distinct acute central episode of chest pain, sweating, and then hypotensive symptoms, with onset of pleuritic pain as gastric fluid leaks into the chest cavity. Dysphagia also may be pronounced. A CT scan with a contrast swallow can be diagnostic, showing air to have leaked into the mediastinum (Figure 21-6).

The pain associated with peptic ulcer disease, biliary colic, or pancreatitis generally begins 1 or 2 hours after eating. Pain associated with peptic ulcer disease may lessen or worsen with eating. The pain associated with biliary colic and pancreatitis frequently is accompanied by nausea and vomiting.

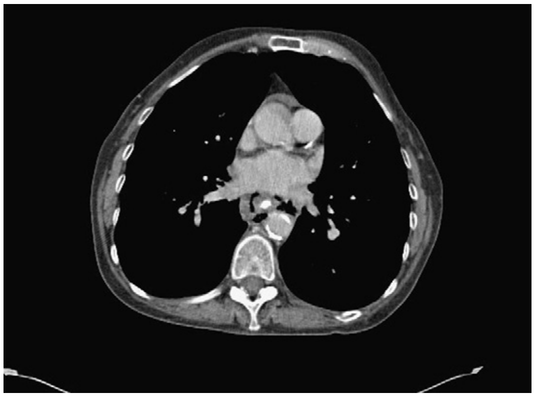


Figure 21-6 Computed tomography (CT) scan performed with contrast swallow shows the esophagus with air surrounding it in the mediastinum. This appearance is highly suggestive of esophageal rupture.

PSYCHIATRIC DISORDERS

Psychiatric disorders should always be considered only if physical explanations have been exhausted. Of note, however, chest pain is a well-recognized manifestation of anxiety, as, for example, in a patient with a near relative of emotional importance (i.e., with whom the patient identifies) who has suffered a heart attack. Depression can produce a myriad of physical symptoms, as can fixative ideology. It often can be most useful to ask the sufferer of chest pain about a particular anxiety regarding the cause of the pain, or if the person knows someone with a similar symptom.

PHYSICAL EXAMINATION

Although the physical examination may provide a number of clues, the findings may be entirely normal even when the pain results from a life-threatening condition. Shallow, more rapid respirations may suggest pleural inflammation or a musculoskeletal cause of pain. Cyanosis may suggest hypoxemia from a variety of pulmonary or cardiac problems. Xanthelasma and tuberous xanthomas suggest the presence of coronary disease. The onset of clubbing heralds intrapulmonary pathology, as may the finding of significant lymphadenopathy.

In addition to the standard vital signs, blood pressure should be measured in *both* upper extremities, because a disparity would suggest aortic dissection. Heart rate and rhythm abnormalities suggest acute ischemia or pulmonary embolism. Fever points away from musculoskeletal pain and suggests pneumonia, pulmonary embolus, pancreatitis, or biliary obstruction. Patients with myocardial infarction may be febrile, but the temperature rarely exceeds 38° C.

Elevated jugular venous pressure, abnormalities in the carotid upstroke, crackles, a pleural or pericardial rub, signs of parenchymal consolidation, gallop rhythms, paradoxical or fixed splitting or an increased intensity of the pulmonary component of the second heart sound, and cardiac murmurs have a high specificity for many of the cardiopulmonary disorders associated with chest pain. The sensitivity of these physical findings probably is low, however, because the physical examination may be entirely normal in patients with severe ischemia, pulmonary emboli, and many of the gastrointestinal causes of pain.

Attempts can be made to reproduce or exacerbate the pain by moving the patient's arms and shoulders and by thoroughly palpating the chest wall, particularly over the peristernal region and the costochondral junctions, as well as the subacromial bursae, the deltoid tendons, the shoulders, and the abdomen. Asking the patient to perform the maneuvers that produce the pain also can be helpful.

Intercostal neuritis frequently is associated with hyperalgesia or anesthesia over the distribution of affected intercostal nerves. Biliary colic and pancreatitis frequently are associated with right upper quadrant and midline abdominal tenderness, respectively. Clearly, it is vital not to miss important physical disease in the chest wall. Careful, gentle palpation with both hands over the skin, musculature, ribs, and vertebrae may identify tender areas that signify a serious problem (Figure 21-7, *A* and *B*).

DIAGNOSTIC TESTS

Patients without a previous diagnosis of coronary artery disease are not likely to have an acute myocardial infarction as the explanation for the acute onset of chest pain if the pain does not radiate to the neck, left shoulder, or arm and if the electrocardiogram and serial serum troponin levels are normal. Although the finding of flat or downsloping ST segment depression greater than 0.1 mV increases the likelihood that an episode of chest pain is caused by myocardial ischemia, the tracing may be normal at rest, between attacks, or even in the presence of active ischemia. Up to 80% of patients with coronary disease exhibit these ST segment changes during exercise, but such changes also may be found in up to 15% of patients with no evidence of disease at cardiac catheterization. Nonspecific ST-T wave changes have been documented in the setting of acute cholecystitis and esophageal spasm, as well as in other conditions for which chest pain is a presenting symptom (Table 21-1).

Chest radiographs should be obtained in all patients with chest pain unless a clear-cut musculoskeletal cause of the pain

Table 21-1 Electrocardiographic Findings in Conditions Manifesting with Chest Pain

Condition	Electrocardiographic Finding(s)
Acute cholecystitis	Inferior ST segment elevation
Pulmonary embolism	Inferior ST segment elevation
Dissecting aortic aneurysm	ST segment elevation ST segment depression
Pneumothorax	Poor R wave progression Acute QRS axis shift
Pericarditis	ST segment elevation (generally diffuse)
Myocarditis	ST segment elevation

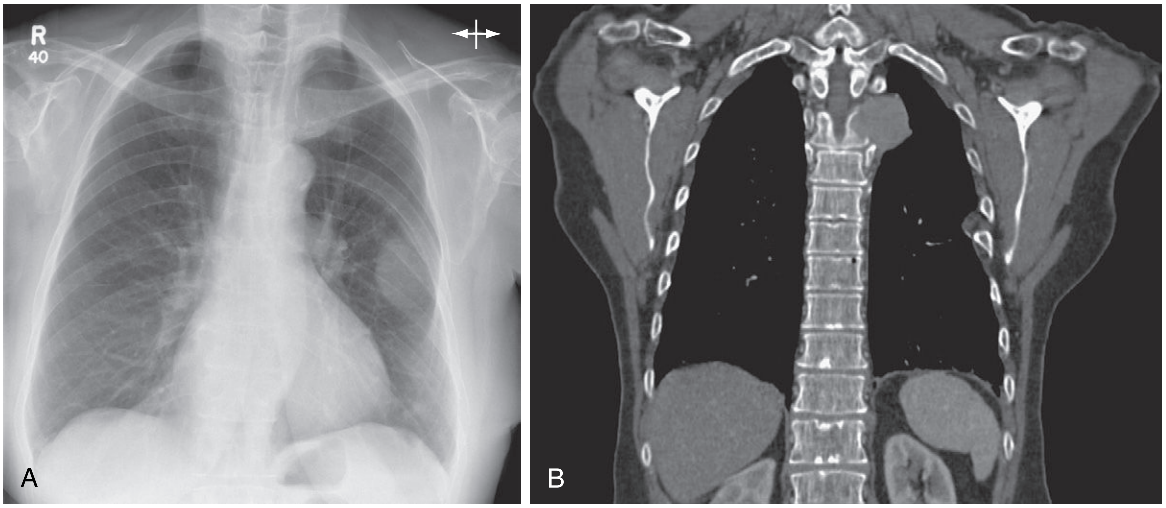

Figure 21-7 **A,** Chest radiography showing two soft tissue masses originating from bone. Clinical findings included tenderness on the left side of the chest and over the upper thoracic spine. **B,** Coronal computed tomography (CT) image showing the soft tissue mass invading and destroying a thoracic vertebra.

is evident on clinical evaluation. With myocardial ischemia or infarction, the chest radiograph may be entirely normal in appearance. Alternatively, it may reveal pulmonary edema, upper lobe vascular redistribution, valvular disease, or pericardial disease.

Chest radiographs may be normal-appearing in the setting of acute pulmonary emboli, although minor degrees of atelectasis, small effusions, or distention of the central pulmonary vessels may be seen. A small or an apical pneumothorax can be difficult to see, but if this lesion is suspected, a film exposed with the patient in full expiration will make it much larger and obvious. Careful radiographic review of all ribs should identify a fracture, most commonly located in the lower ribs if due to coughing. Local rib tenderness always warrants a chest radiograph (Figure 21-8). Anatomic anomalies such as a cervical rib, which may be the cause of root pain, should be looked for as appropriate. If pleuritic pain is associated with minor change, such as the obliteration of a costophrenic angle, obtaining a follow-up radiograph 24 hours later may show obvious development of the cause of chest pain. Pericardial causes of pain will become evident only if an effusion is gathering by causing the cardiac outline to enlarge; an effusion also may be a sign of malignant disease elsewhere within the chest, or of joint disease in connective tissue disorders.

A widened mediastinum or an apical effusion on films exposed with the patient in the supine position (Figure 21-9) suggests the possibility of a ruptured aortic aneurysm.

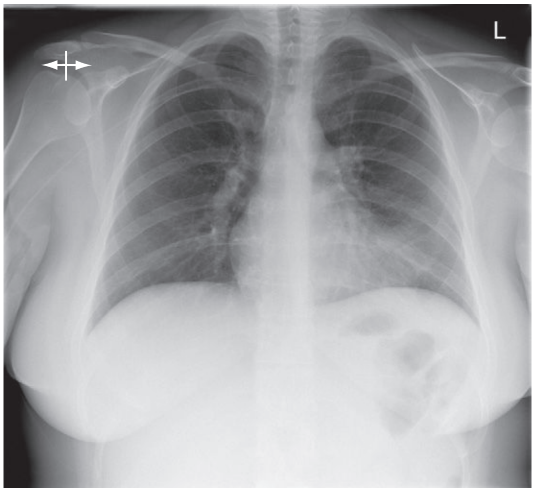

Figure 21-8 Splaying of the left sixth rib by a metastasis from a Ewing sarcoma manifesting as a soft tissue mass. The patient was a young man who presented with vague chest pain.

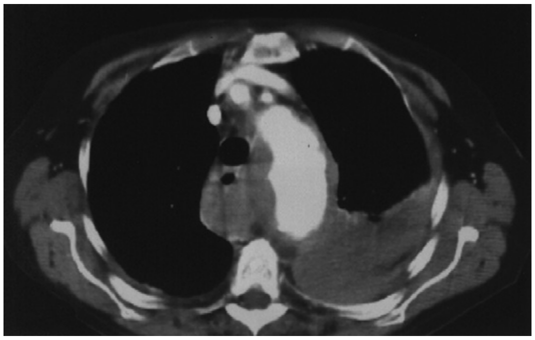

Figure 21-9 Aortic aneurysm. Chest computed tomography (CT) scan showing a dissecting aortic aneurysm.

A set of routine blood tests should be performed to identify abnormality of white cell count or renal or liver function an abnormality here may focus further investigations as appropriate. In addition, troponin T increases 4 to 12 hours after myocardial infarction and is a better predictor of acute infarction than creatine kinase–MB, because the latter increases in both infarction and ischemia. Troponin T can increase as a result of rhabdomyolysis in absence of ischemia, however. A normal result on D-dimer assay excludes pulmonary embolism for all practical purposes in all patients except those believed to be at high risk for this condition.

Computed tomography can be diagnostic for pulmonary embolism (especially when performed as a CT pulmonary angiogram), as well as for pneumothorax, esophageal rupture, pericardial disease, small pleural effusions, superior sulcus tumors, and mediastinal disease.

TREATMENT

Pharmacotherapy for patients with myocardial infarction or an acute coronary syndrome (e.g., patients with unstable angina or those with myocardial infarction but without non–ST segment elevation) includes aspirin, nitrates, β-adrenergic blockers, and low-molecular-weight heparin. Further details of management of these clinical entities are beyond the scope of this discussion.

The acute pericarditis that occurs in the setting of large myocardial infarctions generally responds to aspirin. Nonsteroidal antiinflammatory agents or corticosteroids may be contraindicated, because these agents slow the rate at which myocardial scar formation occurs and, therefore, may be associated with an increased frequency of myocardial rupture. The pain associated with Dressler syndrome (i.e., pericarditis developing 1 to 2 months after an infarction in association with fever, leukocytosis, and elevations of antimyocardial antibodies) is treated with nonsteroidal antiinflammatory agents. Systemic corticosteroids may be needed in more severe cases.

The pain associated with pulmonary inflammation may respond to nonsteroidal antiinflammatory agents, although opiates occasionally are needed. The pain associated with pneumothorax may be quickly replaced by that associated with the chest tube, and opiates may be required, to circumvent “guarding”-induced limitation of chest wall movement, with associated risk of respiratory infection.

In addition to elevating the head of the bed (or use of the reverse Trendelenburg position in markedly obese subjects), the pain associated with esophageal reflux also may be reduced by avoiding food or liquid intake before reclining, eliminating substances known to reduce the lower esophageal sphincter pressure (e.g., coffee, chocolate, alcohol, mint), and the use of antacids, calcium channel blockers, histamine H_2 receptor antagonists, metoclopramide, nitroglycerin, or proton pump inhibitors. Gastroplasty may be indicated in selected patients. Esophageal dysmotility has been treated with long-acting nitrates and calcium-channel blockers. Antacids, proton pump inhibitors, H_2 antagonists, sucralfate, and agents effective against *Helicobacter pylori* may be needed to eliminate the pain associated with peptic ulcer disease. The pain of pancreatitis generally requires narcotics. Meperidine is favored over other opiates, because it does not contract the sphincter of Oddi. Intractable pain is a common indication for surgical or invasive endoscopic approaches.

Patients with musculoskeletal pain can be treated with nonsteroidal antiinflammatory agents or the stretching exercises that are used in physical therapy. The chest pain associated with fibromyalgia may be relieved with use of amitriptyline. Most chest physicians see large numbers of patients with musculoskeletal pain, which can continue for months; an essential component of management of such patients is reassurance that the symptom is self-limiting and will go away over time. In some instances, a CT examination may be necessary to demonstrate the absence of a specific cause for the pain. Whiplash-associated pains within the chest and pain caused by seatbelts after road traffic accidents are common and can last for months; initial management should consist of reassurance, with regular analgesia only in the early days after the trauma. Long-term antiinflammatory medication is associated with its own problems, so physiotherapy, ultrasound, and graded exercise programs are very useful and important in this clinical scenario.

The pain associated with herpes zoster infections may be so severe as to require narcotics for control. Amitriptyline and fluphenazine also have been used, as have systemic corticosteroids.

INFECTIOUS DISEASES

Chapter **22**

Pulmonary Host Defenses

Theo J. Moraes • Chung-Wai Chow • Gregory P. Downey

The epithelial surface of the lung is continuously exposed to a variety of potentially pathogenic microorganisms, allergens, particulate pollutants, and other noxious agents. An intricate defense system has evolved over time to protect the lungs from these potentially harmful entities while preserving homeostasis and lung function (Figure 22-1). This system of defense mechanisms has two components: an innate (nonspecific) response and an adaptive or acquired (specific) response.

The *innate* immune response is evolutionarily conserved to provide immediate (occurring over seconds to minutes) host defense in a broad, nonspecific manner. Only vertebrates have an additional, *adaptive* immune system, which is directed at specific pathogens or molecules. Although the two systems work in concert to protect the host, each has several distinctive features. With rare exceptions, the innate component of the immune system depends on proteins and signaling pathways that exist in a fully functional form, does not require priming, and is not strengthened with subsequent exposures. By contrast, the adaptive immune response requires additional time (days to weeks) (see Figures 22-2 and 22-3) to ramp up to full capacity, is specific to the pathogen (and even to specific molecular determinants of the pathogen), and has memory to provide for stronger responses with subsequent attacks (“anamnestic response”).

Together, these immune responses provide a formidable force to combat invading pathogenic microbes, as indicated by the rarity with which healthy humans succumb to lung infections. Specific components of the innate and adaptive host defense mechanisms are reviewed in this chapter.

STRUCTURAL DEFENSES

With a surface area in adults of 70 m^2, which comes into contact with roughly 10,000 L of air a day, the lung is confronted with constant threats from microbes. In addition to inhaled pathogens, high bacterial concentrations are present in oropharyngeal secretions (10^8/mL), and aspiration of these secretions also may pose a serious risk for invasive infection (aspiration pneumonia). Historically, the lung has been considered to be a sterile environment; recent developments in molecular analysis have provided evidence for the presence of a microbial flora of considerable diversity in the lung, which moreover is altered in disease states. Accordingly, the respiratory tract has developed a series of structural barriers that are designed both to minimize the number of pathogenic microbes entering the lungs and to hasten their clearance before an infection can be established (Table 22-1).

Particle size is an important factor determining the degree of penetration into the airways (Table 22-2). Very large particles are filtered by vibrissae (nasal hairs). Particles approximately 30 μm in diameter are removed in the nasal passages, where turbulent airflow results in prolonged air-mucosa contact, with subsequent particle impaction. Most particles between 10 and 30 μm in diameter also will be deposited on the turbinates and nasal septum, carina, or within the larger bronchi. The branching nature of the airways provides two additional mechanisms of protection: (1) the secondary, tertiary, and quaternary carinae force particles to embed in the airway mucosa, thereby preventing further penetration into the lung, and (2) reduced airflow with increased airway branching allows gravity to sediment most particles larger than 2 μm. Particles less than 0.2 to 0.5 μm across tend to stay suspended as aerosols and are exhaled. Much smaller particles (less than 0.1 μm) may be deposited as a result of brownian motion (bombardment with gas molecules).

Thus, only particles roughly between 2 and 0.2 μm in diameter will reach the alveoli. Unfortunately, most bacteria are from 0.5 to 2 μm in size and, when inhaled, may reach the terminal bronchioles, where they have the potential to establish an infection. Some exceptionally pathogenic bacteria require exceedingly small numbers (e.g., only 2 to 50 organisms) to establish infection.

In addition to particle size, other factors such as shape, charge, and state of hydration may influence the depth of penetration. For example, the grass heads of timothy grass, or *Alternaria*, can penetrate deeper into the lung than would be expected from their physical size.

NARES

The efficiency of the nose in filtering inspired air and trapping aerosolized particles has been highlighted by inhaled drug delivery studies that demonstrate better pulmonary drug deposition with mouth inhalers than with mask inhalers. Nasal congestion and increased mucus production also contribute to trapping of unwanted particles or microbes, preventing them from going further into the airways.

In addition to filtration, the nose functions to warm and humidify inspired air, thus protecting cells from physical stress and ensuring optimal performance of the mucociliary system. Olfaction also is protective, because sniffing allows potentially harmful gases to be detected before they contact the lower airways.

As noted previously, however, the upper respiratory tract may be a source of infection when aspiration of small amounts of upper airway secretions leads to compromise of the host pulmonary system. Microbial colonization is normal, and although potential pathogens can be isolated from the

Figure 22-1 Pulmonary host defense. The pulmonary host defense system is composed of multiple components, including physical barriers such as the nose and mucous layer that lines the airways. Mechanisms also exist to remove offending microbial pathogens or noxious particles, either directly by phagocytosis or endocytosis or indirectly by mediator-regulated responses. Activation of the immune and inflammatory responses usually will facilitate resolution of the injury and clinical recovery of the patient. However, if these immune and inflammatory responses are excessive or unregulated, tissue injury and disease ensue.

2. Expression of growth factors, inflammatory mediators leads to tissue repair
1. Expression of inflammatory mediators leads to damage of the epithelial barrier
2. Exudation of plasma and mediators contributes to and enhances antimicrobial properties of airway surface liquid
1. Expression of chemokines, adhesion molecules leads to leukocyte recruitment and activation
2. Antigen presentation by dendritic cells/monocyte-macrophages induces lymphocyte recruitment and activation

nasopharynx of healthy persons, under normal conditions, resident flora competitively inhibit the growth of pathogens.

COUGH/SNEEZE

Mechanical or chemical stimulation of receptors in the nose, larynx, or trachea or elsewhere in the respiratory tree may produce bronchoconstriction to prevent deeper penetration of irritants and also may trigger the cough or sneeze reflex to expel particles deposited in the airways (Table 22-3). The cough reflex aids mucociliary transport to remove trapped particles. Mucus usually is conveyed to the carina by the cilia and then expelled by coughing from this location. Disruption of the cough reflex (e.g., in smokers or patients with vocal cord palsy or stroke) results in a predisposition to pneumonias.

GLOTTIS

The digestive tract and the respiratory tract share both an embryologic origin and an opening to the external world (the mouth). The glottis protects the lungs from potential contamination of the airways with digestive tract material. Nevertheless, small amounts of aspiration do occur from the nasopharynx and oropharynx or esophagus in healthy people, usually without pathologic consequences. Of importance, frequent aspiration or episodes of aspiration of large amounts of material, as is seen

Table 22-1 **Structural Defenses of the Airway**

Structure	Functions
Nose	Filters air Warms and humidifies air Sediments particles Olfaction Sneeze reflex
Glottis	Protects from gastrointestinal and nasopharyngeal contamination Cough reflex
Mucociliary escalator	Traps foreign particles Facilitates physical removal of particles
Epithelium	Barrier to microbes Mucociliary escalator Production of antimicrobial factors Cytokine production Adhesion molecule expression

Table 22-2 **Effect of Particle Size on Penetration into Airways**

Particle Size	Fate
>>>30 µm	Filtered by vibrissae
>30 µm	Nasopharyngeal impaction
10 to 30 µm	Nasopharyngeal, tracheal, and large bronchial impaction
2 to 10 µm	Sedimentation in airways
0.2 to 2 µm	Reach alveoli
0.2 to 0.5 µm	Exhaled
<0.2 µm	Exhaled or deposited (brownian motion)

Table 22-3 **Phases of Cough/Sneeze**

Component	Event(s)
1. Inspiratory phase	Deep inspiration, usually 1 to 2 times tidal volume
2. Compression phase	Begins with closure of the glottis and contraction of respiratory muscles, resulting in the generation of high intrathoracic pressure (up to 100 to 200 cm H_2O in adults)
3. Expressive phase	Glottal opening, with airflow at rates as high as 25,000 cm/sec (partly helped by compression of airway cross section)
4. Relaxation phase	Relaxation of respiratory muscles with temporary bronchodilatation

in persons with glottic dysfunction, can lead to bacterial pneumonia and chemical pneumonitis and possibly contribute to pulmonary fibrosis.

RESPIRATORY EPITHELIUM

The respiratory epithelium is a highly effective barrier to microbes. Conducting airways are lined with pseudostratified columnar epithelial cells that become cuboidal as the branches extend to the alveoli. Specialized structures termed tight junctions separate the epithelial monolayer into apical (luminal) and basolateral components that form an important barrier to the passive passage of molecules and microbes from the airway lumen or alveolar space.

In addition to this important physical barrier function, epithelial cells, including ciliated cells, goblet cells, serous cells, basal cells, and Clara cells, are integral to the normal function of the mucociliary escalator, the production of a variety of antimicrobial molecules, and the initiation and regulation of inflammatory responses (see Figure 22-4).

MUCOCILIARY ESCALATOR

The airway epithelium is lined from the trachea to the respiratory bronchioles by the airway surface liquid (ASL), a 5- to 25-µm-thick surface film the primary function of which is to trap and facilitate the physical removal of foreign particles, as well as to provide an environment conducive to the activity of antimicrobial molecules (**Table 22-4**).

ASL is a critical component of the mucociliary escalator and is the result of secretion by glands and serous cells and of plasma transudation (**Table 22-5**). The inner low-viscosity periciliary sol facilitates the coordinated beating action of the cilia that propels the outer viscous mucous blanket toward the glottis, thereby facilitating the removal of trapped pathogens or particles by expectoration or ingestion. The viscous mucus is composed of mucopolysaccharides, produced predominantly by submucous glands in the larger airways, with increasing contributions from goblet cells and Clara cells with successively larger airway generations.

Dysfunction of the ASL is seen in conditions such as asthma and chronic bronchitis, in which excessive mucus is produced, resulting in airway obstruction. In cystic fibrosis, defects in ion transport are thought to reduce ASL volume, thus increasing viscosity of the mucus. This altered environment impairs mucociliary clearance and predisposes the lungs to bacterial colonization, highlighting the importance of the antimicrobial function of normal ASL.

The cilia are the second key component of the mucociliary escalator and are present from the upper airways down to the terminal bronchioles. There are approximately 200 cilia per ciliated cell. Each of these protuberances is approximately 6 µm long and 0.2 µm in diameter. The cilia are arranged longitudinally to coordinate a beating activity of 500 to 1500 beats/minute, which serves to efficiently propel the mucous layer. Abnormal ciliary function may be related to primary ciliary dyskinesia (most frequently consequent to defects in the microtubule structure of the cilia) and predisposes the lungs in affected persons to development of pneumonia and bronchiectasis. In turn, bronchiectasis, whether associated with genetic causes such as cystic fibrosis or arising as an acquired condition such as sequelae of pulmonary infections, including pulmonary tuberculosis, can lead to localized ciliary dysfunction.

Although these structural components of the respiratory system are not formally considered to be part of the immune system, together they nonetheless constitute a vital and early component of the microbial defense systems of the lung.

SPECIFIC CELL RESPONSES

Diverse cell populations contribute to the host defense system of the lung. In addition to the cells of the respiratory

epithelium, these include other structural cells of the lung, the pulmonary vascular endothelium and fibroblasts, resident leukocytes, and, at later stages of immune responses, recruited immune cells (Table 22-6), as reviewed next.

EPITHELIAL CELLS

The contribution of the respiratory epithelium is not limited to its roles as a structural barrier and facilitator of mucociliary clearance (Box 22-1). Respiratory epithelial cells actively participate in the regulation of inflammation and are capable of mounting an immune response by internalization of organisms and secretion of cytotoxic and antimicrobial peptides. Inhaled microbial pathogens including bacteria and viruses and other antigens can trigger activation of pathogen recognition receptors (such as Toll-like receptors [TLRs], discussed later in some detail under "Innate Immune Receptors") expressed by epithelial cells. Epithelial cells are induced by bacterial components, such as LPS, and by cytokines such as tumor necrosis factor (TNF)-α and interleukin-1β (IL-1β) to express various gene products (by the NFκB signaling pathway, discussed later on) that modulate the inflammatory response (Figure 22-4). Such inducers include the following:

- Cytokines such as TNF-α, IL-1β, and thymic stromal lymphopoietin (TSLP)
- Chemokines that include macrophage inflammatory protein (MIP)-2, CXC chemokines, monocyte chemoattractant protein (MCP)-1, IL-7, IL-8, IL-15
- Nitric oxide (NO) and reactive nitrogen species ($ONOO^-$)
- Adhesion molecules such as β-integrins and intercellular adhesion molecule-1 (ICAM-1)
- TLRs such as TLR-2 and TLR-4
- TNF-α receptors, TNFR1 and TNFR2
- Growth factor receptors such as epidermal growth factor receptor (EGFR) and platelet-derived growth factor receptor (PDGFR)
- Plasminogen activator receptors

TSLP, also produced by fibroblasts, is thought to aid in the maturation of dendritic cells. Consequently, epithelial products lead to innate cell (neutrophil) recruitment to limit local infection. Epithelial products can promote dendritic cell maturation and thus induce an adaptive immune response (including memory T cells and neutralizing antibodies). In addition to these molecules, pulmonary epithelial cells also express a number of antimicrobial mediators that are unique to the lung. These include the surfactant proteins SP-A and SP-D (members of the collectin family) and the β-defensins, potent antimicrobial peptides (discussed later on).

ENDOTHELIAL CELLS

Endothelial cells also play a pivotal role in the regulation of host defense and propagation of the inflammatory response. Like epithelial cells, endothelial cells also form tight junctions that separate the endothelial monolayer into apical and basal surfaces and prevent passive movement of particles and molecules. In addition to this physical barrier, activated endothelial cells modulate the expression of numerous proteins involved in different pathways that contribute to host defense. These include the following:

- Reactive nitrogen and oxygen species, including nitric oxide ($NO^\bullet$), peroxynitrite ($ONOO^-$), superoxide (O_2^-), and hydrogen peroxide (H_2O_2), which are cytotoxic to microorganisms and cells
- Inflammatory cytokines such as TNF-α, IL-1β, and IL-6, as well as chemokines such as IL-8, RANTES (*r*egulated on *a*ctivation, *n*ormal *T* cell–*e*xpressed and *s*ecreted), and MIP-1, which activate and recruit leukocytes
- Cytokine and chemokine receptors such as TNFR1 and IL-1R
- Adhesion molecules, including ICAM-1, ICAM-2, platelet endothelial cell adhesion molecule (PECAM), vascular cell adhesion molecule-1 (VCAM-1), E-selectin, and P-selectin, which have differential binding specificities for specific leukocyte populations
- Toll-like receptors (TLRs)
- Procoagulants and protease-activated receptors
- Proteases
- Leukotrienes and prostaglandins
- Growth factors such as vascular endothelial growth factor (VEGF) and transforming growth factor (TGF)-β
- Alterations in the surface adhesion molecules, cytoskeleton, and intercellular (junctional) proteins to allow for leukocyte adhesion transmigration and to regulate changes in vascular permeability

FIBROBLASTS

Although fibroblasts are classically viewed as structural cells and passive responders to exogenous influences, they are actually integral to the regulation of host defense. Fibroblasts synthesize extracellular matrix proteins, such as collagen and fibronectin, which are required to maintain the structural integrity of the lung during normal tissue turnover and tissue repair after infection and injury. They also express and secrete matrix-degrading proteases such as matrix metalloproteinases and cytokines such as IL-1, TNF, and TSLP, which play important roles in leukocyte recruitment and activation.

IMMUNE CELLS

Several leukocyte populations play distinct and vital roles in host defense in the lung and can be broadly classified as those that are normal residents of the lung (monocyte-macrophages, mast cells, dendritic cells) and those recruited in response to infection in injury (neutrophils and lymphocytes) (Table 22-7). Studies in animal models and in humans have demonstrated the increased risk of lung infection associated with defects in or absence of these cell types.

Monocyte-Macrophages

Macrophages (literally, "big eaters") are present within the interstitial tissues and alveolar spaces and on mucosal surfaces throughout the body. They function to provide

- Constant immune surveillance
- Orchestration of the immune response
- A bridge between the innate and adaptive arms of the immune system

Macrophages are derived from myeloid precursors in bone marrow, spleen, and fetal liver. Precursor cells termed *monocytes* leave the vascular space in response to chemokines or other

Table 22-7 Leukocyte Defense Mechanisms

Immune Cell	Primary Role(s)	Primary or Unique Inflammatory Mediators
Neutrophils	Killing and elimination of invading organisms	Reactive oxygen and nitrogen species Proteolytic enzymes and cationic proteins TNF-α, IL-1β, IL-6
Macrophages	Immune surveillance Killing and containment of invading microorganisms Removal of particulate matter Antigen presentation	TNF-α, IL-1β, IL-6 TGF-β ICAM-1 Reactive oxygen and nitrogen species

tissue-specific homing factors. The environment of the destination heavily influences the function of macrophages such that macrophages resident in different tissues display different patterns of function.

In response to infection or injury, the resident tissue macrophages can contribute to the innate immune response by phagocytosis, as well as expression of a variety of inflammatory and antimicrobial compounds, the pattern of which is differentially regulated by the microenvironment of the different tissues. Moreover, macrophages can function in antigen recognition, processing, and display to cells of the adaptive immune system (lymphocytes). Recent studies have determined that lung macrophages may be polarized along two lines, termed the M1 and M2 phenotypes, in response to specific cytokines and other mediators in their environment. The M1 phenotype, produced in response to exposure to microbial compounds (e.g., LPS) or interferon-γ, is a potent producer of reactive oxygen (O_2^-) and nitrogen ($NO^\bullet$) species and mediates resistance against intracellular microbial parasites and tumors. By contrast, the M2 phenotype, produced in response to IL-4 and IL-13, participates in regulation of inflammatory and adaptive immune responses, scavenges debris, and promotes angiogenesis and tissue remodeling and repair.

Mast Cells

Mast cells are key elements in the innate immune system and have been termed the "antennae" of the immune response. Mast cells are located throughout the body in close proximity to epithelial surfaces, near blood vessels, nerves, and glands, placing them at strategic locations for detecting invading pathogens. In addition, mast cells express a number of receptors that allow them to recognize diverse stimuli.

In sensitized individuals, IgE is bound to Fcε receptors on the mast cell surface, and binding of antigen to surface-bound IgE results in mast cell activation. Thus, multiple stimuli (foreign antigens) may trigger the same class of receptor. However, there is specificity in this system as a result of multiple signal transduction pathways that are differentially activated on the basis of antigen size, receptor location, number, and subtype.

In addition, human mast cells also express TLRs: TLR-1, TLR-2, TLR-6, and TLR-4. TLRs are pattern recognition receptors that recognize specific molecular patterns of microorganisms. Expression of TLRs, in combination with other receptors, allows the mast cell to recognize many potential pathogens and mount a specific response. Of importance, mast cells are capable of releasing many immune modulating molecules that stimulate inflammation, and the adaptive immune response can polarize T cell subpopulations toward specific subtypes. Mast cell products include the following:

- Pre-formed mediators that are granule-associated (such as histamine)
- Mediators synthesized de novo (such as leukotriene C_4, platelet-activating factor, and prostaglandin D_2)
- A vast array of cytokines and chemokines, including IL-1, IL-3, IL-4, IL-5, IL-6, IL-8, IL-10, IL-13, IL-16, TNF-α, VEGF, TGF-β, MIP-1α, and MCP-1

In summary, the strategic location of mast cells in the body, their diversity of receptors, and cytokines indicate an important role for mast cells in regulating innate and adaptive immunity.

Dendritic Cells

Dendritic cells function as "conductors" of the immune response. These cells, resident within tissues, develop in vivo from hematopoietic precursor cells. Dendritic cells bind, internalize, and process antigens and then display them on their surface in the cleft of major histocompatibility complex (MHC I) or MHC II molecules. Activated dendritic cells then travel to local lymph nodes with processed antigen on their cell surface. These antigens are then "presented" to cells of the adaptive immune system (primarily lymphocytes). When a naive T lymphocyte recognizes an antigen-presenting dendritic cell with the requisite costimulatory signals, T lymphocyte differentiation usually occurs. A number of T helper (T_H) subsets have been described, including T_H1, T_H2, and T_H17 and regulatory T cells. These subsets are defined by cell surface markers, transcription factors expressed, and cytokines produced. Each subset is thought to be optimized for specific microbial challenges. Thus, T_H1 responses eliminate intracellular microorganisms, T_H2 responses eliminate parasites, and T_H17 responses eliminate conventional bacterial threats.

Recent studies have provided evidence for an increasing number of lung dendritic cell subsets identified and defined by their cell surface markers, cytokines produced, and functional attributes. Most of this work has been done in the murine models, although studies to define dendritic cell subsets in humans are being conducted. Further studies will reveal the relevance of various dendritic cell populations in host defense and lung pathology.

Eosinophils

Eosinophils (Figure 22-5) are considered to be effector cells of allergic responses and of parasite elimination. These bone marrow–derived cells contain four distinct granule cationic proteins: (1) major basic protein; (2) eosinophil peroxidase; (3) eosinophil cationic protein; and (4) eosinophil-derived neurotoxin.

During allergic inflammation, eosinophils release granule contents, as well as inflammatory mediators including lipid mediators such as leukotriene C_4 and platelet-activating factor, which may cause dysfunction and destruction of other cells.

Polymorphonuclear Neutrophils

The primary function of neutrophils in the innate immune response is to contain and kill invading microbial pathogens. Neutrophils merit particular mention in pulmonary host defense as the pulmonary microvascular endothelium preferentially recruits this leukocyte population in response to infection and inflammation (see Figure 22-6) by the expression of adhesion molecules and chemokines that target neutrophils. Recently it has been recognized that the T_H17 pathway involving the production of IL-17 and IL-23 can lead to neutrophil recruitment. Different stimuli including allergen sensitization, mast cell activation, various infections and TNF production, can promote a T_H17 response and thereby recruit neutrophils to the lung.

Neutrophils achieve their antimicrobial function through a series of rapid and coordinated responses that culminate in phagocytosis and destruction of the pathogens (Figure 22-7). Neutrophils have a potent antimicrobial arsenal that includes the following roles:

- Oxidants
- Powerful proteolytic enzymes (proteinases)
- Cationic peptides

Oxidants such as O_2^- and H_2O_2 are produced by a multicomponent enzyme termed the phagocyte NADPH oxidase

(NOX2). Granules within the cytoplasm of polymorphonuclear neutrophils (i.e., leukocytes) (PMNs) contain potent proteinases and cationic proteins that can digest a variety of microbial substrates. These compounds are released directly into the phagosome, compartmentalizing both the pathogen and the cytotoxic products (Figure 22-8). Conversely, neutrophil serine proteinases can be externalized in a weblike fashion together with nucleosomes to function as a trap for pathogens. These neutrophil extracellular traps (NETs) have been described in the vasculature and in the airways. NETs have an important antimicrobial function independent of phagocytosis by bringing and immobilizing microbial pathogens in close proximity to proteinases. NETs also provide a physical barrier to microbial spread. Of interest, some evidence suggests that eosinophils also produce NET-like structures in the lung.

ANTIMICROBIAL MOLECULES

Antimicrobial molecules (Table 22-8) are expressed by multiple cell types and play important roles in destruction and removal of pathogens. An overview of the important factors that have been shown to impede microbial growth and infection in the context of host defense of the lung is presented next.

ANTIMICROBIAL COMPONENTS IN THE AIRWAY SURFACE LIQUID

The acidic pH (6.4 to 7.3) of the ASL is inhibitory to microbial proliferation, as well as providing an optimal environment for the activity of the antimicrobial molecules found in the ASL. Important among these are lactoferrin and lysozymes.

Figure 22-8 Neutrophil-derived antimicrobial products. O_2^- and H_2O_2 are produced by a multicomponent enzyme, termed the phagocyte NADPH oxidase, which is expressed by neutrophils (PMNs) and macrophages. Leukocytes also contain unique secretory granules, the primary and secondary granules, which release potent proteolytic enzymes and cationic proteins that can digest a variety of microbial substrates. *fMLP-R*, fMet-Leu-Phe receptor; *hCAP-18*, human cathelicidin antimicrobial protein-18; *NADPH*, nicotinamide adenine dinucleotide phosphate (reduced); *PMNs*, polymorphonuclear neutrophils [leukocytes].

Table 22-8 Antimicrobial Factors in Airway Surface Liquid

Factor	Role(s)/Function(s)
Lactoferrin	Binds iron Inhibits bacterial growth Enhances PMN function Modulates LPS activity
Lysozyme	Hydrolyzes peptidoglycan
Fibronectin	Binds to bacteria
Complement	Opsonization Chemotactic Bacterial lysis
Immunoglobulins IgA and IgG	Opsonization Complement activation
Defensins	Pore formation in microbial membranes Chemotactic Promotes cytokine production Stimulates dendritic cells
Cathelicidins	Modulates LPS Chemotactic Stimulates dendritic cells
Collectins	Binds carbohydrate domains of organisms, with reduced virulence and increased phagocytosis

LPS, lipopolysaccharide; *PMN*, polymorphonuclear neutrophil [leukocyte].

Lactoferrin

Lactoferrin is an iron-binding protein that is secreted by serous epithelial cells and neutrophils that competes with bacteria for iron, thereby inhibiting bacterial growth. Lactoferrin also possesses other antimicrobial properties, including the following:

- Enhancement of neutrophil functions—motility, adherence, and superoxide production
- Inhibition of biofilm formation by *Pseudomonas aeruginosa*
- The ability to injure bacterial membranes with resultant release of LPS
- Modulation of LPS activity by competitively binding LPS, thus preventing LPS-binding protein from binding and promoting an LPS-CD14 interaction, which would result in cell activation

Some evidence also suggests that lactoferrin can upregulate expression of various cytokine and growth factor genes such as IL-12 and IFN-β.

Lysozyme

Lysozyme is an enzyme produced by serous cells, macrophages, and PMNs that can hydrolyze peptidoglycan, a major component of gram-positive bacterial cell membranes, thus providing defense against infection by this type of bacteria. Lysozyme also aids in the defense against gram-negative bacteria and acts synergistically with lactoferrin, secretory leukoprotease inhibitor (SLPI), and LL-37 (an antimicrobial peptide) to provide multiple mechanisms for bacterial destruction and removal.

COMPLEMENT

Complement proteins are sequentially activated in a cascade encompassing three distinct pathways: (1) the classic antibody-antigen complex–dependent pathway, (2) the alternate pathway that is initiated by foreign or microbial products, and (3) a more recently identified pathway that is initiated by mannose-binding lectin (MBL), a member of the collectin family, and a related family of proteins called ficolins that are present in the lung. Complement proteins exude from plasma into airways in response to inflammation and are also produced by macrophages, type II pneumocytes, and fibroblasts. Specific complement components have important roles in host defense:

C*5a*: potent anaphylatoxin and chemoattractant that recruits neutrophils into the lung and enhances neutrophil-mediated microbial killing

C*3a*: another potent anaphylatoxin that also stimulates mucus production from goblet cells and enhanced LPS-induced synthesis of TNF and IL-1 by adherent phagocytes while decreasing synthesis in nonadherent cells

C*5a*-C9 *complex*: also known as the membrane attack complex (MAC), which creates pores in cell membranes, effectively killing bacteria

Multiple complement components can function as opsonins aiding phagocytosis of foreign particles (Figure 22-9). Of importance, hereditary deficiency of specific components of the complement pathway results in recurrent respiratory tract infections.

ANTIMICROBIAL PEPTIDES

A number of antimicrobial peptides are present in the airways. These can be classified conveniently into four groups on the basis of structural motifs: defensins, cathelicidins, histatins, and collectins.

DEFENSINS

Defensins are single-chain strongly cationic peptides that have a broad spectrum of antimicrobial activity against gram-positive bacteria, gram-negative bacteria, fungi, and viruses. They work synergistically with other host defense molecules such as lysozyme and lactoferrin. The antimicrobial activities of defensins include the ability to form pores in target membranes, to interfere with protein synthesis, and to directly damage DNA. Defensin activity is influenced by the salt concentration of the ASL, with higher concentrations decreasing their antimicrobial activity.

3. Nucleus: Induction of chemokine and cytokine production and release
4. Antigen presentation

Figure 22-9 Immune defense mechanisms mediated by receptor-mediated phagocytosis and signaling. Internalization of pathogens or particulate matter induces multiple host defense mechanisms, including degradation of the offending agent (*1*), induction of the NADPH oxidase (neutrophils and macrophages) or iNOS (*2*), induction of chemokine and cytokine expression (*3*), and antigen presentation (particularly in dendritic cells and macrophages) (*4*). *iNOS*, inducible nitric oxide synthase; *NADPH*, nicotinamide adenine dinucleotide phosphate (reduced); *NO*, nitric oxide; *ROS*, reactive oxygen species.

Defensins are defined by the presence of six cysteines and three intramolecular disulfide bridges and are classified into three different subgroups: α, β, and θ defensins. Only α and β defensins are of relevance in humans. The first four human α defensins (HD 1 to HD 4) are produced by neutrophils and are found in the airways, and the other two (HD 5 and HD 6) are found in the small intestine and female urogenital tract. Of the 28 human β defensins identified, 6 (HBDs 1 to 6) are expressed mainly by epithelial cells. HBDs 2 to 4 are inducible in response to a variety of stimuli, including bacterial and viral infection, IL-1, TNF, and LPS. The levels of HDs 1 to 4 are increased in inflammatory processes as a result of release by activated neutrophils.

In addition to their direct antimicrobial properties, defensins also contribute to host defense in other ways:

- Enhanced bacterial binding and killing and cytokine production by airway epithelial cells
- Chemotaxis for monocytes and immature dendritic cells
- Direct binding to CCR6 receptors on dendritic cells, thus linking the innate immune system to adaptive immunity (β-defensins)
- Promotion of phagocytosis in macrophages and neutrophils

- Downregulation of the inflammatory response by increasing SLPI release from airway epithelial cells, inhibiting the complement cascade, and reducing macrophage cytokine release and neutrophil oxidant production

CATHELICIDINS

The only human cathelicidin is LL-37, a peptide with a broad spectrum of antimicrobial activity that acts synergistically with lysozyme and lactoferrin. LL-37 is stored as a precursor, hCAP-18, in specific granules and also is secreted by mast cells and the respiratory epithelium. Other host defense activities of LL-37 include the following:

- Neutralization of LPS
- Chemotactic for neutrophils, eosinophils, mast cells, and T lymphocytes
- Direct interaction with dendritic cells to form T_H1 cells
- Mast cell degranulation
- Induction of cytokine and chemokine expression by epithelial cells and monocytes
- Induction of angiogenesis
- Induction of epithelial wound healing

HISTATINS

Histatins are a family of cationic histidine-rich peptides that are strongly antifungal and may have LPS-neutralizing properties. Histatins are present in saliva and play an important role in preventing oral infections. They have not been isolated from airway secretions.

COLLECTINS

The collectins, or collagenous C-type lectins, are a family of polypeptides that bind collagenous carbohydrates. Collectin proteins that play a role in pulmonary host defense include MBL and the surfactant proteins SP-A and SP-D. These molecules are secreted by the respiratory epithelium and are present in the airways. The collectins have broad antimicrobial activity against viruses, bacteria, and fungi by binding to conserved carbohydrate domains. In addition, collectins can bind organic antigens, apoptotic cells, nucleic acids, and host proteins. As discussed previously, MBL can activate the complement cascade and also has been shown to induce inflammatory mediator production from monocytes. The importance of these molecules is illustrated by the susceptibility of SP-A– and SP-D–deficient mice to various lung infections. In addition, some clinical studies suggest a link between severe pneumonia and reduced lung levels of SP-A or SP-D.

Together, these groups of antimicrobial molecules in the ASL function to destroy or inhibit microbes before they have a chance to proliferate and compromise the health of the host. If pathogens evade structural defenses and then survive the antimicrobial properties of the ASL, they can come into contact with host cell membranes, which allows for interaction with Toll-like receptors.

INNATE IMMUNE RECEPTORS

As highlighted earlier, the respiratory epithelium and other structural cells of the lung express innate immune receptors. These receptors function primarily as pattern recognition receptors to recognize conserved molecular patterns in microbial pathogens, called pathogen-associated molecular patterns (PAMPs), which are not normally found in the host (Table 22-9). This "pre-recognition" allows the host to respond to specific microbial products in the absence of an adaptive response; thus, the response does not require priming and is always present. Innate immune receptors include the membrane bound Toll-like receptors (TLRs) and additional cytosolic receptors. The 10 human TLRs share a protein structure characterized by an extracellular domain with a number of leucine-rich repeats (LRRs) and a cytoplasmic domain containing a Toll/IL1 receptor homology domain (TIR). They are highly expressed by leukocytes and in tissues in contact with the external environment, such as the lung. Cellular expression of TLRs is modulated by microbial stimuli. TLRs are found as homodimers with the exception of TLR-1 and TLR-6, which form heterodimers with TLR-2. TLR activation after binding of its cognate ligand triggers signal transduction pathways that ultimately lead to altered gene expression. The signaling pathway after recruitment of MyD88 is conserved for all TLRs (see Figure 22-10) with the exception of TLR-3, which utilizes TRIF. In addition, specific LPS chemotypes can activate TLR-4 in an MyD88-independent manner. Binding of MyD88 to the activated TLR leads to recruitment of IL-1 receptor–associated kinase (IRAK) and IRAK autophosphorylation. TNF receptor–

Table 22-9 Toll-Like Receptors (TLRs) and Their Ligands

Receptor	Reported Ligands
TLR-1	Heterodimerization with TLR-2, lipopeptides
TLR-2	Peptidoglycan and lipoteichoic acid (components of gram-positive bacteria) LPS Bacterial lipoproteins (components of *Borrelia burgdorferi*) Components of mycobacterial cell walls Mannuronic acid polymers (components of *Pseudomonas aeruginosa*) Glycosylphosphatidylinositol lipid (components of *Trypanosoma cruzi*) Phenol-soluble modulin (from *Staphylococcus epidermidis*) Soluble tuberculosis factor (19-kDa lipoprotein secreted by *Mycobacterium tuberculosis*) Whole bacteria (heat-killed *Listeria monocytogenes*)
TLR-3	dsRNA, polyinosinic : polycytidylic acid (poly I : C)
TLR-4	LPS Mannuronic acid polymers (components of *Pseudomonas aeruginosa*) RSV fusion protein Endogenous inflammation-related products (heat shock proteins HSP-60 and HSP90, fibronectin)
TLR-5	Flagellin
TLR-6	Heterodimerization with TLR-2, lipopeptides
TLR-7	ssRNA, antiviral compounds
TLR-8	ssRNA, antiviral compounds
TLR-9	Unmethylated CpG, bacterial DNA
TLR-10	?

CpG, cytosine-phosphate-guanine [DNA sequence]; *dsRNA*, double-stranded RNA; *LPS*, lipopolysaccharide; *RSV*, respiratory syncytial virus; *ssRNA*, single-stranded RNA.

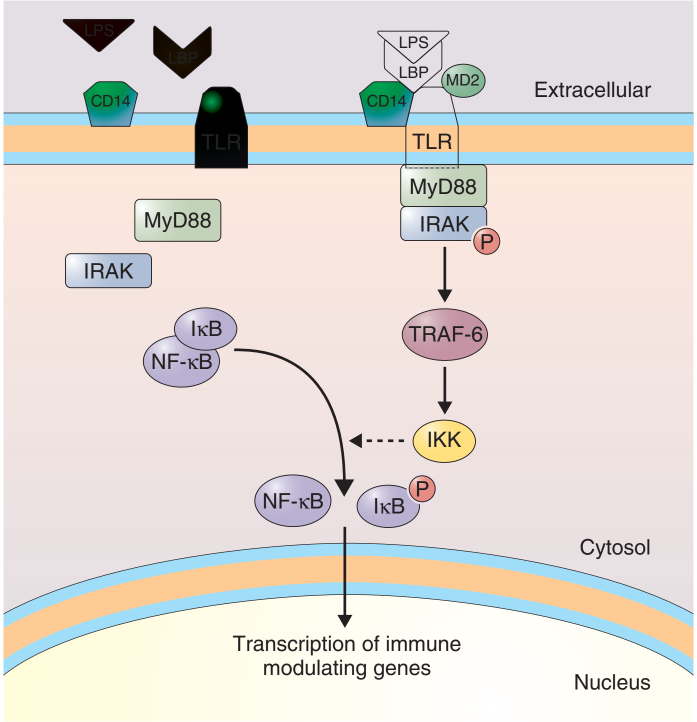

Figure 22-10 Toll-like receptor (TLR) signaling. The classical signaling pathway triggered by TLRs involves MyD88/IRAK (interleukin-1 receptor–associated kinase) and TRAF-6 (tumor necrosis factor [TNF] receptor–associated factor-6), leading to transcriptional regulation of immune and inflammatory genes. *IκB*, inhibitor of nuclear factor κB; *IKK*, IκB kinase; *LBP*, lipopolysaccharide-binding protein; *LPS*, lipopolysaccharide; *NFκB*, nuclear factor κB.

associated factor-6 (TRAF-6) links with this complex and activates IκB kinase (IKK). IKK phosphorylates IκB, leading to its dissociation from nuclear factor κB (NFκB). NFκB then translocates to the nucleus to activate gene transcription. Alternatively, TRIF leads to activation of IRF3 (interferon regulatory factor 3) that can translocate to the nucleus and lead to the transcription of interferon-α and -β. This pathway also activates NFκB.

Additional nonmembrane receptors enable cytosolic detection of microbial products. NOD1 and NOD2 (nucleotide-binding oligomerization domain proteins 1 and 2) are members of the NLR family of proteins (nucleotide-binding domain, leucine-rich repeat–containing) that recognize bacterial products and eventually lead to NFκB activation. NOD2 also may bind to single-stranded RNA and thus sense viruses. RNA viruses are recognized in the cytoplasm by retinoic acid–inducible gene (RIG)-I–like receptors (RLRs). These include RIG-1, MDA-5 (melanoma differentiation-associated gene-5), and LGP2 (laboratory of genetics and physiology-2). These proteins have a helicase domain and induce interferon production when activated. Double-stranded RNA (dsRNA) also can activate protein kinase R (PKR). PKR has an amino-terminal (N-terminal) RNA-binding domain and a carboxyl-terminal (C-terminal) kinase domain that is proapoptotic. PKR also can induce activation of other important molecules, including NFκB.

These innate immune receptors, whether on the membrane or in the cytosol, are critical for initiating an appropriate innate immune response to a microbial threat. In addition, strong evidence indicates that in the absence of appropriate TLR signaling, the adaptive immune response is impaired. The TLR response represents a "danger signal" and marks an associated antigen for an immune response. This signaling may be particularly relevant for the lung, which is constantly exposed to antigens yet must maintain a noninflamed environment in order to maximize gas exchange.

TOLL-LIKE RECEPTOR-2

Toll-like receptor-2 (TLR-2) is expressed on the surface of numerous cells and has a large number of reported ligands. These include components of gram-positive and gram-negative bacteria, mycobacteria, the protozoan parasite *Trypanosoma cruzi*, and zymosan, a yeast wall component. Additional ligands include secreted factors from *Staphylococcus epidermidis* and *Mycobacterium tuberculosis*, as well as whole bacteria (*Listeria monocytogenes*). TLR-2 does not recognize these PAMPs in isolation but rather forms heterodimers with TLR-6 and TLR-1, thus contributing to the diversity and specificity of TLR-2–mediated immune response.

TOLL-LIKE RECEPTOR-3

Toll-like receptor-3 (TLR-3) is activated by dsRNA), a marker of viral infection, and, through the activation of NF-κB, triggers the production of type I interferons. TLR-3 is found on plasma membranes, where it is believed to contact dsRNA after the lysis of infected cells and release of dsRNA into the extracellular milieu. Of note, additional evidence suggests that TLR-3 is found inside cells in vesicles associated with the endocytic pathway. TLR-3 is thought to have a more restricted pattern of expression but is found in dendritic cell populations.

TOLL-LIKE RECEPTOR-4

Toll-like receptor-4 (TLR-4) is the prototypical and most extensively studied of the TLRs. It recognizes lipopolysaccharide (LPS) (i.e., endotoxin), mannuronic acid polymers (components of *Pseudomonas aeruginosa*), and the F protein of the respiratory syncytial virus (RSV). Unlike the other TLRs, TLR4 also recognizes several endogenously derived molecules, including heat shock proteins HSP60 and HSP70 and fibronectin.

TOLL-LIKE RECEPTOR-5

Toll-like receptor-5 (TLR-5) recognizes a highly conserved cluster of 13 amino acid residues in flagellin, the structural component of flagella found in many pathogenic bacteria. This interaction triggers an innate immune response, resulting in cytokine production from leukocytes and dendritic cell activation and maturation.

TOLL-LIKE RECEPTOR-9

Toll-like receptor-9 (TLR-9) binds to unmethylated CpG (i.e., cytosine-phosphate-guanine sequence) elements in DNA and triggers a predominantly T_H1-weighted immune response. Unmethylated CpG dinucleotides are present at high frequencies in most bacterial genomes, whereas in the human genome, these dinucleotides are suppressed, methylated, and flanked by bases that are immune-neutralizing. TLR-9 is believed to be localized within endosomal compartments, thus facilitating its interaction with bacterial DNA.

OTHER TOLL-LIKE RECEPTORS

TLR-1 and TLR-6, as mentioned previously, interact with TLR-2 and function as a complex that recognizes a broad range of antigens. TLR-10 is related to TLR-1 and TLR-6, but its role remains to be clarified. TLR-7 and TLR-8 recognize single-stranded RNA.

INFLAMMATORY MEDIATORS

CYTOKINES

Cytokines (Table 22-10) are soluble, low-molecular-weight proteins that play important roles in host defense by regulating the inflammatory response and are expressed not only by leukocytes but also by endothelial cells, epithelial cells, and fibroblasts. Expression of cytokines is transcriptionally regulated, and secretion can be quickly enhanced after cell stimulation.

Signaling through cognate receptors, cytokines exert distinct responses in specific cell populations, stimulating some populations to activate, proliferate, and differentiate while having an inhibitory effect on other cell types. In this way, cytokines play a major role in regulating the intensity and duration of the inflammatory response. The cytokines that play important roles in inflammation, particularly in the early proinflammatory phase, include TNF-α, IL-1β, IL-6, and IL-10. Significant elevations of these cytokines are observed in generalized inflammatory states and particularly in gram-negative sepsis.

CHEMOKINES

Chemokines (Table 22-11) are 8- to 10-kDa glycoproteins that, although structurally related to cytokines, are distinct from them in their ability to bind and signal via G protein–coupled receptors. Chemokines are both chemotactic and cellular activating factors for leukocytes and can be classified into four groups on the basis of their amino acid structure. The two primary groups that play an important role in host defense are the CC chemokines (e.g., MCP-1, MIP-1α, and RANTES), which are chemotactic for monocytes, lymphocytes, basophils, and eosinophils and the CXC chemokines (e.g., IL-8, GRO-α [growth-related oncogene α], and ENA-78 [epithelial cell–derived neutrophil-activating peptide-78]), which act primarily on neutrophils.

The chemokine receptors are structurally related seven transmembrane–spanning proteins that transmit their signals through heterotrimeric G proteins. As with cytokines, the effect of chemokine activation results in diverse physiologic responses that are cell- and stimulus-specific. The binding specificity of individual chemokine receptors is determined by a region in the amino terminus of the protein. Some receptors

Table 22-10 **Cytokines and Chemokines and Their Functions**

Cytokine	Function	Other Clinical Roles
TNF-α	Proinflammatory Neutrophil activation in ARDS	Proximate cytokine released in response to inflammatory stimulus
IL-1β	Proinflammatory Neutrophil activation in ARDS Upregulation of adhesion molecules on leukocytes, endothelium, and airway epithelium	One of first cytokines to be released in response to inflammatory stimulus
IL-6	Proinflammatory Leukocyte activation Promotes proliferation of myeloid progenitor cells Induces pyrexia Acute-phase reactant	Circulating levels are a marker of severity of ARDS of different causes
IL-10	Antiinflammatory Inhibits release of TNF-α, IL-1β, and IL-6 from monocyte-macrophages Stimulates the production of IL-1 receptor antagonist (IL-1RA) and soluble p75 TNF receptor	
GM-CSF	Alveolar macrophage function Lung host defense Surfactant homeostasis	Low circulating levels associated with poor prognosis in sepsis
PAF	Acts by way of receptors on platelets, leukocytes, and endothelial cells Increases vascular permeability Leukocyte recruitment Primes and triggers leukocyte secretion	
ICAM-1	Leukocyte recruitment and retention	Increased in inflammation
C5a	Product of classical and alternate complement cascade Potent anaphylatoxin and chemoattractant Acts via C5aR Can be both pro- and antiinflammatory	
Substance P	Neuropeptide that acts through its receptor NK1R Proinflammatory and associated with development of lung injury	

ARDS, acute respiratory distress syndrome; *GM-CSF*, granulocyte-macrophage colony-stimulating factor; *ICAM-1*, intercellular adhesion factor-1; *IL*, interleukin; *NK1R*, neurokinin 1 receptor; *TNF*, tumor necrosis factor; *PAF*, platelet-activating factor.

Table 22-11 Chemokine Families

Family	Member(s)	Function(s)
CXC	IL-8 MIP-2 GRO-α ENA-78 NAP-2	Chemotactic for and stimulatory to neutrophils
CC	MCP-1 MCP-2 MCP-3 RANTES MIP-1α MIP-1β	Chemotactic for and activation of: • monocytes • lymphocytes • eosinophils • basophils • mast cells
C	Lymphotactin	Attracts T cells
CXXXC	Fractalkine	Attracts T cells and monocytes Promotes adhesion

ENA-78, epithelial cell–derived neutrophil-activating peptide-78; *GRO-α*, growth-related oncogene; *IL-8*, interleukin-8; *MCP*, monocyte chemoattractant protein; *MIP*, macrophage inflammatory protein; *NAP-2*, neutrophil-activating protein-2.

are highly specific, whereas others bind multiple chemokines of both CC and CXC families. Differential regulation and expression of the chemokine receptor in different cell types play an important role in determining the biologic result of chemokine activation.

SUMMARY

It is apparent that the lung has multiple lines of defense against microbial pathogens and noxious environmental agents. These include physical barriers such as mucus and soluble factors such as antimicrobial peptides and proteins produced by epithelial cells, as well as leukocytes of the innate and adaptive immune systems. It is this combination of diversity and redundancy that enables the lung to thwart infection under most circumstances.

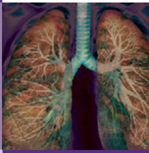
Section 5
INFECTIOUS DISEASES



Chapter 23
Approach to the Diagnosis of Pulmonary Infection
Mark A. Woodhead

The various clinical manifestations of respiratory tract disease are somewhat limited in scope and not specific to the causative disorder. The common signs and symptoms of cough, dyspnea, and chest pain and lung crackles or wheezes can be caused by infection but also by many other diseases. Accordingly, some detective work will be required to separate infection as a likely cause of illness from other possible etiologic conditions and then to identify the likely causative pathogen or pathogens and treat the infection.

Chapters 24 through 27 describe in detail aspects of pneumonia caused by specific pathogens. This chapter provides a framework from which to approach the individual patient in whom a pulmonary infection is likely. Assessment may begin by gathering specific information consisting of answers to the set of questions presented in **Box 23-1**. In this chapter, each of these questions is addressed in turn, although in clinical practice, the steps in this approach to the patient may be considered in parallel. Answers to the questions “Is it infection?” and “How severe is the illness?” are perhaps the most important.

THE APPROACH

IS IT INFECTION?

A careful history and physical examination are essential. No universally effective approach is recognized, however, and good clinical judgment often will be needed (**Table 23-1**). Typically, the patient with pulmonary infection will be pyretic and will have a cough characterized by purulent sputum. Rigors are even more specific to this disorder but occur only in more severe infections. An abrupt onset with pleuritic chest pain is a classical presentation in pneumonia but often is lacking. Wheeze may be present in airway infections, and focal chest signs are common in pneumonia. The more specific pneumonia signs of bronchial breathing, egophony, and whispering pectoriloquy are rare. Unfortunately, in real life, the presence of advancing age and immunosuppression can mean that infection is present despite the absence of any of these signs, and underlying lung disease may mean that some of them are present in the absence of infection.

For these reasons a confident diagnosis of pneumonia is difficult outside the hospital, where the cardinal feature of consolidation on the chest radiograph may be difficult to obtain. Even this feature may have other causes, but in the context of symptoms and signs suggesting infection, pneumonia is the likely diagnosis.

Very often the most important clinical considerations are whether an antibiotic should be prescribed (i.e., is this a bacterial infection?) and whether the patient should be admitted to the hospital. Historically, sputum purulence and the raised peripheral blood white cell count were considered to be suggestive of bacterial infection. Inflammatory markers such as C-reactive protein may be more specific and sensitive than the white cell count, and the hormokine procalcitonin may be an even more accurate marker of the presence or absence of bacterial infection. Available data are inconclusive, however, to allow recommendation of its routine use. The decision about hospital admission should be guided mainly by illness severity (see further on), but instability of comorbid diseases (e.g., diabetes mellitus) and social issues also are relevant to this decision.

Identification of a microorganism should be the best way to confirm infection, but this approach too has a number of limitations, most important of which is the insensitivity of available tests.

WHAT TYPE OF INFECTION IS IT?

Classification of Pulmonary Infections

The traditional anatomic classification of lung infection (e.g., upper respiratory, lower respiratory, pleural) forms a useful but far from perfect template on which to base a discussion of this topic. Although many infections are limited by anatomic boundaries (e.g., a lobar pneumonia), others do not fit easily into this classification schema (e.g., influenza virus infection).

The two main groups of acute adult pulmonary infections encountered in hospital practice are *acute exacerbations of chronic obstructive pulmonary disease* (COPD) (see Chapter 43) and *pneumonia* (Chapters 24 and 25). A chest radiograph is the key to separating these two, because it is the most sensitive screening method for detecting pulmonary consolidation (**Figure 23-1**, *A* and *B*). The presence of focal crackles is the most common feature of underlying consolidation. A pleural rub, or features of pleural effusion, may coexist. Other less common features include diarrhea, hypotension, and, in the elderly, mental confusion, hypothermia, and urinary incontinence. When pneumonia is suspected on clinical grounds and the chest radiograph is normal in appearance, a chest computed tomography (CT) scan may show changes in the lung parenchyma. However, other diseases may mimic pneumonia or be complicated by pneumonia (**Figures 23-2** to **23-4**).

It is important to identify the likely type of pneumonia according to the setting in which the infection was acquired

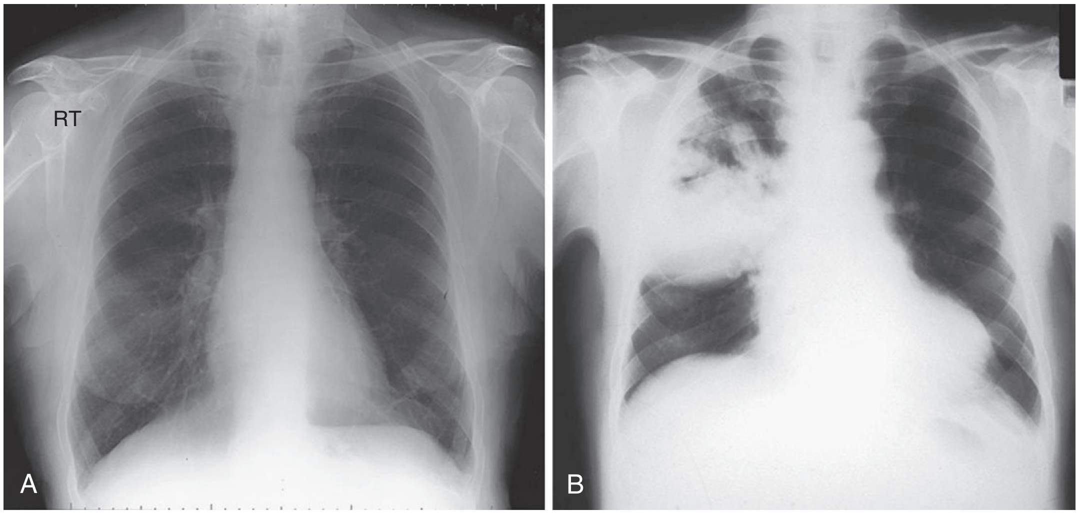


Figure 23-1 Chest radiographs obtained in two patients with underlying chronic obstructive pulmonary disease (COPD) who presented with cough, purulent sputum, and dyspnea. **A,** Uncomplicated COPD exacerbation with no lung consolidation. **B,** COPD exacerbation caused by pneumonia with right middle zone consolidation.

Box 23-1 Approach to the Patient with Suspected Pulmonary Infection

1. Is it infection?
2. What type of infection is it?
3. How severe is the illness?
4. What is the likely pathogen?
5. How is the causative pathogen best identified?
6. Is pathogen identification necessary?

Table 23-1 Features of Respiratory Infection and Alternative Causes

Feature	Pointer to Infection	Other Common Causes
Cough	Purulent sputum	Most other lung diseases
Temperature	Pyrexia Rigor	Bronchial carcinoma Pulmonary infarction
Sweats	“Drenching” and occurrence at night suggestive of tuberculosis	Septicemia Menopause
Chest signs	Features of consolidation	Bronchial carcinoma Any cause of alveolitis Pulmonary infarction
White cell count	Raised	Steroid therapy Bronchial carcinoma
C-reactive protein	Raised	Connective tissue disease
Chest radiographic appearance	Focal shadowing	Bronchial carcinoma Any cause of alveolitis Pulmonary infarction

(Table 23-2). The spectrum of pathogens differs for the five pneumonia types—community-acquired, early, and late nosocomial; immunosuppression-related; and aspiration.

Other roles for plain chest radiography include assessing the extent of disease, for which it is especially useful; detecting complications (e.g., cavitation, abscess, pneumothorax, pleural effusion); identifying the lesions of additional or alternative diagnoses (e.g., bronchiectasis, pulmonary fibrosis, bronchial neoplasm); and, in some cases, guiding invasive investigation.

Table 23-2 Classification of the Pneumonias According to Likely Origin and Immune Status

Pneumonia Group	Likely Pathogens
Community-acquired	Gram-positive bacteria *Mycoplasma, Chlamydia, Coxiella* Common viruses (e.g., influenza viruses)
Nosocomial, early	As for community-acquired pneumonias
Nosocomial, late	Gram-negative enterobacteria *Staphylococcus aureus* Antibiotic-resistant bacteria
Immunocompromised	Opportunistic organisms
Aspiration	Oropharyngeal anaerobic bacteria, chemical pneumonitis

HOW SEVERE IS THE ILLNESS?

The severity of clinical illness guides decisions about the optimal setting in which to manage the patient—home versus hospital, general ward or intensive care unit (ICU)—and also may guide specific investigations and treatment strategies.

In the patient with an exacerbation of COPD, measures of respiratory distress (e.g., respiratory rate) and gas exchange are the best markers of illness severity.

Among patients with community-acquired pneumonia (CAP), those who die usually are severely ill at presentation, so the correct interpretation of presenting features is important. This information should be supplemented by the results of investigations as they emerge. Scoring systems have been developed as an aid to clinical judgment to assess CAP severity. The Pneumonia Severity Index (PSI) is a two-step severity score built from 20 clinical and laboratory features (Figure 23-5). It has been validated in a number of studies mainly as a tool for keeping low-risk patients out of the hospital. The simpler CURB-65 index also is well validated and is based on just five clinical features (Figure 23-6), whereas CRB-65, which may be used outside the hospital setting, is based on four. Comparisons of the scores confirm the slightly greater accuracy of the PSI but simpler application of CURB-65 and CRB-65. Use of these scoring systems is recommended in the most recent CAP management guidelines.

In nosocomial pneumonia as well as pneumonia in the immunocompromised patient, the importance of presenting features as opposed to features that develop during the course of the illness is less clearly defined than for patients who have CAP. Previous or inappropriate antibiotic therapy, renal failure, prolonged mechanical ventilation, coma, shock, and infection with *Pseudomonas aeruginosa*, *Acinetobacter* spp., and methicillin-resistant *Staphylococcus aureus* (MRSA) are additional markers for severe nosocomial pneumonia (Box 23-2).

High levels of lactate dehydrogenase that persist in peripheral blood, alveolar-arterial oxygen gradient greater than 30 mm Hg, and more than 5% neutrophils in bronchoalveolar lavage (BAL) fluid are markers for severe *Pneumocystis jiroveci* infection in patients with human immunodeficiency virus (HIV) infection.

WHAT IS THE LIKELY PATHOGEN?

A wide range of microbial pathogens can cause pulmonary infection. In most patients, the cause of the infection is never identified. In those in whom a pathogen is found, a delay always occurs between the time of clinical presentation and the availability of culture results. Because therapy should be started immediately, it is helpful to identify markers that may help to determine the cause of infection and hence to guide

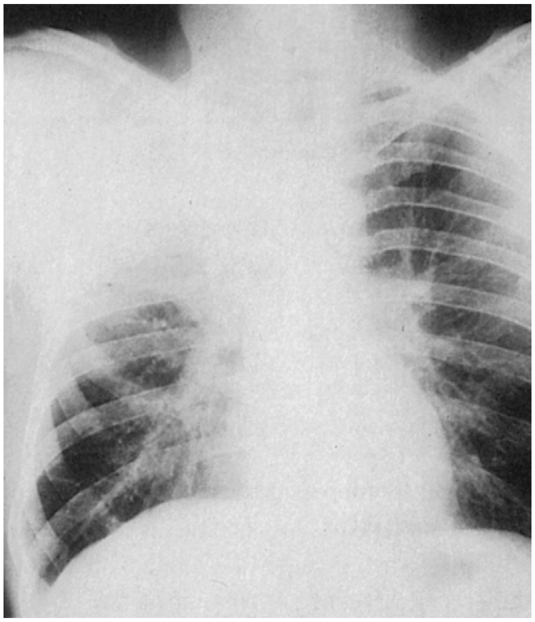

Figure 23-2 Pulmonary eosinophilia. Right upper lobe consolidation may mimic pneumonia, as in this case.

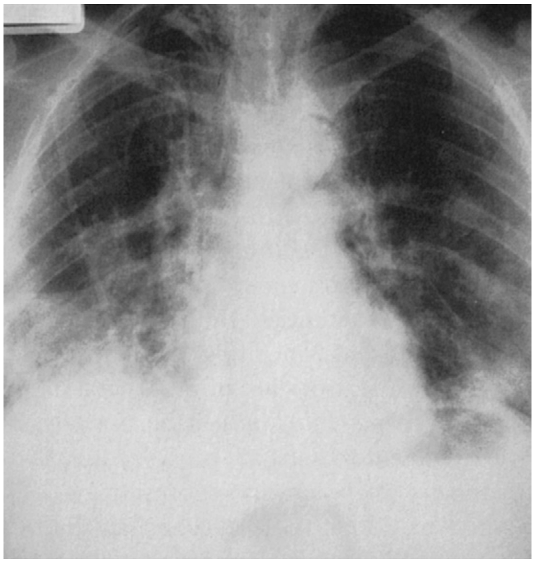

Figure 23-3 Drug-induced lung disease. Bilateral, patchy, predominantly basal consolidation was secondary to bleomycin administration.

Box 23-2 Clinical Characteristics of Severe Nosocomial Pneumonia

- Requirement for admission to the intensive care unit
- Respiratory failure (mechanical ventilation or the need for greater than 35% oxygen to maintain an artificial oxygen saturation above 90%)
- Rapid radiographic progression, multilobar pneumonia, or cavitating pneumonia
- Severe sepsis with hypotension and/or end-organ dysfunction:
  - Shock systolic blood pressure less than 90 mm Hg or diastolic blood pressure less than 60 mm Hg
  - Requirement for vasopressors for more than 4 hours
  - Urine output less than 20 mL/hour or total urine output less than 80 mL/hour in 4 hours (without other explanation)
  - Acute renal failure necessitating dialysis

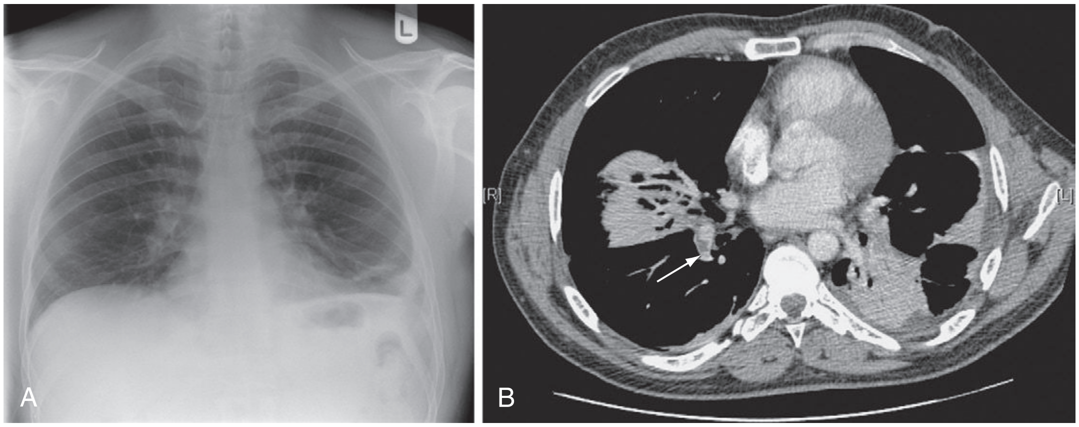

Figure 23-4 **A,** Appearance of left basal lung consolidation on chest radiograph. **B,** Contemporary computed tomography (CT) scan shows that consolidation is more extensive and is secondary to pulmonary embolism (*arrow*).

decisions about therapy. Generally, information obtained at presentation may point to potential groups of pathogens, rather than to individual pathogens, because few features are pathogen-specific.

Airway infections often are of viral origin. When bacteria are present, *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Moraxella catarrhalis* are most frequently found, although such organisms may simply represent colonization, rather than being the responsible pathogens. These bacteria are important in bronchiectasis, in which *S. aureus* and *P. aeruginosa* also may be important. The latter two organisms are particularly important in patients with cystic fibrosis. In patients who suffer from bronchiectasis, knowledge of previous sputum culture results may be helpful (see Chapters 44 and 45).

The range of potentially treatable pathogens that may cause pneumonia is much more diverse. Classification of the pneumonia according to the immune status of the patient and the likely origin of the infection (see Table 23-2) is helpful. Risk factors for unusual exposures (e.g., birds for psittacosis, grazing animals for Q fever, or local ongoing outbreak, as with Q fever or Legionnaires' disease) and immunocompromise (e.g., unsuspected intravenous drug abuse or sexual contact for HIV infection risk) must always be sought in the history.

In CAP, the same pathogens usually are important regardless of age group, with *S. pneumoniae* the most frequent cause (see Table 23-2). The exception is that of a lower incidence of *Mycoplasma* infection in elderly persons. Gram-negative members of the family Enterobacteriaceae (e.g., *Escherichia coli*, *Proteus mirabilis*) may be a more frequent cause of pneumonias in some elderly nursing home populations, and MRSA is now being recognized as a community pathogen in this setting. Only varicella-zoster virus pneumonia has specific clinical features (i.e., the vesicular rash), but the presence of coincident skin or soft tissue infection may be a marker for the recently recognized community-associated MRSA pneumonia.

All of the pathogens encountered in the community setting can produce illnesses of variable severity, although *Legionella*, staphylococcal, and gram-negative enterobacterial infections are more commonly identified in severely ill patients (**Table 23-3**).

It may be helpful to retain the terms *atypical* and *typical* in the context of pneumonia to describe groups of pathogens

Table 23-3 **Prediction of Microbial Etiology in Community-Acquired Pneumonia**

Potential Agent of Community-Acquired Pneumonia	Factor(s) With Higher Frequency of Association
Streptococcus pneumoniae	Abrupt illness onset
Haemophilus influenzae	Preexisting lung disease
Staphylococcus aureus	Concurrent influenza epidemic Radiographic cavitation Severe illness Intravenous drug abuse
Legionella species	Recent foreign travel Concurrent epidemic Countries that border the Mediterranean
Mycoplasma pneumoniae	Age <65 years
Chlamydophila psittaci	Recent bird contact At-risk occupation
Coxiella burnetii	Animal contact (hoofed animals, cats, rabbits) At-risk occupation
Franciscella tularensis	Tick bites Rabbit contact
Brucella abortus	Cattle, sheep, goat, pig contact At-risk occupation (abattoirs, farming, veterinary work)
Gram-negative members of Enterobacteriaceae	Nursing home resident South Africa
Pseudomonas pseudomallei	Southeast Asia, northern Australia
Hantavirus pulmonary syndrome	Rodent contact
Mycobacterium tuberculosis, other mycobacteria	Nonindustrialized countries
Pneumocystis jiroveci	Risk factors for human immunodeficiency virus (HIV) infection Iatrogenic immune compromise

("atypical" referring to intracellular pathogens such as *Mycoplasma pneumoniae*, *Chlamydophila pneumoniae*, and *Coxiella burnetii*, and "typical" referring to conventional bacteria such as *S. pneumoniae* and *H. influenzae*), but recent studies have shown that a clinical distinction may not be helpful. *Legionella* pneumonia has been included in the "atypical" pneumonia group. In fact, the clinical features of this illness have much more in common with severe pneumococcal infection.

Radiographic features also usually do not help to differentiate among causative pathogens; however, cavitation occurs most commonly in staphylococcal, anaerobic (Figure 23-7), fungal, and tuberculous infections, and rarely with other pathogens.

It is helpful to distinguish nosocomial pneumonias that develop within the first 5 days of hospitalization from those that develop thereafter. *S. pneumoniae* and *H. influenzae* are not uncommon within the first 5 days, but are rarely found after 5 days, when *S. aureus* (both methicillin-sensitive and methicillin-resistant strains), *Acinetobacter* species, and *P. aeruginosa* are the most commonly seen. No specific clinical or laboratory features allow an accurate prediction of the causative pathogen in nosocomial pneumonia; however, *P. aeruginosa* is less common in patients who have nosocomial pneumonia that developed outside the intensive care unit.

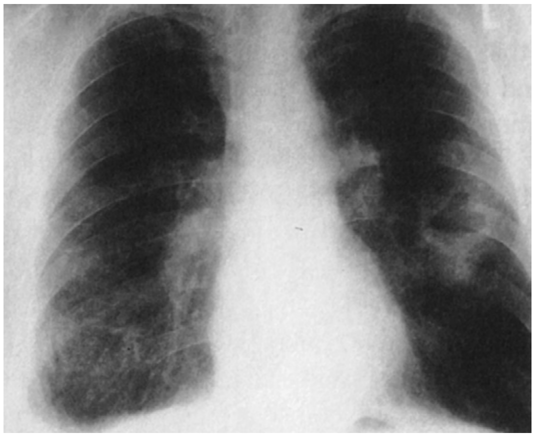

Figure 23-7 Cavitating pneumonia. Left midzone consolidation was caused by anaerobic infection.

Bacterial antibiotic resistance is becoming increasingly important in both community-acquired and nosocomial pathogens. Patterns of resistance in community-acquired organisms usually are specific to the geographic region, whereas those in nosocomial organisms often are limited just to the treating institution. Knowledge of local resistance frequencies is therefore important in guideline-based empirical therapy.

The range of pathogens that cause pneumonia in the immunocompromised patient, in addition to routine bacterial and viral infections, also includes opportunistic organisms—those that usually are nonpathogenic in the immunocompetent host. Polymicrobial infections also occur more commonly in these patients. Prediction of likely pathogens is again imprecise, but attention should be paid to the nature and degree of the immunosuppression, time course of events, cytomegalovirus (CMV) status of donor and recipient, use of prophylactic therapies, and radiographic features (Table 23-4). Symptoms and signs, as in nosocomial pneumonia, are seldom helpful, although pancytopenia commonly accompanies CMV infections.

HOW CAN THE CAUSATIVE PATHOGEN BE IDENTIFIED?

Minimally Invasive Tests

Throat Swab Examination and Other Modalities

A throat swab may be used to identify some predominantly intracellular pathogens such as viruses (including influenza viruses), *Mycoplasma*, and *Chlamydophila*, by direct immunofluorescence (*Chlamydophila*, viruses) or cell culture. The yields are low and the methods often labor-intensive, which means that in adults, this approach usually is impractical, other than for research. In children, detection of respiratory syncytial virus by this method may be helpful. Increasingly, polymerase chain reaction (PCR) techniques are being used on such samples to detect organism-specific nucleotide sequences on throat swabs and other samples. Such tests are best for noncommensal organisms, for which significantly increased sensitivity over the older methods listed previously is found.

Sputum Examination

In many patients who have respiratory infection, sputum is easy to obtain. When such specimens are not available, sputum production may be induced by administration of nebulized

Table 23-4 Predicting Microbial Etiology in Pneumonia in Immunocompromised Patients

Feature	Criteria	Organism
Nature of immunosuppression	B cell dysfunction T cell dysfunction	Bacterial Opportunist
	Neutropenia	Bacteria Fungi
Severity in HIV infection	$CD4^+$ >200 cells/μL	Bacteria Tuberculosis
	$CD4^+$ <200 cells/μL	*Pneumocystis jiroveci* pneumonia (PCP) Other opportunists
Time course of events	0-1 month after transplantation	Bacterial infection
	1-6 months after transplantation	Opportunist
Cytomegalovirus (CMV) status	CMV-positive donor to CMV-negative recipient	CMV
Prophylactic therapy	PCP prophylaxis	PCP less likely + atypical presentations
Radiology	Focal consolidation	Bacterial infection
	Nodule	Lung abscess Fungi
	Diffuse shadowing	PCP CMV

HIV, human immunodeficiency virus.

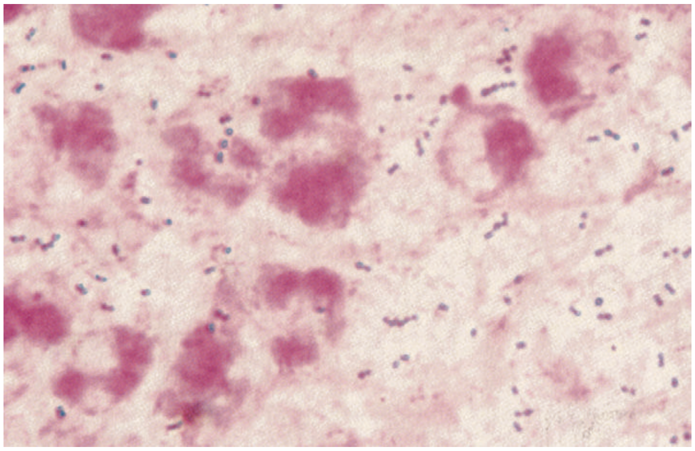

Figure 23-8 Sputum Gram stain. Gram-positive diplococci can be seen surrounded by degenerate neutrophils, which suggests pneumococcal infection.

hypertonic saline. This modality probably is of value only for the detection of *Mycobacterium tuberculosis* or of *Pneumocystis jiroveci* in immunocompromised patients. The value of examining sputum has been studied exhaustively, and its usefulness remains controversial. The main problem is that organisms identified in sputum may not be representative of what is happening in the lung. Second, bacteria may colonize the normally sterile airways when host defenses are compromised (e.g., by chronic bronchitis or intubation). The clinical illness may be attributed to these organisms when found in sputum even though another process (e.g., viral infection) is responsible.

Because some organisms are always pathogens (e.g., *Mycobacteria*, *Pneumocystis*, *Legionella*), their identification in sputum is always helpful. For other organisms, determination of the quality of the sputum sample is essential. Samples that contain 25 neutrophils and 10 or fewer squamous epithelial cells per high-power microscope field are considered to be representative of the lower respiratory tract. Other samples should be discarded, unless the pathogens listed previously are being sought.

Various tests can be performed on sputum; Gram stain and routine culture are the best known (Figure 23-8). Visualization of an organism on Gram stain is more specific than its identification by culture but is less sensitive. Culture is important for the identification of antibiotic-resistant strains. In a patient with CAP for which a predominant organism is identified within a purulent sputum sample, that organism usually is the cause of the pneumonia. Some organisms are identified in sputum only if appropriate stains are applied (e.g., with *Pneumocystis*) or if culture is performed on specific media (as for *Legionella*, and some fungi).

Tracheal Aspiration

In nosocomial pneumonia, a tracheal aspirate can be obtained from the endotracheal tube. Even though the upper respiratory tract is bypassed, the frequency of colonization means that, as for sputum, microbiologic results from such a sample should be interpreted with caution. Culture results often are polymicrobial. Recent studies suggest that quantitative culture of tracheal aspirates may be as accurate as and less harmful than bronchoscopy in nosocomial pneumonia (see later under "Bronchoscopy").

Blood Culture

Blood culture is readily available and highly specific if positive. Its drawback is its relative insensitivity: Positive culture results are obtained in only 10% to 20% of hospitalized adult patients who have CAP. Its yield is even less in nosocomial pneumonia and very low in children with pneumonia.

Pleural Fluid/Tissue Sampling

When present, pleural fluid should be sampled, because the results are highly specific. Lymphocytosis suggests the possibility of tuberculosis. Pleural pH, as well as cell content, may help in the diagnosis of empyema. Pleural biopsy for histopathologic examination and culture may assist in the diagnosis of tuberculosis.

Urine Testing

Enzyme-linked immunosorbent assay (ELISA) testing of urine for *Legionella* antigen is now the most frequently performed test, yielding the most rapid results, for the diagnosis of *Legionella* infection. Minor drawbacks are that assay results are positive only in *Legionella pneumophila* serogroup I infection (more than 90% of cases of *Legionella* infection), that results may be negative if the assay is performed too early (antigen excretion begins on approximately day 3 of clinical illness), and that antigen excretion may persist for up to 1 year after the clinical illness. Urine antigen tests for *S. pneumoniae* probably are more sensitive and specific than is sputum examination, but their cost-effectiveness is uncertain.

Serologic Testing

In CAP, serologic studies may be the only method of diagnosis available for detection of *Mycoplasma*, *Chlamydia*, *Coxiella*, *Legionella*, and viral infections. This approach does not usually help in immunocompromised persons or in patients affected by nosocomial infections, unless *Legionella* is specifically suspected (e.g., during an ongoing epidemic). To establish such diagnoses, with certain exceptions, it is necessary to identify a four-fold rise in specific antibody titers to at least 1 : 128 between acute and convalescent samples. A single high titer of 1 : 256 is presumptive evidence of infection. The need to wait for the second sample limits the clinical value of this method, which is now being replaced in routine practice by PCR methodology.

Invasive Tests

Transtracheal Aspiration

Transtracheal aspiration performed by passing a catheter through the cricothyroid membrane was used quite frequently in the past. The associated risks of hemorrhage and subcutaneous emphysema, however, have rendered it rarely used today.

Bronchoscopy

Bronchoscopy allows direct sampling from the lungs, but because the bronchoscope passes through the nasopharynx and upper airway, it is important to use an approach that minimizes contamination. This technique is most useful for obtaining samples in patients who are not producing sputum. As other drawbacks, the procedure and the associated local anesthetic and sedation may further compromise the patient's already altered ventilatory status; transbronchial biopsy may cause hemorrhage or pneumothorax; and the bronchoscope itself may introduce infection. An advantage of BAL is that a wider area of the lung is sampled, but the risk of contamination is increased. Protected specimen brush (PSB) sampling may be more specific but is less sensitive, because only a small area is sampled. Bronchoscopy has been the most commonly used diagnostic technique in immunocompromised patients and those with nosocomial pneumonia; it is most strongly validated in the former.

The utility of bronchoscopic samples in the management of nosocomial pneumonia remains unclear; PSB sampling probably is better than BAL. Endotracheal aspirates may contain the same bacteria, and no outcome benefit has been conclusively shown. The technique cannot at present be recommended routinely.

In CAP, no evidence supports the routine addition of bronchoscopy to noninvasive sampling. It may be of value in the patient in whom initial therapy fails to produce improvement.

Percutaneous Fine Needle Aspiration

Percutaneous fine needle aspiration is performed by inserting a 22-gauge needle percutaneously into consolidated lung tissue through an 18-gauge needle placed in the chest wall. This technique carries a risk of pneumothorax and lung hemorrhage and cannot be recommended other than for research purposes in experienced hands.

Open Lung Biopsy

The value of open lung biopsy has not been systematically evaluated because of the potential risks. Anecdotally, it has helped to obtain a more definitive diagnosis in all three types of pneumonia when the patient has failed to respond to empirical therapy and when other tests have been unhelpful.

Other Techniques

Molecular biologic methods, especially polymerase chain reaction (PCR) techniques, are beginning to be used selectively for pathogen identification. Other roles of PCR analysis may be to detect multiple organisms at the same time in a single sample (so-called multiplex PCR assay) and to identify antibiotic resistance by detection of the specific gene defect that determines such resistance (e.g., rifampicin resistance in tuberculosis).

Interest also has emerged in "near-patient" tests that rely on antigen or nucleic acid detection, usually with a colorimetric marker. These tests enable a microbiologic diagnosis at the bedside, both in and outside the hospital. None are yet in routine use.

Is It Necessary to Identify the Causative Pathogen?

In some patients, it may be inappropriate to seek the causative pathogen because such investigation is impractical or is not cost-effective, or the potential risk to the patient outweighs any benefit. Within the community, 95% or more of respiratory infections are managed empirically without an attempt to identify the pathogen. In this setting, microbiologic investigations may be needed only when the patient fails to respond to initial therapy.

Microbiologic investigations on hospitalized patients are routine. However, in prospective studies of CAP in which intensive investigation is undertaken, pathogens are detected only in approximately 25% to 50% of patients, and the impact on treatment is small. Outcome benefit for bronchoscopic investigations in nosocomial pneumonia remains controversial. The reasons for the poor yield are multiple and relate to previous antibiotic therapy, inadequate sample collection, transport delays, and the use of insensitive laboratory methods that often depend on the presence of intact and viable organisms for a positive result. This situation may change with the advent of newer microbiologic methods, but because empirical, broad-spectrum antibiotics are easy to give and patients who are not severely ill usually recover, it can be argued that airway infections or CAP microbiologic investigations should be limited (or not performed at all) in the mildly ill and used extensively only in the severely ill patient. In nosocomial pneumonia and immunocompromise-related pneumonia, microbial investigation may be more important, because it often is necessary to differentiate infective from noninfective pathology. Possible approaches in CAP, nosocomial pneumonia, and the immunocompromise-related pneumonia are shown in Figures 23-9, 23-10, and 23-11, respectively.

CONTROVERSIES AND PITFALLS

CONTROVERSIES

- Pneumonia cannot be diagnosed without a chest radiograph.
- The distinction between typical and atypical pneumonias is clinically accurate and useful.
- Routine sputum examination is useful in CAP.
- Bronchoscopic sampling is useful in nosocomial pneumonia.

PITFALLS

- The symptoms and physical signs of respiratory infection are shared with other respiratory tract diseases.
- The elderly, the very young, and the immunosuppressed may not manifest typical features of respiratory infection.

BURDEN OF DISEASE

Pneumonia and influenza remain common causes of death in the United States (ranked 7th) and globally (ranked 6th). More than 60,000 deaths were attributed to pneumonia in 2005 in the United States. In Europe, the incidence of lower respiratory tract infections reached 25.8 million in 2002, yielding only to diarrheal illness as a most common disease. The mean length of hospital stay for pneumonia exceeds 5 days, and readmission rate within 30 days after hospital discharge approaches 20%. The overall economic health care system burden associated with community-acquired pneumonia (CAP) is approximately $40 billion annually in the United States and reaches €10 billion in Europe. According to British Thoracic Society guidelines, age-standardized rate of hospital admissions due to CAP rose by 34% from 1997 to 2004. CAP also is the most common cause of severe sepsis. Admission to the intensive care unit (ICU) is required in up to 20% of cases of CAP. Because the incidence of pneumonia is substantially higher among elderly persons, it is anticipated that in view of the aging population, the incidence and health care burden of pneumonia will only increase. In the United States, approximately 4.2 million outpatient clinic visits for pneumonia were recorded for 2006, and this number has been increasing ever since. At the same time, despite introduction of novel antimicrobials, imaging modalities, and biomarker testing, mortality attributable to CAP has not changed significantly since the introduction of penicillin.

CLINICAL PRESENTATION

The clinical presentation and diagnosis of CAP are complex. Presence of classic symptoms such as fever, generalized fatigue, cough, sputum production, dyspnea, pleuritic chest pain, and hemoptysis is highly variable, and ranges from nearly 90% for cough to less than 15% for hemoptysis. Many factors influence the clinical presentation of CAP, including the patient's age, comorbid conditions, and lifestyle factors, as well as the causative microbe. Presence of certain symptoms, as discussed further on, may help identify the offending organism. However, the significant variability in the clinical presentation of CAP makes it virtually impossible to diagnose the disease, let alone the causative agent, from the clinical presentation alone, and further diagnostic tests are usually needed.

Probability of an atypical presentation, in which the classic symptoms are lacking, increases with patient age and number of comorbid conditions. In general, any compromise of the patient's immune system can lead to silencing of clinical symptoms despite rapidly progressive underlying infection. Absence of fever and cough is common in the elderly population; rather, altered mental status, generalized malaise, tachypnea, and tachycardia are often the only manifestations of pneumonia in this population. Such atypical clinical presentations can delay the correct diagnosis and treatment by several days, which probably leads to increased mortality.

The major causes of pneumonia have been divided into the typical organisms, such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Klebsiella pneumoniae*, and the atypical pathogens, such as *Mycoplasma pneumoniae*, *Chlamydophila* spp., *Coxiella burnetii*, and viruses. Historical descriptions of differences in clinical presentation between these two groups of pathogens have been widely used and still are commonly regarded as important. CAP caused by the typical organisms has been characterized as of more acute onset, with manifestations including fever with intense chills, along with cough, usually productive of purulent or bloody sputum and occasionally associated with pleuritic chest pain. Findings suggestive of pulmonary consolidation (such as dullness to percussion, rales, bronchial breathing) also were thought to be part of the typical presentation, as well as leukocytosis with neutrophil predominance and occasionally presence of circulating immature leukocytes (bands).

By contrast, pneumonia caused by "atypical" pathogens has been described as being of more gradual onset, with lower body temperature, nonproductive cough, and white blood cell counts in the normal to high-normal range. Systemic manifestations such as generalized malaise and muscle aches can dominate the clinical picture.

Unfortunately, studies have failed to demonstrate the accuracy of such purported differences in clinical presentation of CAP in distinguishing between the typical and atypical pathogens. Accordingly, this distinction should not be relied on to make an etiologic diagnosis or decisions about antibiotic treatment.

RISK FACTORS

Certain risk factors are associated with higher frequency of infections with particular pathogens.

Age Increased age favors infection with *S. pneumoniae*, group B streptococci, *Moraxella catarrhalis*, *H. influenzae*, gram-negative bacilli, and *Chlamydophila pneumoniae*. Aspiration pneumonia risk increases with age as well as risk for pneumonia due to multiple organisms. It seems that an apparent decrease in frequency of *Legionella* infection has been noted among persons older than 80 years. Every year over 65 increases the risk for pneumonia. The annual incidence of CAP in noninstitutionalized elderly people is estimated to be 25 to 44 per 1000, compared with 4.7 to 11.6 per 1000 in the general population. The risk of infection severe enough to necessitate hospital admission also increases markedly with age, ranging from 1.6 per 1000 adults 55 to 64 years of age to 11.6 per 1000 after age 75. Age is one of the main predictive factors for mortality associated with CAP. The death rate for pneumonia or influenza has been evaluated at 9 per 100,000 in the elderly population, rising to 217 per 100,000 among patients with one risk factor and to 979 per 100,000 among those with more than one.

Alcoholism Alcohol consumption may potentially lead to impaired level of consciousness, predisposing the drinker to aspiration pneumonia by impairing the cough reflexes, with alterations in the mechanisms of swallowing and mucociliary clearance. Owing to the immunosuppressive effects and impairment of innate lung defenses attributable to high alcohol intake, heavy drinking increases the risk of infection with gram-negative organisms. Alcohol impairs the function of lymphocytes, neutrophils, monocytes, and alveolar macrophages. Each of these factors contributes to the reduced bacterial clearance from the airways in these patients. Whether alcoholism predisposes to increased pneumonia severity in general is controversial; however, *S. pneumoniae* infections tend to be more severe in alcoholic patients. Also, infections caused by gram-negative bacilli and *L. pneumophila* occur more frequently in heavy drinkers.

Airway Colonization Airway colonization is common in patients with chronic obstructive pulmonary disease (COPD), as is impairment of innate lung defense mechanisms. Patients with COPD appear to be at increased risk for CAP, and pathogens such as *H. influenzae* and *M. catarrhalis* become more prevalent. Very pronounced decrease in forced expiratory volume in 1 second (FEV_1), along with bronchiectasis, predisposes affected patients to infection with *Pseudomonas aeruginosa*. Invasive aspergillosis has been described as an often fatal complication of high-dose corticosteroid treatment of exacerbations of COPD in patients with severely compromised lung function. Conditions leading to altered level of consciousness (narcotic use, alcohol consumption, cerebrovascular disease, dementia), poor dental hygiene, history of head and neck surgery affecting swallowing mechanisms, and upper gastrointestinal tract disease all are predisposing factors for development of aspiration pneumonia. Usual culprit organisms include anaerobes and members of the oral and enteric flora.

Organisms such as *S. pneumoniae*, *S. aureus*, group B streptococci, and *H. influenzae* frequently cause superinfections after viral illnesses such as influenza and RSV infection.

Altered Immunity Patients with a compromised immune system are at increased risk for development of CAP. The list of possible pathogens is long and only increases with worsening degree of immunodeficiency. Immunosuppression achieved with medications predisposes to infections with otherwise rare pathogens such as *Pneumocystis jiroveci*, *Mycobacterium avium* complex, *Histoplasma* spp., *Coccidioides* spp., *Cryptococcus neoformans*, Mucoraceae spp., and *Toxoplasma*, to name a few. Some examples of comorbid conditions leading to an immunocompromised state are chronic liver disease, heart failure, cancer, diabetes, lymphoproliferative disease, human immunodeficiency virus (HIV) infection/acquired immunodeficiency syndrome (AIDS), and immunoglobulin deficiencies. Malnutrition, which frequently accompanies such conditions, also leads to alterations in cellular immunity and decreased levels of secretory immunoglobulin A (IgA), increasing the chance of airway colonization and/or infection with gram-negative bacilli.

Environmental Factors Geographic location and professional history also seem to play a role in susceptibility to CAP. Occupations associated with exposure to dusts, fumes, and various chemicals (such as construction work, painting, and mining, to name a few) increase the risk of acquiring CAP in general, with *S. pneumoniae* being the most likely pathogen. Exposure to contaminated water supply and cooling towers of air-conditioning units increases the chance of acquiring Legionnaire's disease. *Legionella* organisms thrive in warm water, and could then be spread in water mist. Contact with animals may lead to pneumonia due to *Yersinia pestis* (plague, for which rodents constitute a natural reservoir), *Francisella tularensis* (tularemia, with rabbits, voles, and muskrats as carriers), C. *burnetii* (Q fever, transmitted by sheep, dogs, and cats), *Rhodococcus* (present in horses) or C*hlamydophila psittaci* (psittacosis, transmitted by birds).

In certain settings, bioterrorism must be considered as well. Potential agents utilized for such purposes include those organisms causing anthrax, tularemia, and plague.

Institutionalization Both the frequency and the severity of pneumonia increase in institutionalized patients. Oropharyngeal colonization by gram-negative bacilli or *S. aureus* plays a major role here. Epidemics of viral infections also are frequent in this patient population. The main microorganisms isolated in cases of pneumonia diagnosed in institutional environments are, in order of decreasing frequency, *S. pneumoniae, S. aureus,* gram-negative bacilli, and *H. influenzae.*

Nutrition Susceptibility to infection is increased by a number of malnutrition-related phenomena, such as a decreased level of secretory IgA, a failure of macrophage recruitment, and alterations in cellular immunity. As a result, the frequency of respiratory tract colonization by gram-negative bacilli is increased in patients with malnutrition and the incidence and severity of respiratory infections are increased. Malnutrition acts in association with other comorbid conditions frequently found in patients with pneumonia, such as alcohol consumption, COPD, chronic respiratory failure, and neurologic disease.

Smoking Smoking alters mucociliary transport, humoral and cellular defenses, and epithelial cell function and increases adhesion of *S. pneumoniae* and *H. influenzae* to the oropharyngeal epithelium. Also, smoking predisposes to infection by influenza viruses, *L. pneumophila*, and *S. pneumoniae.* Smoking itself, however, is not a risk factor for pneumonia severity.

PATIENT EVALUATION/DIAGNOSTICS

Clinical presentation of CAP can be rather nonspecific, especially in elderly and debilitated persons. Risk factors for specific causative agents, such as history of recent travel into endemic areas, is an important part of the clinical history in a patient with suspected CAP. Because of the inaccuracy of a purely clinical diagnosis, additional investigations are required to confirm the diagnosis, identify the causative pathogen, and initiate appropriate treatment. These are discussed in Chapter 23. **Table 24-1** summarizes the American Thoracic Society/

Table 24-1 Clinical Indications for Diagnostic Testing for Community-Acquired Pneumonia

Indication	Blood Culture	Sputum Culture	*Legionella* UAT	Pneumococcal UAT	Other
Intensive care unit admission	X	X	X	X	X*
Failure of outpatient antibiotic therapy		X	X	X	
Cavitary infiltrates	X			X	X†
Leukopenia	X		X		
Active alcohol abuse	X	X	X	X	
Chronic severe liver disease	X		X		
Severe obstructive/structural lung disease		X			
Asplenia (anatomic or functional)	X		X		
Recent travel (within past 2 weeks)			X		X
Positive *Legionella* UAT result		X‡	NA		
Positive pneumococcal UAT result	X	X		NA	
Pleural effusion	X	X	X	X	X¶

*Endotracheal aspirate if patient is intubated, possibly bronchoscopy or nonbronchoscopic bronchoalveolar lavage.
†Fungal and tuberculosis cultures.
‡Special media for *Legionella* culture.
¶Thoracentesis and pleural fluid cultures.
NA, not applicable; *UAT*, urinary antigen test.

Infectious Diseases Society of America (ATS/IDSA) recommendations of tests proven to be useful in different settings for investigating and treating CAP.

SPECIFIC PATHOGENS

Streptococcus Species

S. pneumoniae is the most common bacterium isolated from patients with CAP. It is a saprophyte of the respiratory tract, which can easily proliferate as soon as natural defenses decline (as with increasing age, alcoholism, diabetes, smoking, or immunosuppression). In the classic presentation, the onset of pneumococcal pneumonia is abrupt, characterized by intense and prolonged chills and considerable pleuritic chest pain. Symptoms and signs are rapidly progressive, with high fever (core body temperature close to 40° C [104° F]), tachycardia, and tachypnea; cough is common, as are oliguria and cyanosis. At this stage, a nasolabial herpes simplex lesion may develop, crackles are heard, and chest radiographs show homogeneous lobar or segmental consolidation. Without antibiotic treatment, cough persists, with eventual production of rust-colored sputum. Leukocytosis is frequent, and blood cultures are positive in 10% to 20% of patients if specimens are obtained before antibiotic therapy. Arterial blood gas analysis reveals decreases in PaO_2 and PaCO_2. Recrudescence of symptoms may occur after a few days; then the fever resolves and an abundant diuresis ensues. Radiologic and physical signs characteristically regress rapidly and considerably. The rapid rate of multiplication of *S. pneumoniae*, together with the high risk for secondary complications (e.g., empyema, meningitis, septicemia), makes any case of *S. pneumoniae* pneumonia a medical emergency.

Streptococcal species other than *S. pneumoniae* rarely cause pneumonia, but among these, *S. pyogenes* most often is involved, more in the young than in the elderly. Pneumonia caused by *S. pyogenes* occurs after viral infections such as measles, varicella, or rubella in infants and after influenza, measles, or varicella in adults. The clinical presentation is that of typical pneumonia. Pleural effusion and empyema frequently develop, and other complications include pneumothorax, pericarditis, mediastinitis, and bronchopleural fistula.

Staphylococcus Species

The severity of *Staphylococcus* infection is due to the prevalence of its resistance to multiple antibiotics and to lung tissue lysis as part of the infection, leading to formation of bullae and their subsequent rupture into the pleura (pneumothorax, pneumopyothorax), with consequent serious ventilatory defects and septicemia. Staphylococcal infection is acquired by inhalation or aspiration through the airways or occurs by hematogenous spread. Airborne contamination may follow a viral infection such as influenza or measles, or it may be linked to comorbidity (COPD, carcinoma, laryngectomy, seizure); hematogenous spread is the result of bacteremia (endocarditis, infective foci with discharge into the bloodstream). Direct bloodstream infection caused by intravenous drug abuse is the most common cause in many inner-city hospital emergency departments. The clinical presentation may be unusual compared with typical pneumonia when the infection develops through vascular dissemination (e.g., dyspnea, cough, and purulent sputum might be masked by symptoms of endocarditis or the primary infective focus) or when the infection is causing a pleural effusion, empyema, or lung abscess. The chest radiograph may show two possible features: central or segmental consolidation secondary to aspiration or multiple infiltrates that are generally nodular early on and can subsequently progress to parenchymal consolidation with or without cavitation after vascular spread of the infection. Abscess, pleural effusion, and empyema are frequent, as well as septicemia. Overall outcome depends on associated diseases, spread of infection, and resistance of *Staphylococcus* to antibiotics.

Community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) has emerged as a frequent infectious agent associated with skin and soft tissue infections in the community setting. Community-acquired MRSA also can cause severe pulmonary infections, including necrotizing pneumonia and empyema. It is more virulent than health care–associated MRSA isolates. Community-acquired MRSA usually contains the gene encoding Panton-Valentine leukocidin and the SCC*mec* type IV element and belongs to the USA300 pulsed-field gel electrophoretic pattern. Panton-Valentine leukocidin is a toxin that creates lytic pores in the cell membranes of neutrophils and induces the release of neutrophil factors that promote inflammation and tissue destruction. Community-acquired MRSA typically is more susceptible to a wider class of antibiotics than those with activity against health care–associated MRSA. The optimal antibiotic treatment for Panton-Valentine leukocidin-positive community-acquired MRSA infection is unknown; however, antibiotics with activity against MRSA and the ability to inhibit toxin production may be optimal (linezolid or clindamycin for susceptible isolates).

Haemophilus influenzae

Most invasive infections due to *H. influenzae* result from encapsulated, typable strains rather than from nonencapsulated, nontypable strains. An exception is in patients with COPD, in whom the nontypable strains often are the etiologic agents of pneumonia and occasionally even cause an associated bacteremia. A history of upper respiratory tract infection is common. Small pleural effusions can occur, but empyema and cavitation are rare.

Mycoplasma pneumoniae

Mycoplasma pneumoniae pneumonias usually occur in small epidemics, particularly in closed populations. The clinical presentation commonly is that of an atypical pneumonia, as described earlier. *M. pneumoniae* infections mimic, to some extent, the presentation of viral respiratory infections, but the incubation period is longer (10 to 20 days) than for viruses, and the fever generally is of mild to moderate severity, with core body temperature below 39° C (102.2° F). Within a few days, most symptoms subside, although the low-grade fever and cough frequently persist. A history of a preceding upper respiratory tract infection may be found in up to 50% of patients. A variety of extrapulmonary manifestations may be encountered, including arthralgia, cervical lymphadenopathy, bullous myringitis, diarrhea, immune hemolytic anemia, meningitis, meningoencephalitis, myalgia, myocarditis, hepatitis, nausea, pericarditis, skin eruptions, and vomiting. Diffuse crackles occasionally are heard. Infiltrates usually are localized in the lower lobes and regress very slowly over 4 to 6 weeks. Pleural effusions and mediastinal lymphadenopathy are rare.

Chlamydia Species

Psittacosis is a pneumonia caused by an intracellular bacterium, *Chlamydia psittaci*, which is responsible for ornithosis in domestic fowl. *C. psittaci* can be transmitted to humans by inhalation from infected birds, including canaries, parakeets, parrots, pigeons, and turkeys. The clinical presentation is that of an atypical pneumonia. After a 7- to 14-day incubation period, the onset may be abrupt. Fever with temperatures of 38° to 40° C (100.4° to 104.0° F), possibly with chills, is associated with arthralgia, headache, myalgia, dyspnea, and thoracic pain. Cough may be severe, and sputum, if any, usually is mucoid. Splenomegaly and a macular rash are evocative of psittacosis. The radiographic appearance is variable but typically includes lower lobe infiltration. Hepatitis, phlebitis, encephalitis, myocarditis, renal failure, and intravascular coagulation are unusual complications. Despite the efficiency of antibiotics such as tetracycline and erythromycin, psittacosis is associated with a mortality rate of approximately 1%. Relapse is prevented by continuing treatment for 2 weeks after return to a normal temperature.

Previously known as the TWAR (*T*ai*w*an *a*cute *r*espiratory) agent, *Chlamydia pneumoniae* has been recognized as a pathogen responsible for pneumonia since 1985. The incidence of pneumonia caused by *C. pneumoniae* is uncertain because of the lack of reliable diagnostic tests. However, it does appear to be an important cause of pneumonia in all age groups. The clinical presentation is that of an atypical pneumonia in young adults; in elderly persons, the course may be severe, particularly if comorbid conditions are present. Sore throat may precede the onset of fever (with temperatures in the range of 37.7° to 39° C [100° to 102.2° F]) and a nonproductive cough. The chest radiograph shows subsegmental infiltrates, which usually clear over 2 to 4 weeks.

Legionella pneumophila

Legionella organisms are aerobic gram-negative intracellular bacilli; approximately 30 species have been identified, the most common being *L. pneumophila*. Water- and air-conditioning systems are their natural reservoirs; spread of the bacilli occurs by air, but no transmission between human beings has been reported. *L. pneumophila* infection may cause an asymptomatic seroconversion, a single episode of pyrexia, and mild to severe pneumonia. The nonpneumonic illness is known as Pontiac fever and is associated with fever, chills, headache, and upper respiratory tract symptoms. Pneumonia occurs either sporadically or in small epidemics and is more likely to occur in immunocompromised persons. After 2 to 8 days of incubation, headache, myalgia, high fever, and chills precede pneumonia by a few days. Initially, there is a nonproductive cough that may become productive of watery or even purulent sputum. Dyspnea, hemoptysis, and chest pain are frequent manifestations. Extrapulmonary symptoms and signs are numerous and include abdominal pain, agitation, watery diarrhea, arthralgia, confusion, skin rash, headache, hematuria, hyponatremia, hypophosphatemia, myalgia, nausea, oliguria, proteinuria, renal failure, seizures, splenomegaly, and vomiting. Leukocytosis, neutropenia, lymphopenia, and hepatic inflammation may be observed. The chest radiograph shows consolidation, often unilateral and dense, initially localized and then spreading gradually. Pleural effusion frequently is present; cavitation is rare. The outcome depends on the early clinical recognition and treatment and on comorbid conditions. Mortality is increased in immunosuppressed patients and in those who have complications of the infection.

Gram-Negative Bacilli

Gram-negative bacilli include various members of the families Enterobacteriaceae and Pseudomonadaceae, in particular *K. pneumoniae*, *Escherichia coli*, *Pseudomonas aeruginosa*, and *Acinetobacter* spp. Gram-negative bacilli are more often responsible for nosocomial pneumonia than for CAP. CAP attributable to these agents may result from their colonization of the oropharynx, followed by inhalation or microaspiration of the organisms; however, most of these patients meet criteria for health care–associated pneumonia, such as residence in long-term care facilities. Comorbidity is usual in patients who acquire these pneumonias. The clinical presentation is that of a typical pneumonia. The prognosis is poor, particularly in cases featuring immunodepression, alcoholism, neutropenia, and old age.

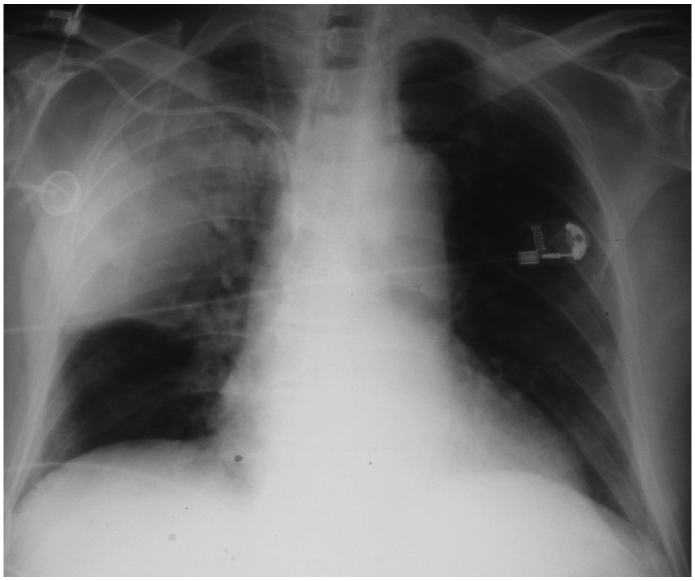

Figure 24-1 *Klebsiella* pneumonia. Chest radiograph shows a bulging fissure. *(From Rabbat A, Huchon G: Bacterial pneumonia. In Albert RK, Spiro SG, Jett JR, editors:* Clinical respiratory medicine, *ed 3, Philadelphia, 2008, Mosby.)*

Friedländer's pneumonia (caused by *K. pneumoniae*) typically occurs in men older than 40 years; alcoholism, diabetes mellitus, and chronic lung disease are predisposing factors. Historically, patients were thought to produce particularly large volumes of thick and bloody sputum; they were likely to present with prostration and hypotension and to have multiple patches of consolidation, particularly in the upper lobes, with bulging fissures (Figure 24-1) and multicavitation on chest radiographs (i.e., an expanding pneumonia).

E. coli pneumonia and *P. aeruginosa* pneumonia typically occur in chronically ill patients; hemoptysis is rare, and the lung infection usually involves the lower lobes. Abscessation and empyema occur frequently. *Acinetobacter* pneumonia progresses very quickly, with development of severe hypoxemia, shock, bilateral consolidation, and empyema and even death within a few days.

Pseudomonas pseudomallei, which causes melioidosis, is an aerobic, gram-negative bacillus found in soil, vegetation, and water in tropical regions. Infection of the lung occurs more commonly as a result of spread through the bloodstream after cutaneous infection than as a result of inhalation. The clinical presentation may be either acute or chronic. Acute melioidosis manifests with high fever, dyspnea, chest pain, cough with purulent sputum, and hemoptysis. Local cellulitis and lymphangitis may be seen at the place of cutaneous inoculation. The chest radiograph shows diffuse miliary nodules, infiltrates, or cavitation. Chronic melioidosis may occur years after contraction of the infection in an endemic area. Signs and symptoms either are absent or may resemble those of pulmonary tuberculosis: asthenia, anorexia, weight loss, low-grade fever, productive cough, and hemoptysis. Chest radiographs show apical infiltrates, possibly with cavitations.

Anaerobic Bacteria

Anaerobic bacterial pneumonia results from aspiration; therefore, it typically occurs in situations involving alcoholism, coma, seizure, and general anesthesia. Chronic dental infection; head, neck, and lung cancer; and bronchiectasis are additional risk factors. Anaerobic pneumonia begins as a typical pneumonia with pleuritic pain; pulmonary infiltrations preferentially involve the lower lobes, particularly the right lower lobe. If patients aspirate while lying supine, the segments involved typically are the posterior segment of the right upper lobe and the apical segment of the right lower lobe. Necrosis and suppuration follow, and fever with temperatures higher than 39° C (102.2° F), dyspnea, and pleuritic pain persist. Sputum is purulent and fetid, which often is obvious on entering the patient's room. Leukocytosis is high, and segmental infiltrations with small transparent areas of necrosis are seen. Abscess and empyema occur frequently. The outcome is closely related to treatment—delay in antibiotic treatment or inappropriate antibiotic choice probably will result in necrotizing pneumonia, abscess formation, and empyema, which increases the fatality rate.

Coxiella burnetii

C. burnetii is the causative agent of Q fever and is the most frequent pathogen responsible for pneumonia among the rickettsial organisms. Ticks are vector agents, and various wild and domestic animals (cattle, sheep, goats) are infected with no evidence of disease; *C. burnetii* multiplies in the placenta of pregnant animals and spreads during parturition. Although *C. burnetii* is present in numerous species of ticks, the main route of transmission is by inhalation of infectious aerosols. *C. burnetii* is particularly resistant to chemical and physical agents. The clinical presentation is that of an atypical pneumonia. The onset occurs after a 2- to 4-week incubation period. Patients present with high fever (i.e., body temperature of 40° C [104° F] or more), chills, myalgia, and headache, all of abrupt onset; cough usually is nonproductive. Abdominal and thoracic pain, pharyngitis, and bradycardia also may be features. There usually is no rash, in contrast with other rickettsial infections. Hepatomegaly and splenomegaly may be found on physical examination. The chest radiograph shows dense nodular infiltrates; pleural effusion and linear atelectasis may be seen. Leukocytosis is not a feature, and mild hepatitis may be found. The course usually is benign.

Nocardia Species

Nocardia asteroides and, to a lesser extent, *Nocardia brasiliensis* are responsible for most cases of *Nocardia* pneumonia. Nocardiae are aerobic, gram-positive bacilli present mainly in soil. Approximately 50% of patients have no underlying disease. The others tend to have predisposing problems such as immunosuppression, malignancy, or long-term corticosteroid therapy. The onset of the infection is usually subacute, but it can be fulminant; in the latter case, there is a high fatality rate. Symptoms include fever, asthenia, anorexia, productive cough, and chest pain. Multiple subcutaneous abscesses may be present, as well as neurologic signs when there is central nervous system involvement. Chest radiograph abnormalities vary, ranging from infiltration to lobar consolidation; cavitation, nodules, abscesses, and pleural effusion also may be seen. The prognosis depends on whether the infection disseminates, but it is usually good in the case of isolated lung disease. Metastatic infection may occur anywhere but is particularly common in the central nervous system and the skin. Infection also may reach the pleura and the chest wall.

Actinomyces israelii

Both *Actinomyces* and *Arachnia* can cause actinomycosis, but *Actinomyces israelii* is the main responsible organism. These are

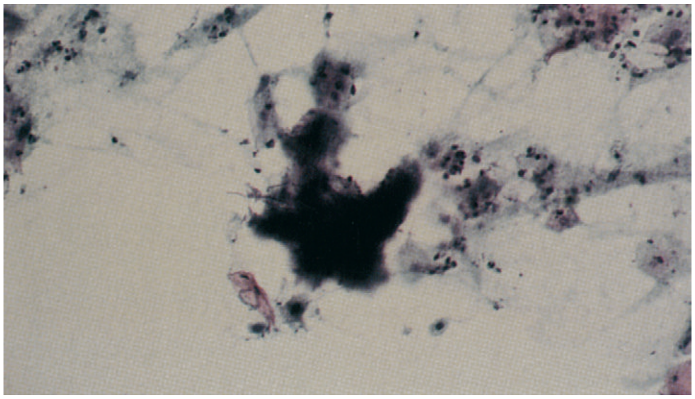

Figure 24-2 Sputum Gram stain showing *Actinomyces* organisms (center). *(From Rabbat A, Huchon G: Bacterial pneumonia. In Albert RK, Spiro SG, Jett JR, editors:* Clinical respiratory medicine, *ed 3, Philadelphia, 2008, Mosby.)*

anaerobic, gram-positive, filamentous, branching bacilli (**Figure 24-2**) that were incorrectly thought to be fungi for many years. They normally reside in the oropharynx and become invasive pathogens when there is a defect in the anatomic barrier or when they are inhaled, at which time the infection may extend directly from one place to an adjacent area. Bad dentition, bronchiectasis, and COPD are risk factors for pulmonary infection. Men are far more frequently affected than women. The clinical presentation suggests tuberculosis, carcinoma, or chronic fungal infection; asthenia, anorexia, weight loss, and low-grade fever may precede cough and chest pain by months. Cervicofacial and thoracic involvement coexists rarely. When infection progresses to the pleural space and chest wall, the opening of a sinus tract may disclose pus. Radiographic features are variable and include small cavitary nodules confined to one segment; cavitary infiltration; extension of infection to the interlobar fissure, chest wall, bone, or pleura; and empyema.

Pasteurella multocida

Pasteurella multocida is a gram-negative coccobacillus present in the oropharynx of mammals. It causes cutaneous infection in humans after animal bites. Pneumonia has been reported in patients with chronic pulmonary diseases. The clinical presentation is nonspecific and includes fever, cough, purulent sputum, and dyspnea. Chest radiographs show lower lobe infiltrates; pleural effusion and empyema may occur.

Francisella tularensis

Francisella tularensis is a gram-negative bacillus found in various mammals and insects of the Northern Hemisphere. Tularemia occurs after the bite of, or contact with, an infected animal. The onset of pneumonia is abrupt; fever, chills, and malaise precede dyspnea, cough, and chest pain. Painful ulceroglandular infection with adenopathy may be found at the site of bacterial inoculation. The chest radiograph shows signs of pneumonia, possibly with hilar adenopathy or pleural effusion.

Yersinia pestis

Yersinia pestis (formerly called *Pasteurella pestis*) is a short gram-negative rod that causes plague. It is a disease of rodents (squirrels, rabbits, rats) that is transmitted to humans by flea bites or by person-to-person contact through aerosol inhalation. Initial signs and symptoms are chills, fever, prostration, delirium, headache, vomiting, and diarrhea. There are three forms of plague: bubonic, septicemic, and pneumonic. Bubonic plague consists of lymphadenopathy, with palpable masses forming in the cervical, axillary, femoral, and inguinal areas. Signs of septicemia are those of shock and petechial hemorrhages. Plague pneumonia results from either metastatic infection or inhalation of the pathogen. Pneumonia occurs within a week of initial exposure and is characterized by chest pain, productive cough, dyspnea, and hemoptysis. The chest radiograph shows lower lobe infiltrates, possibly nodules, lymphadenopathy, and pleural effusions.

Bacillus anthracis

Bacillus anthracis is a large gram-positive rod that causes anthrax. *B. anthracis* is found in the soil, water, and vegetation and infects cows, sheep, and horses, which in turn infect humans after contact with contaminated materials. Fever and malaise usually appear progressively. Three forms of anthrax are found: cutaneous, intestinal, and pneumonic. Inoculation of *B. anthracis* into superficial wounds or skin abrasions causes cutaneous anthrax, which is characterized by a black-crusted pustule on a large area of edema. Intestinal anthrax results from ingestion of contaminated material, and the resulting illness can be severe. Pneumonic anthrax is due to inhalation of the contaminated material. Nonproductive cough and chest pain precede dyspnea, stridor, tachypnea, cyanosis, and edema of the neck and anterior chest. Peribronchovascular edema, enlargement of the mediastinum, and pleural effusions usually are seen on the chest radiograph.

Brucella Species

Brucella organisms are gram-negative coccobacilli found in the genitourinary tract of cows, pigs, goats, and dogs. Brucellosis results from contact with infected animals or from ingestion of unpasteurized milk products. The pathogen then spreads through the body by way of the bloodstream. General symptoms include fever, malaise, and headache. Hepatic enlargement and splenomegaly are common, as is lower back pain. Respiratory symptoms are less frequent than abnormalities on the chest radiograph, which include nodules, miliary infiltrates, and lymphadenopathy.

Moraxella catarrhalis

Moraxella catarrhalis, formerly named *Branhamella catarrhalis*, is a gram-negative diplococcus that commonly is found in the oropharynx of normal persons. *M. catarrhalis* pneumonia is seen in patients with underlying chronic diseases such as COPD, congestive heart disease, or malignancy. Symptoms and radiographic findings are nonspecific. Leukocytosis is common, and the course usually is favorable.

TREATMENT

SITE OF CARE DECISION

A crucial decision in the treatment of CAP is whether or not the patient's condition warrants hospital admission. Numerous factors contribute to such decision making, including risk of death from the pneumonia, disease severity, presence of comorbid conditions, need for advanced diagnostics, ability to take oral medications, and the degree of social support. In the past, hospital admission was an instinctive "knee jerk" response to the diagnosis of CAP. However, hospitalization is associated with an increased risk of acquiring multidrug-resistant nosocomial bacterial strains, increased risk for thromboembolic events, up to a 75-fold increase in cost, and less patient satisfaction.

Box 24-1 **American Thoracic Society Criteria for Admission of Patients with Community-Acquired Pneumonia to an Intensive Care Unit**

Major Criteria

Invasive mechanical ventilation
Vasopressor use

Minor Criteria

Hypotension requiring aggressive fluid resuscitation
Hypothermia (core body temperature <36° C)
Thrombocytopenia (platelet count <100,000/dL)
Leukopenia (white blood cell count <4000/dL)
Uremia (BUN >20 mg/dL)
Confusion or disorientation
Multilobar radiographic involvement
PaO_2/FIO_2 ratio <250
Respiratory rate ≥30 breaths/minute

BUN, blood urea nitrogen.
Modified from Mandell LA, Wunderink RG, Anzueto A, et al: Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults, *Clin Infect Dis* 44(Suppl 2):S27–S72, 2007.

Informed practitioners have therefore mounted a vigorous effort to reduce unnecessary admissions for CAP, primarily by better identification of patients who can be safely treated at home.

Several outcome tools have been developed to predict prognosis in CAP, and these are now being used to identify patients at low risk of mortality and appropriate for treatment at home rather than in hospital. Among the well-validated ones are the Pneumonia Severity Index (PSI) and the CURB-65 and CRB-65 indices. These are summarized in Chapter 23, Figures 23-5 and 23-6.

CURB-65 or CRB-65 (which is CURB-65 without the blood urea nitrogen level) indices are significantly more user-friendly scoring systems requiring consideration of four or five readily assessed variables (see Chapter 23, Figure 23-6).

Another sometimes challenging decision is whether and when to admit the patient to an ICU. Generally, patients with high scores on mortality prediction indices (such as class V PSI or group 3 CURB-65) are likely to benefit from early ICU admission. Emerging data suggest that early admission to the ICU in appropriate patients can improve outcomes. The challenge is identifying these patients among the larger group of patients at risk for higher mortality. Latest ATS/IDSA guidelines defined need for ICU admission as the presence of one of the major criteria (need for invasive mechanical ventilation or hemodynamic instability requiring vasopressor use) or three of nine minor criteria listed in **Box 24-1**. Several scoring systems (CURXO, SMART-COP, and CAP-PIRO) tested criteria similar to the ATS minor criteria set and found them to be similar in terms of predicting need for admission to intensive care. All of the aforementioned scoring systems, however, are not without limitations, especially when applied in younger populations. Development and validation of a dedicated scoring system to predict need for ICU treatment will be useful.

These scoring systems have contributed significantly to the objective assessment of the severity and prognosis prediction of CAP. Such systems, however, should not be used as the sole parameter for determining the need for hospital admission. In practice, as many as 40% of patients with CAP who are at low risk for dying as assessed by these scores get admitted for management of the pneumonia. In many of these patients, comorbid conditions requiring inpatient management or social factors that make home treatment unsafe necessitate hospital care. A combination of a prognostic scoring system and assessment for comorbidity and risk factors related to the patient's social situation should guide decisions about site of care for CAP.

ANTIMICROBIAL TREATMENT

Eradication of the offending pathogen from the lower respiratory tract is the goal of antimicrobial CAP therapy. Ideally, the identity and the antimicrobial susceptibility of the pathogen should be known before initiation of treatment, so that an antibiotic that has the narrowest antimicrobial spectrum, least side effects, and the lowest cost can be prescribed. However, diagnostic testing able to identify causative organisms so rapidly that the results would be available before initiation of antimicrobial therapy are still lacking. The lack of sensitivity and specificity of current diagnostic testing is also a concern. Biomarkers and molecular detection may ultimately provide the necessary diagnostic tools to support pathogen directed treatment, but are not adequately validated for clinical use at present. Furthermore, there is evidence that earlier administration of appropriate antimicrobial therapy (with one or more antibiotics effective in vitro against the causative pathogen and given in adequate doses) improves outcomes in CAP. Therefore, delay in initiation of antimicrobial therapy while awaiting the results of microbiologic studies, or even for obtaining such studies (e.g., waiting for the patient to produce an adequate sputum sample) could have deleterious effects on patient outcome.

These considerations have prompted the current emphasis on broad-spectrum empirical therapy, with or without subsequent adjustment of antimicrobial spectrum once diagnostic results become available. Empirical choice of antimicrobials depends on factors such as severity of illness, knowledge of the most common pathogens associated with the patient's condition, local resistance patterns, and the growing understanding that CAP frequently can be a polymicrobial infection, most commonly consisting of a combination of a virus or an atypical pathogen with a typical bacterial pathogen. In view of the lack of sensitivity of current diagnostic testing, hesitation to adjust the antibiotic regimen is common if the patient is responding to therapy, even if diagnostic data support narrowing of the antimicrobial spectrum. Current recommendations also emphasize rapid administration of antibiotics in CAP, with retraction of previous guidelines on specific time intervals at which antibiotics should be administered. Therefore, current guidelines do not include specific timing for administration of antibiotics for CAP, except that antibiotics should be started in the emergency department if that is the facility admitting the patient to the hospital.

A major consideration determining empirical antibiotic choice in the current ATS/IDSA guidelines is the site of care, which serves as a surrogate marker for disease severity (outpatient, inpatient, and ICU settings) (**Box 24-2** and **Table 24-2**). In the outpatient setting, choice of antibiotics is influenced primarily by presence of comorbid conditions and by recent antibiotic use. These two risk factors portend poor outcomes and infection by drug-resistant pathogens. Recent antibiotic use (within 3 months) should prompt choice of an agent from an antibiotic class other than the one to which the patient has already been exposed. Local resistance patterns also should be

ICU, intensive care unit.
Modified from Mandell LA, Wunderink RG, Anzueto A, et al: Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults, *Clin Infect Dis* 44(Suppl 2):S27–S72, 2007.

kept in mind in choosing agents for empirical antimicrobial therapy; for example, high-level macrolide resistance (minimum inhibitory concentration [MIC] of 16 μg/mL or higher) at a prevalence of 25% or more should discourage macrolide use as a single agent. Of the multitude of potential causative agents, five or six pathogens typically account for a majority of cases of CAP; nevertheless, the possibility of unusual pathogens should always be kept in mind. A thorough recent travel or exposure history and an awareness of specific pathogen association with certain epidemiologic settings are necessary to consider these unusual pathogens in CAP.

With respect to management, inpatients with CAP treated in the non-ICU setting are quite similar to the outpatients with equivalent risk factors. Pathogen spectra for these patient groups also are similar, except that *Legionella* and aspiration are more common in inpatients. Parenteral therapy is the preferred mode in the hospitalized patients.

With CAP severe enough to warrant admission to an ICU, an expanded list of likely pathogens has been reported. Although *S. pneumoniae* remains the most common, *Legionella*, *S. aureus*, and gram-negative bacilli including *P. aeruginosa* are identified with increasing frequency and warrant consideration for empirical coverage (Table 24-3). Those patients with CAP admitted to the ICU are by definition severely ill, and available data point to improved outcomes with use of antibiotic combinations in these patients; thus, monotherapy with fluoroquinolones or beta-lactams is not indicated. All patients should receive antibiotic combinations active against the most likely offending organisms. Presence of certain comorbid conditions such as bronchiectasis and severe COPD and other factors such as frequent antibiotic and systemic corticosteroid use are associated with increased probability of infection with *P. aeruginosa;* in such instances, empirical treatment effective against this pathogen is warranted. If *S. aureus* infection is suspected, coverage for community-acquired MRSA with agents such as vancomycin or linezolid should be provided. If necrotizing pneumonia is evident, clindamycin should be added to the regimen.

ROUTE AND DURATION OF THERAPY; HOSPITAL DISCHARGE

Most patients with CAP severe enough to warrant hospital admission are treated with intravenous antibiotics. Switching to oral therapy should be considered once the patient has achieved clinical stability (Box 24-3), is able to tolerate oral medications, and has a functioning gastrointestinal tract. In general, either the same agent or same class of antimicrobials should be used for the oral therapy regimen. Early initiation of oral therapy leads to earlier hospital discharge and overall

Table 24-3 Empirical Coverage for Uncommon Pathogens Causing Community-Acquired Pneumonia

Suspected Pathogen	Special Considerations
Pseudomonas	Piperacillin-tazobactam, cefepime, imipenem, or meropenem PLUS either ciprofloxacin or levofloxacin (750 mg) OR Aminoglycoside and azithromycin OR Aminoglycoside and antipneumococcal fluoroquinolone OR Substitute beta-lactam (piperacillin-tazobactam, cefepime, imipenem, or meropenem) with aztreonam in patients allergic to penicillin
Community-acquired methicillin-resistant *Staphylococcus aureus*	Vancomycin (+ clindamycin in patients with necrotizing pneumonia) OR Linezolid

Data from Mandell LA, Wunderink RG, Anzueto A, et al: Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults, *Clin Infect Dis* 44(Suppl 2):S27–S72, 2007.

Box 24-3 Criteria for Clinical Stability in Management of Community-Acquired Pneumonia

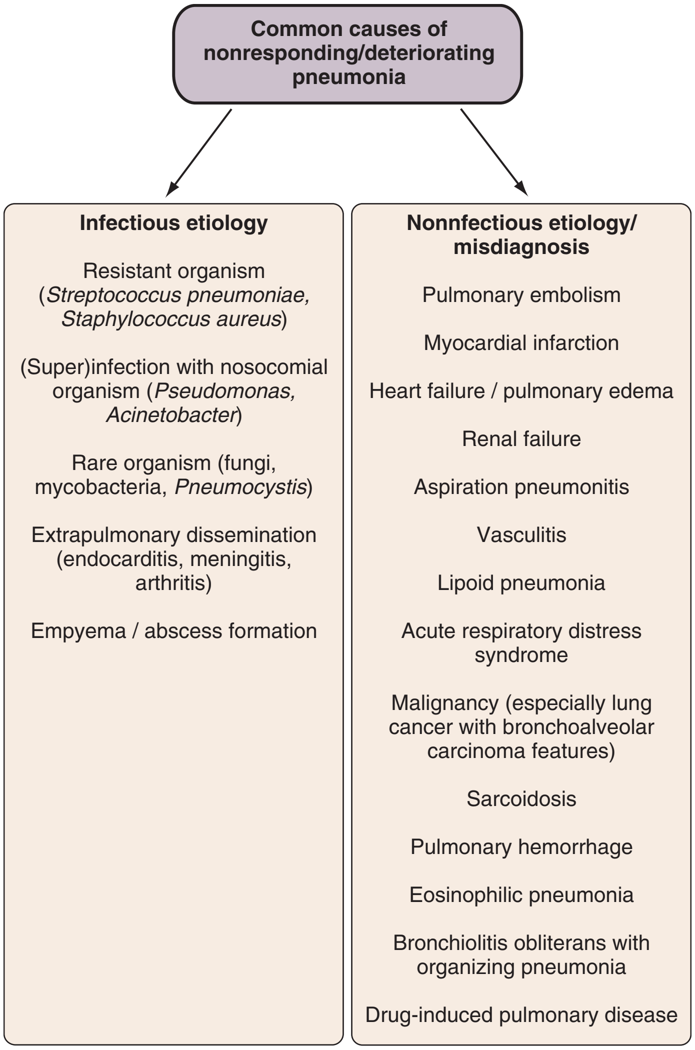
- Temperature ≤37.8° C
- Heart rate ≤100 beats/minute
- Systolic blood pressure ≥90 mm Hg
- Respiratory rate ≤24 breaths/minute
- Oxyhemoglobin saturation ≥90% or P_{O_2} ≥60 mm Hg on preadmission level of oxygen supplementation

Modified from Mandell LA, Wunderink RG, Anzueto A, et al: Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults, *Clin Infect Dis* 44(Suppl 2):S27–S72, 2007.

decreased number of adverse events. In-hospital observation before discharge is unnecessary after the switch to oral medications if the patient meets at least four of the five stability criteria (see Box 24-3), is free from comorbid conditions of clinical significance, and has adequate social supports in place.

In an effort to decrease the rate of adverse events of antibiotic therapy along with cost optimization, shorter durations of antimicrobial therapy have been considered, with current ATS/IDSA guideline recommendations denoting 5 days as minimal duration of therapy. Antibiotics can be discontinued once clinical stability has been achieved and maintained for 48 to 72 hours. Biomarker-guided determination of therapy duration has been attempted, suggesting that even 3-day therapy may be a viable option; however, further studies are needed to validate such an approach.

More than 7 to 10 days of total antibiotic administration is rarely required, unless extrapulmonary infections such as endocarditis or meningitis are present, initial therapy was not active against a subsequently identified offending pathogen, or *P. aeruginosa* infection, *S. aureus* bacteremia, or tissue necrosis was present.



Common causes of nonresponding/deteriorating pneumonia
Infectious etiology
Resistant organism (*Streptococcus pneumoniae, Staphylococcus aureus*)
(Super)infection with nosocomial organism (*Pseudomonas, Acinetobacter*)
Rare organism (fungi, mycobacteria, *Pneumocystis*)
Extrapulmonary dissemination (endocarditis, meningitis, arthritis)
Empyema / abscess formation
Nonfectious etiology/ misdiagnosis
Pulmonary embolism
Myocardial infarction
Heart failure / pulmonary edema
Renal failure
Aspiration pneumonitis
Vasculitis
Lipoid pneumonia
Acute respiratory distress syndrome
Malignancy (especially lung cancer with bronchoalveolar carcinoma features)
Sarcoidosis
Pulmonary hemorrhage
Eosinophilic pneumonia
Bronchiolitis obliterans with organizing pneumonia
Drug-induced pulmonary disease

Figure 24-3 Common causes of lack of response to treatment in patients with community-acquired pneumonia (CAP).

COMPLICATIONS/FAILURE TO RESPOND TO THERAPY

A lack of response to empirical therapy is observed in up to 10% of outpatients and 15% of patients hospitalized with CAP. Challenges remain in the definition of nonresponse and treatment failure; however, the general consensus is that treatment adjustments probably should be withheld in the first 72 hours unless the patient's condition is deteriorating. Failure to achieve clinical stability using the aforementioned criteria within the first 3 days is suggestive of nonresponse to therapy, although in up to 25% of patients (especially those of advanced age and with multiple comorbid conditions), 6 days or longer may be needed to meet these criteria.

Several factors may potentially lead to lack of response to empirical therapy, including misdiagnosis of CAP, infection or superinfection with resistant organisms, infection dissemination with or without abscess formation, and others (Figure 24-3). However, no apparent cause for lack of response can be identified in up to 30% to 44% of such cases, with suggested reasons including comorbidity and possibly variations in inflammatory response.

Failure of empirical antimicrobial therapy usually results in a combination of further diagnostic testing, broadening of the antibiotic treatment regimen and/or transfer to higher-level care. An aggressive and complete reevaluation is still required in nonresponding and especially deteriorating patients. Exhaustive review of the findings on the history and physical examination, with increased attention to risk factors including personal habits and environmental, occupational, social, and travel history, is indicated. Reevaluation of patient's immune status could be helpful if compromise of any sort is suspected (e.g., HIV infection, common variable immunodeficiency). Valuable information occasionally can be obtained from the patient's social contacts, rather than directly from the patient.

Obtaining repeat microbiologic studies with evaluation for less common pathogens might be of benefit, although one must be aware of decreased sensitivity of bacterial studies obtained during antimicrobial therapy. Abscesses (if present) and pleural effusions should be drained, acquired fluid sent for microbiologic studies. Alternative sources of infection should be excluded. If no explanation emerges from these measures, bronchoalveolar lavage (BAL) could be considered, with differential cell count often providing important clues to the possible cause of nonresponse. For example, neutrophil-predominant BAL fluid is suggestive of bacterial infection and possibly bronchiolitis obliterans; lymphocyte-predominant BAL fluid is common in tuberculosis, sarcoidosis, and hypersensitivity pneumonitis; hemosiderin-laden macrophages are seen in alveolar hemorrhage; and a predominance of eosinophils is suggestive of fungal, *Pneumocystis*, or drug-induced diseases and eosinophilic pneumonia. In intubated patients, tracheal aspirates should be carefully examined. Absence of multidrug-resistant pathogens in the aspirate suggests that such organisms are less likely to be responsible for the lack of clinical improvement; however, the reverse is not true because of high rates of colonization by such pathogens in intubated patients.

Radiologic evaluation with a computed tomography (CT) scan of the chest with contrast simultaneously assess the lung parenchyma, pulmonary vasculature, and the pleural space and could provide valuable clues for the reason for nonresponse. For example, presence of nodules with a halo sign may suggest invasive aspergillosis complicating CAP in a patient with COPD on systemic corticosteroids.

Empirical escalation of antibiotic therapy could be considered, especially in patients with risk factors for potentially untreated pathogens; however, little evidence points to better outcomes with this approach. Severity of illness at presentation and comorbid conditions seem to be responsible for the failure to respond to guidelines-based therapy in a majority of such cases of CAP.

SPECIFIC COMPLICATIONS

ASPIRATION PNEUMONIA

Mendelson originally described the syndrome of aspiration of gastric contents in 1946 in 61 obstetric patients in whom aspiration pneumonia developed after ether anesthesia. Manifestations appear very rapidly after the event and include cough (dry or productive of pink sputum from bronchoalveolar hemorrhage), tachypnea, tachycardia, fever, diffuse crackles, cyanosis, and bronchospasm in some cases. The chest radiograph shows extensive atelectasis and infiltrates, and arterial blood gas analysis reveals hypoxemia and normocapnia or hypocapnia. In the most severe cases, the $\mathrm{Pa}_{\mathrm{CO}_2}$ may be elevated, and a metabolic acidosis may be present.

A number of clinical features help distinguish aspiration pneumonia from other CAPs. Aspiration pneumonia tends to have a more insidious course, such that the patient may have an empyema, lung abscess, or necrotizing pneumonia at the time medical care is first sought. The sputum may be putrid because of anaerobic bacteria, and weight loss is common. Chest imaging commonly shows necrotizing infiltrates or multiple abscesses, typically located in dependent regions of the lung (Figure 24-4).

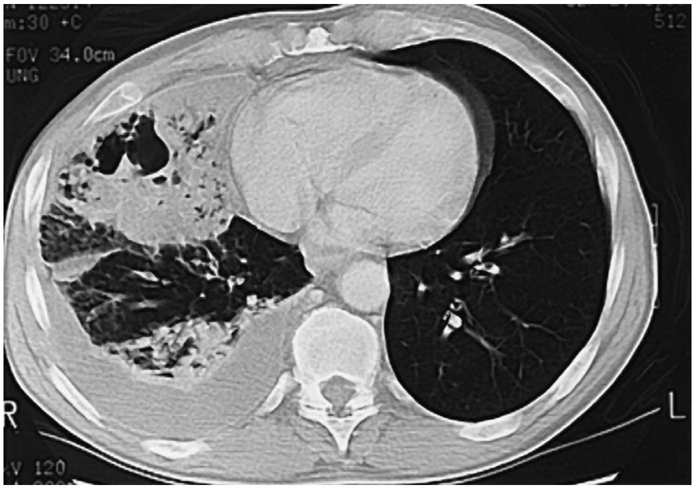


Figure 24-4 Necrotizing aspiration pneumonia. Chest computed tomography scan demonstrates involvement of the entire right middle lobe (which suggests pulmonary gangrene) and an effusion, which was found to represent an empyema. *(From Rabbat A, Huchon G: Bacterial pneumonia. In Albert RK, Spiro SG, Jett JR, editors:* Clinical respiratory medicine, *ed 3, Philadelphia, 2008, Mosby.)*

LUNG ABSCESS

The incidence of pulmonary abscess has decreased over the past decade. Lung abscess is associated with several conditions, including poor dental status or periodontal disease, chronic alcoholism, intravenous drug use, and head and neck cancer. Lung abscess may complicate bronchiectasis (Figure 24-5) and the course of aspiration pneumonia in persons with impaired consciousness, dysphagia and gastroesophageal reflux, or acute or chronic neurologic diseases, but it also may occur with bronchial obstruction by a foreign body or bronchial carcinoma.

Pulmonary abscesses usually are polymicrobial, with a predominant anaerobic flora, such as *Streptococcus intermedius*, *Streptococcus salivarius*, *Streptococcus constellatus*, *Fusobacterium* spp., *Prevotella* spp., or *Bacteroides* spp.

Clinical manifestations usually develop insidiously, particularly before onset of frank necrosis. This period may last several weeks after an initial aspiration. By the time of diagnosis of the lung abscess, patients may have lost weight and have a high fever, chills, putrid expectoration, and chest pain. Pleural involvement with an empyema is a frequent complication of lung abscess. Laboratory findings include a very high white cell count and considerable elevation of inflammatory and catabolic markers.

Radiologic features of lung abscess typically consist of a peripheral cavity more than 2 cm in diameter in the dependent lung regions. CT is useful to distinguish empyema with bronchopleural fistula from lung abscess.

Appearance of the sputum Gram stain often is misleading. Bronchoscopic sampling such as bronchial aspiration, protected specimen brush procedures, or BAL should be performed with inoculation onto anaerobic media. Percutaneous fluoroscopic or ultrasound or CT-guided fine needle aspiration may be a useful diagnostic technique. Aspirates should be grown on

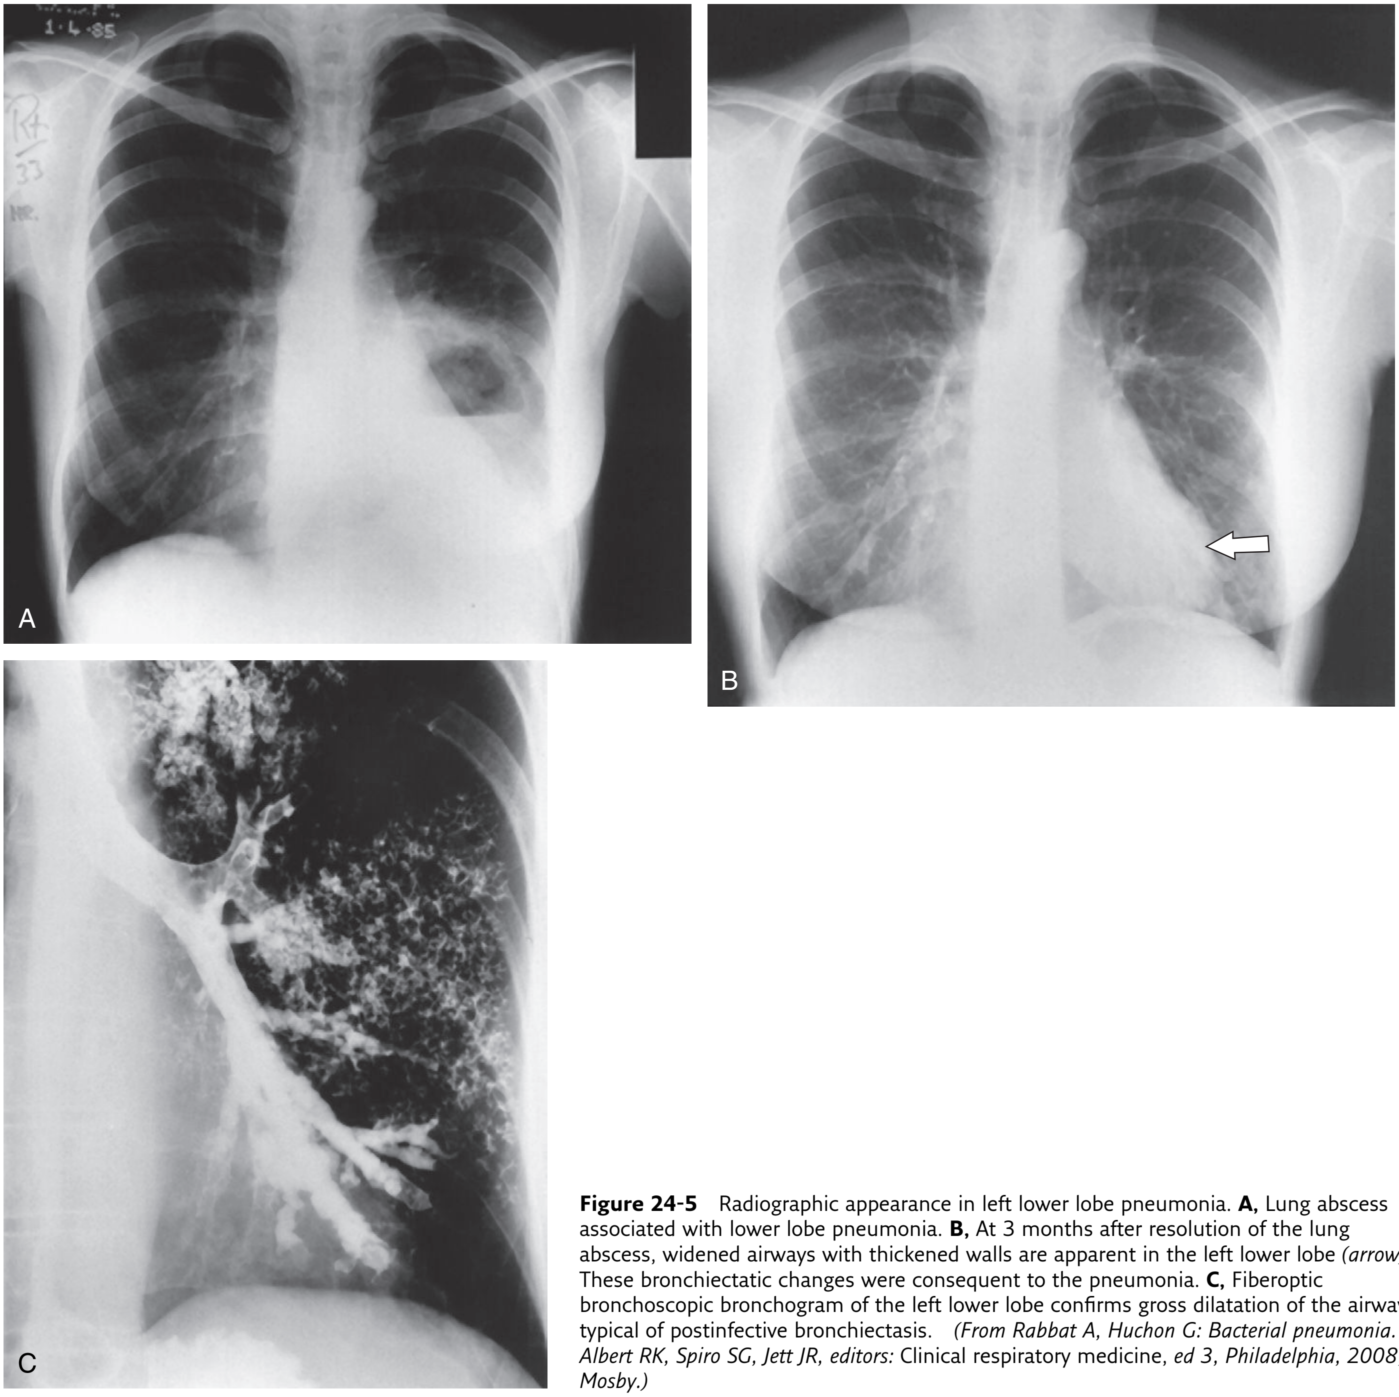

Figure 24-5 Radiographic appearance in left lower lobe pneumonia. **A,** Lung abscess associated with lower lobe pneumonia. **B,** At 3 months after resolution of the lung abscess, widened airways with thickened walls are apparent in the left lower lobe *(arrow).* These bronchiectatic changes were consequent to the pneumonia. **C,** Fiberoptic bronchoscopic bronchogram of the left lower lobe confirms gross dilatation of the airways, typical of postinfective bronchiectasis. *(From Rabbat A, Huchon G: Bacterial pneumonia. In Albert RK, Spiro SG, Jett JR, editors:* Clinical respiratory medicine, *ed 3, Philadelphia, 2008, Mosby.)*

anaerobic media, and samples should be sent promptly to the laboratory for specific anaerobic cultures.

PARAPNEUMONIC EFFUSION AND EMPYEMA

The signs and symptoms suggestive of a parapneumonic collection are increased breathlessness, swinging pyrexia, and raised levels of inflammatory markers. The chest radiograph usually demonstrates the collection of fluid. A lateral radiographic view or an ultrasound scan is useful to confirm the presence of fluid.

All pleural fluid specimens should be submitted for Gram stain and culture, because the identification of significant bacterial cultures confirms the diagnosis of infection and aids in antibiotic choice. Unfortunately, approximately 40% of infected pleural effusions are culture negative, and in this situation, biochemical pleural fluid markers (pH, lactate dehydrogenase, white blood cell count, and glucose) are central to establishing a diagnosis. Fluid drainage by means of a chest tube and prolonged antibiotic therapy is necessary in all cases of complicated parapneumonic pleural effusion and empyema. (See Chapter 69 for a more detailed description of these two clinical entities.)

BRONCHOPLEURAL FISTULA

A bronchopleural fistula is caused by a connection between the pleural space and the consolidated lung; it can complicate either an empyema or a lung abscess. The bronchopleural fistula causes a pyopneumothorax (i.e., air-fluid level in the pleural space), so that, on drainage of an empyema, not only pus but also air comes out through the chest drain. A bronchopleural fistula will not seal unless infection is controlled. Initial treatment is conservative, with antibiotics and tube drainage, to allow healing of the fistula. If this approach fails, surgery may be necessary to attempt primary closure of the fistula or closure of the potential space with other living tissues, such as muscle flaps. The management of bronchopleural fistulas that do not close with conservative treatment requires the surgical skills of a thoracic specialist.

ORGANIZING PNEUMONIA

Organizing pneumonia, sometimes known as *cryptogenic organizing pneumonia* (now the preferred designation for *bronchiolitis obliterans organizing pneumonia* [BOOP]), is a condition in which an organizing inflammatory exudate with fibroblast proliferation occurs after an episode of pneumonia. The consolidation often is patchy and may be fleeting. Organizing pneumonia subsequent to a bacterial infection is suggested when a residual consolidation (often fleeting) is observed despite adequate antibiotic treatment. Investigation includes examination of sputum or bronchial washings to exclude infection. CT may help to visualize the consolidation and exclude other causes. The definitive investigation is an open lung biopsy showing the typical histologic changes, which along with highly suggestive clinical findings constitute sufficient evidence for a confident diagnosis. A course of steroids usually leads to resolution. When the steroids are stopped, however, relapse may occur; in such cases, treatment for several months may be necessary (see Chapter 50).

Table 24-4 Recommendations for Vaccine Prevention of Community-Acquired Pneumonia

Factor	Pneumococcal Polysaccharide Vaccine	Inactivated Influenza Vaccine	Live Attenuated Influenza Vaccine
Route of administration	Intramuscular injection	Intramuscular injection	Intranasal spray
Type of vaccine	Bacterial component (polysaccharide capsule)	Killed virus	Live virus
Recommended groups	All persons ≥65 years of age	All persons ≥50 years of age	Healthy persons 5-49 years of age,* including health care providers and household contacts of high-risk persons
	High-risk persons 2-64 years of age	High-risk persons 6 months–49 years of age	
	Current smokers[†]	Household contacts of high-risk persons Health care providers Children 6-23 months of age	
Specific high-risk indications for vaccination	Chronic cardiovascular, pulmonary, renal, or liver disease	Chronic cardiovascular or pulmonary disease (including asthma)	Avoid in high-risk persons
	Diabetes mellitus	Chronic metabolic disease (including diabetes mellitus)	
	Cerebrospinal fluid leaks	Renal dysfunction	
	Alcoholism	Hemoglobinopathies	
	Asplenia	Immunocompromising conditions/medications	
	Immunocompromising conditions/medications	Compromised respiratory function or increased aspiration risk	
	Native Americans and Alaska natives	Pregnancy	
	Long-term care facility residents	Residence in a long-term care facility	
		Aspirin therapy in persons ≤18 years of age	
Revaccination schedule	One-time revaccination after 5 years for (1) adults ≥65 years of age, if the first dose is received before age 65 years; (2) persons with asplenia; and (3) immunocompromised persons	Annual revaccination	Annual revaccination

*Avoid use in persons with asthma, reactive airway disease, or other chronic disorders of the pulmonary or cardiovascular system; persons with other underlying medical conditions, including diabetes, renal dysfunction, and hemoglobinopathies; persons with immunodeficiencies or who receive immunosuppressive therapy; children or adolescents receiving salicylates; persons with a history of Guillain-Barré syndrome; and pregnant women.

[†] Vaccinating current smokers is recommended by the Pneumonia Guidelines Committee but is not currently an indication for vaccine according to the Advisory Committee on Immunization Practices statement.

From Mandell LA, Wunderink RG, Anzueto A, et al: Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults, *Clin Infect Dis* 44(Suppl 2):S27–S72, 2007. (Adapted from Harper SA, Fukuda K, Uyeki TM, et al: Prevention and control of influenza: recommendations of the Advisory Committee on Immunization Practices [ACIP], *MMWR Recomm Rep* 54:1–40, 2005.)

BRONCHIECTASIS

Permanent dilatation of the bronchus can be a sequela of severe pneumonia, causing localized bronchiectasis. CT scanning during or after an episode of acute pneumonia may show bronchial dilatation, so the diagnosis cannot be made with confidence until after the pneumonia has completely resolved. The presence of bronchiectasis is suggested by continual cough productive of sputum or recurrent infections in one part of the lung. Investigation consists of sputum examination, when organisms associated with bronchiectasis such as *H. influenzae* or *P. aeruginosa* may be isolated. The diagnostic test of choice is a thin-section, high-resolution CT scan. Management consists of postural drainage of the infected lobe and antibiotic treatment for any acute infection. In patients who have coexisting airflow obstruction, treatment with bronchodilators or inhaled steroids may be helpful. (See Chapter 45 for a full description of this clinical entity.)

PREVENTION

Administration of vaccines targeting *S. pneumoniae* and influenza viruses and risk factor modification such as smoking cessation, aspiration precautions, and cessation of alcohol abuse constitute the main preventive measures for CAP (**Table 24-4**). Vaccination status should be assessed at the beginning of the hospitalization, and vaccination may be performed either at discharge or during outpatient follow-up if needed. Vaccination at discharge is preferred in patients in whom compliance with outpatient follow-up care is likely to be unreliable.

CONTROVERSIES AND PITFALLS

Whether empirical treatment of atypical pathogens, specifically *C. pneumoniae* and *M. pneumoniae*, is essential and clearly beneficial in all patients with CAP is an area of controversy. This is reflected in American guidelines recommending coverage for atypical pathogens in all patients, in contrast with European recommendations making such coverage optional at the discretion of the treating physician.

Health care–associated pneumonia (HCAP) is a more recent designation for a form of pneumonia acquired in the community but warranting treatment more like that for nosocomial pneumonia, because of risk factors that predispose affected patients to infections by pathogens that usually are found in the local hospital setting (see Chapter 27). Current criteria used to distinguish HCAP from CAP are in question as being too broad in scope, potentially leading to excessive use of broad-spectrum antibiotics. It is likely that refinement of these criteria in the near future will redefine the boundaries between HCAP and CAP.

Acknowledgment

In preparation of this chapter, we retained some material from Chapter 27 on bacterial pneumonias, by Antoine Rabbat and Gérard J. Huchon, in the third edition of this book. The contribution of these authors is gratefully acknowledged.

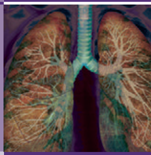
INFECTIOUS DISEASES



Chapter 25
Viral Pneumonia

Ganapathi Iyer Parameswaran • Sanjay Sethi

Despite increasing recognition of the role of viruses in causing pneumonia in adults, either as sole pathogens or as copathogens with bacteria, diagnosis and treatment of viral pneumonias remain difficult clinical problems. Progress has been made in development of precise laboratory tests to diagnose lower respiratory tract infections of viral origin. Wider availability of such tests is likely to spur recognition and give impetus to development of new therapies.

BURDEN OF DISEASE

VIRAL COMMUNITY-ACQUIRED PNEUMONIA

The proportion of pneumonias in adults that are caused by viruses is difficult to quantify with any precision. This lack of certainty is not surprising, because in approximately 50% of pneumonias, an identifiable pathogen cannot be established by conventional laboratory testing. Molecular techniques such as polymerase chain reaction (PCR) analysis improve this number but are rarely performed in routine clinical care. Difficulties in obtaining adequate specimens for viral cultures or molecular testing add to the problem. However, several recent studies have made efforts to quantify the burden of viral community-acquired pneumonias in adults and are summarized in Table 25-1. Although the proportion of viral pneumonias varies in these studies owing to differences in study populations and rigor of testing for viruses, it is clear that viruses cause a significant proportion of pneumonias. Overall, in immunocompetent adults hospitalized with pneumonia, viruses are the responsible pathogens in 15% to 30% of the cases, either by themselves or as copathogens with bacteria. Lower respiratory secretions such as bronchoalveolar lavage (BAL) fluid, tracheal aspirates, or good-quality induced sputum are preferable as specimens for diagnosis of viral pneumonia. Such specimens are more difficult to obtain, however, and most studies have used nasopharyngeal wash samples or swabs for culture and molecular testing. Presence of established pathogens such as influenza virus in such upper respiratory tract samples in a patient with pneumonia most probably implies that the virus is a sole or copathogen in causation of pneumonia; however, this general rule may not be applicable to other viruses. Presence of such viruses as rhinovirus might imply only upper respiratory infection in a patient with pneumonia due to another pathogen. Findings on studies of viral pneumonias must therefore be interpreted with some caution.

VIRAL PNEUMONIA IN IMMUNOCOMPROMISED PATIENTS

Patients who have undergone hematopoietic stem cell transplantation (HSCT) or solid organ transplantation or who are undergoing intensive chemotherapy for leukemias exhibit a higher incidence of viral upper respiratory infections than that in normal control subjects, as well as more frequent involvement of the lower respiratory tract, more severe pneumonias, and higher rates of death from viral pneumonia. All of the pathogens mentioned in Table 25-1 are represented in these patients. Respiratory syncytial virus (RSV), adenovirus, and parainfluenza virus, which usually cause only mild illness in immunocompetent persons, can cause severe pneumonias with high mortality rates in this high-risk patient population. Extrapulmonary manifestations of influenza infection, such as myocarditis, are not unusual in this population. RSV is the most common viral pathogen of the lower respiratory tract in patients who have undergone hematopoietic stem cell or solid organ transplantation, as reported in many series. Fulminant, disseminated adenoviral infections have been reported in patients with advanced human immunodeficiency virus (HIV) disease. Cytomegalovirus (CMV) infection is a major problem in stem cell and solid organ transplant recipients and probably is the most common viral pneumonia among patients who are not on prophylaxis or preemptive treatment regimens.

PATHOGENS

Although some variability has been documented in the frequency with which different viral pathogens are diagnosed as the etiologic agent of pneumonia in specific series, the most frequent pathogens are influenza A virus, influenza B virus, and RSV. In addition, parainfluenza viruses 1, 2, and 3 and adenovirus, coronaviruses, and rhinovirus also may cause pneumonia. Human metapneumovirus (hMPV) and, more recently, bocavirus have been recognized as pathogens. Rarer pathogens are CMV, varicella-zoster virus (VZV), herpes simplex virus (HSV), rubeola virus (the measles virus), and hantavirus.

INFLUENZA VIRUSES

The most frequent viral pathogen implicated in causing pneumonia and increased mortality, influenza virus serotypes A and B, especially A, are responsible for outbreaks of respiratory

Table 25-1 **Summary of Selected Clinical Studies of Viral Pneumonia**

Study	Population/Viral Studies	Results	Comments
Jennings et al, 2008	304 hospitalized adults Nasopharyngeal swab viral culture, DFA, and real-time PCR analysis	Viral etiology established in 88/304 (29%)	Microbial etiology established in 177/304 (58%) Rhinovirus most frequent, followed by influenza virus and RSV
Johnstone et al, 2008	300 adults hospitalized with pneumonia 193 patients had nasopharyngeal swabs, DFA, and NAAT (NASBA and real-time PCR analysis)	Viral etiology established in 29/193 (15%)	Microbial etiology established in 75/193 (39%) Of viruses, influenza virus, hMPV, and RSV most frequent
de Roux et al, 2004	1356 nonimmunocompromised adults hospitalized with pneumonia 338 had paired serologic sample testing for viruses (influenza virus, parainfluenza virus, RSV, adenovirus)	Positive results on paired serologic samples in 61/338 (18%); in 31 (9%) of these, virus established as sole pathogen	Microbial etiology established in. 518/1356 (38%) Influenza A and B viruses most frequent viruses
Marcos et al, 2006	198 hospitalized adults Viral culture, serologic testing, IFA, and nasopharyngeal swab real-time PCR analysis	Positive results on viral testing in 46/198 (23%)	Microbial etiology established in 112 (57%) Influenza A virus, RSV, and adenovirus most frequent
Johansson et al, 2010	184 hospitalized adults with community-acquired pneumonia Nasopharyngeal culture and PCR assay	Virus established as sole or copathogen in 53/184 (29%)	Influenza virus, rhinovirus, RSV, and parainfluenza viruses most frequent

DFA, direct fluorescent antibody test; hMPV, human metapneumovirus; IFA, indirect fluorescent antibody test; NAAT, nucleic acid amplification test; NASBA, nucleic acid sequence–based amplification; PCR, polymerase chain reaction; RSV, respiratory syncytial virus.

illness each winter. Minor changes in hemagglutinin and neuraminidase proteins of the virus causing “antigenic drift” are responsible for seasonal influenza outbreaks. Although people of all ages are exposed to infection, the consequences of influenza-specific respiratory infection are more severe in certain groups of patients—elderly persons, nursing home residents, infants, those with severe coexisting cardiac and respiratory diseases such as congestive heart failure and chronic obstructive pulmonary disease (COPD), pregnant women, patients with immunosuppression due to hematologic malignancies, and those with HIV disease. Most of the deaths attributable to seasonal influenza occur in these groups. In addition, obesity has been associated with more severe disease and higher mortality in the recent H1N1 pandemic.

Major mutations in hemagglutinin and neuraminidase result in “antigenic shifts” and are responsible for pandemics. The most recently described is the current H1N1 (swine origin) virus pandemic starting in 2009. In contrast with seasonal influenza, the proportion of deaths in younger patients (18 to 65 years) has increased during pandemics. This increased mortality has been attributed to lack of previous exposure to a similar strain of the virus, with corresponding lack of protective antibodies, in patients who were not alive at the time of an earlier outbreak with a similar virus. This pattern has been seen in the current H1N1 pandemic.

Thus, influenza-related pneumonia occurs each year during the fall, winter, and spring seasons as a consequence of infection with circulating seasonal influenza viruses. Distinct from this pattern, pandemic influenza viruses cause pneumonias in explosive outbreaks. Such pandemic viral pneumonias differ from the seasonal disease in several ways: (1) Patients 18 to 65 years of age, especially those in the 20- to 45-year-old age group, are affected more often than in seasonal disease; (2) mortality due to influenza-related pneumonia is increased among adults 20 to 45 years of age; (3) the proportion of primary viral pneumonias is higher than in seasonal disease, in which most influenza-related pneumonias are due to bacteria; (4) viral influenza–related illness occurs outside of the usual influenza season; and (5) special risk factors for severe disease and mortality have been recognized, such as pregnancy and severe obesity. The recent H1N1 pandemic has infected more than 50 million persons in the United States alone, and caused approximately 18,000 deaths worldwide. Severe infections, consisting of pneumonia and acute respiratory distress syndrome (ARDS), typically have been seen in adults, with a median age of 40 years.

The true incidence of pneumonia in influenza respiratory infection is unknown, because most patients with influenza-related illness are evaluated and managed as outpatients without radiographs. Of a group of elderly adults with a high vaccination rate (greater than 90%), 2% to 6% were hospitalized with influenza-related illness; of these, only 5% had radiographically confirmed pneumonia. A significant proportion of such patients will have other illnesses, such as congestive heart failure, that precipitate hospitalization. Pneumonia developing during influenza infection can be one of two types: primary viral pneumonia or postinfluenza bacterial pneumonia. Louria and co-workers, reporting on the 1957-1958 pandemic, described four syndromes of lower respiratory tract illness due to influenza in New York City: (1) influenza illness with physical signs of lower respiratory involvement, but no infiltrates on the chest film; (2) influenza illness followed by bacterial pneumonia; (3) acute, rapidly progressive pneumonia due to influenza virus; and (4) concomitant viral and bacterial pneumonia. The histopathologic changes of influenza-related viral infection of the lower respiratory tract consist of desquamation of tracheobronchial epithelium, alveolar duct dilatation, hyaline membrane covering alveolar surfaces, and hemorrhage and inflammatory infiltrate in the alveolar spaces and interstitium.

Pathogenesis of Bacterial Pneumonia in Influenza

The association of influenza lower respiratory infection with bacterial pneumonia is striking. Such influenza-associated bacterial pneumonias, caused by *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus*, including methicillin-resistant strains, are more frequent and severe than primary bacterial pneumonias due to the same pathogens. The seasonal incidence of *S. pneumoniae* infection in a community parallels the incidence of influenza illness. The mechanisms underlying the increased frequency and severity of these influenza-associated bacterial pneumonias are mostly unclear at present, but emerging evidence suggests roles for multiple viral and host factors. Increased apoptosis and desquamation of airway epithelial cells infected with influenza virus exposes multiple surface adhesins for pathogenic bacteria. Influenza viruses expressing PB1-F2, a proapoptotic protein that interferes with mitochondrial function and increases epithelial cell apoptosis, increase susceptibility to *S. pneumoniae* infection. When infected with viral strains lacking PB1-F2, mice were less susceptible to bacterial pneumonia, compared with those infected with wild-type viral strains. Moreover, influenza infection decreases the efficacy of airway mucociliary clearance, and thus clearance of pathogenic bacteria.

Viral neuraminidase increases bacterial growth and dissemination, and adherence of *S. pneumoniae* to airway epithelial cells in mouse models. Influenza strains with high neuraminidase activity are associated with higher mortality after bacterial infection. Influenza virus inhibits neutrophil chemotaxis and phagocytic capacity; inhibits, through induction of IFN-γ, macrophage receptor with collagenous structure (MARCO) production by macrophages. MARCO is a scavenger protein involved in macrophage recognition and killing of bacteria. Influenza virus also causes desensitization of Toll-like receptors (TLRs), and this desensitization persists for several weeks.

Primary Influenza-Related Viral Pneumonia

The true incidence of primary influenza pneumonia is unknown, because many patients do not undergo radiography or detailed clinical evaluation. It originally was considered that most of the deaths in the 1918 influenza pandemic were due to primary viral pneumonia. Later analysis of multiple data sources, however, strongly suggested that a majority of deaths (approximately 80%) from influenza-related pneumonia were due to secondary bacterial (postinfluenza) pneumonias, caused primarily by *S. pneumoniae* and *H. influenzae* and other gram-negative organisms such as *Klebsiella pneumoniae* and *Escherichia coli*. A series of 33 patients with influenza-related pneumonias and deaths from the 1957-1958 pandemic again showed that a majority of deaths were due to bacterial pneumonia. Of 33 patients, 15 had acquired bacterial pneumonia after influenza illness; six had primary viral pneumonia with isolation of influenza virus, but no bacterial pathogen, from lung tissue; and nine had concomitant bacterial and viral pneumonia. In the recent (2009) H1N1 virus pandemic, initial reports suggested that deaths were mostly due to viral pneumonia. Further analysis of autopsy lung specimens showed that in approximately 30% of these deaths, a bacterial pathogen could be identified by molecular studies. However, the proportion of viral pneumonia (approximately 70%) is striking and higher than in previous pandemics. Moreover, *S. aureus*, especially methicillin-resistant *S. aureus* (MRSA), was found in a significant proportion of bacterial pneumonias, with high mortality, especially among teenage patients. Therefore, in summary, primary viral as well as secondary bacterial infections, including those due to MRSA, must be considered in every case of influenza-related pneumonia and treated presumptively until full identification of the pathogens involved is obtained.

The typical clinical course of primary viral pneumonia is described as progression of the initial upper respiratory tract symptoms to shortness of breath, increased cough and sputum, and respiratory failure, as compared with secondary bacterial pneumonia, in which a period of improvement after the initial influenza infection is followed by new and worsening respiratory symptoms due to pneumonia. The sputum often is thin and blood-stained in primary viral pneumonia. Radiographs usually show bilateral interstitial or infiltrative opacities, which may mimic the appearance of congestive heart failure.

RESPIRATORY SYNCYTIAL VIRUS

Long considered to be a pathogen of children only, RSV is now recognized as a significant pathogen in elderly and immunocompromised adults. It is the second most common pathogen in most series of viral pneumonias. Similar to the influenza viruses, RSV causes winter outbreaks of respiratory illness. It is estimated that in most populations of nursing home residents, approximately 10% develop RSV respiratory infections each year. Most of these are self-limiting upper respiratory infections; the remaining 10% or so develop pneumonia. Centers for Disease Control and Prevention (CDC) surveillance data suggest that RSV infections are responsible for about 10,000 deaths annually in elderly patients living in the community. In one prospective series of elderly adults, RSV was the responsible pathogen in 11% of patients hospitalized with pneumonia during winter months. Chest radiographs often show bilateral fluffy infiltrates.

HUMAN METAPNEUMOVIRUS

Since being described as a cause of respiratory illness in children in 2001, hMPV is now recognized to cause pneumonias in adults, especially elderly patients with cardiopulmonary diseases. A prospective study, using reverse transcriptase PCR testing of nasopharyngeal samples, found evidence of hMPV infection in 4% of 193 adults hospitalized with pneumonia during an influenza season. Evidence of hMPV infection was present, by PCR analysis of nasopharyngeal aspirate and/or paired serologic samples, in 4% of adults visiting an emergency department in Canada with pneumonia or exacerbation of COPD.

PARAINFLUENZA VIRUSES 1, 2, AND 3

Parainfluenza viruses 1, 2, and 3 cause upper respiratory infections as well as pneumonia in elderly adults, especially nursing home residents. A study in Sweden found serologic evidence for recent parainfluenza virus infection in approximately 10% of community-acquired pneumonias in elderly persons.

CORONAVIRUSES

Several coronavirus strains cause the common cold during winter months. Pneumonia has been described in elderly persons and immunocompromised patients; the frequency of such infections is not known. In 2002, a novel strain, SARS-CoV, spread around the globe, causing an acute pneumonia and ARDS.

RHINOVIRUS

The most frequent cause of the common cold was thought to be not a pathogen in the lower respiratory tract. However, the advent of molecular methods such as real-time PCR analysis has demonstrated that in many patients, especially in those with chronic respiratory diseases such as COPD or immunosuppression, rhinovirus is present in the lower airways during pneumonia. The role of rhinovirus as a sole pathogen in causation of pneumonia is still a matter of debate and research.

VARICELLA-ZOSTER VIRUS

Pneumonia associated with chickenpox in adults is a well-recognized complication and continues to occur each year in the United States. When chickenpox occurs in adults, the incidence of pneumonia as a complication is increased by approximately 25-fold over that in children. Except in rare instances, such pneumonia is associated with the rash typical of the disease. A study of military recruits revealed that radiographic lung abnormalities are much more common than signs and symptoms of pneumonia—that is, most lung involvement is subclinical. Mortality rates for severe pneumonia leading to respiratory failure have decreased over the last few decades owing to improvements in ventilatory support and prompt therapy with acyclovir.

CLINICAL FEATURES

Viral pneumonias in general have the same clinical symptoms (cough, shortness of breath, increased sputum, and chest pain) and signs (radiographic consolidation, fever, tachycardia, tachypnea, reduced arterial oxygen saturation) as those of bacterial pneumonias. Some clinical features occur more often in viral pneumonias than in bacterial pneumonias, although this distinction is not precise enough for a diagnosis to be made on clinical evaluation without further testing, except in rare situations. Patients with viral pneumonias tend to be older and frailer, with other comorbid conditions such as cardiac failure and COPD; have less chest pain, tachycardia, and fever; and show lower levels of leukocytosis than in the characteristic clinical picture in bacterial pneumonias. Features such as rhinitis, conjunctivitis, and pharyngitis or a typical rash for varicella or measles can point to a viral etiology for pneumonia. Gastrointestinal complaints often accompany influenza-related infections. RSV infections are more likely to be associated with wheezing than influenza virus infections. Chest radiographs show lobar infiltrates or basal atelectasis–like patterns, and infiltrates often are bilateral; these features are not specific enough, however, to allow clinical differentiation between viral and bacterial pneumonia. Varicella pneumonia often causes nodular lung lesions on chest films, although interstitial infiltrates also are described. The difficulties in differentiating between viral and bacterial pneumonias on clinical features alone are illustrated by a study that compared findings on the chest radiograph in children with community-acquired pneumonia. In children with alveolar infiltrates, 71% had a bacterial cause; in those with proven bacterial pneumonia, 72% had alveolar infiltrates; and in those who had only interstitial infiltrates, approximately 50% had a bacterial cause. CT scans show a variety of appearances—ground glass opacities, nodules, and lobular and segmental infiltrates.

Serum procalcitonin levels are being increasingly used to guide decisions regarding the need for antibacterial therapy. A very low level may indicate a low likelihood of bacterial infection in lower respiratory infections. This association, however, does not imply that the cause is viral. To establish a viral cause, another diagnostic method (culture or PCR assay) is still necessary.

DIAGNOSIS

The accuracy of clinical features in predicting a viral infection depends on the pretest probability of viral respiratory infection in a given population. In one series of 258 patients seeking emergency or urgent care for acute respiratory symptoms during influenza season, clinical judgment had sensitivity and specificity of 29% and 92%, respectively, in diagnosing influenza; the figures improved to 67% and 96% if patients presented within 48 hours of symptom onset. Patients with viral pneumonia, however, often do not have accompanying upper respiratory symptoms, and the symptoms and signs overlap with those of bacterial pneumonia.

Attempts at precise definition of the roles and frequency of these viruses in causing pneumonia have been hampered by difficulties in viral culture, and by a nihilistic attitude among medical professionals stemming from lack of effective therapy against many of these viruses. Precise diagnosis of viral causes for pneumonia has multiple benefits: (1) Public health measures against spread of highly infective viruses such as influenza viruses and RSV can be better coordinated. (2) Attempts at development of effective therapies can be supported with increasing recognition of the etiologic roles of these viruses. (3) Unnecessary antibiotic therapy can be curtailed. (4) Infection control and prophylaxis measures can be implemented in hospitals and nursing homes.

A variety of clinical specimens are suitable for diagnosis of viral pneumonia. These include, in order of preference, lung tissue and BAL fluid, nasopharyngeal wash sample, nasopharyngeal swabs, and sputum. BAL often is avoided because of its invasive nature but nevertheless is desirable in immunocompromised and critically ill patients, in whom a specific diagnosis is necessary and co-infections are common. Diagnosis of viral infection in a patient with pneumonia can be attempted by one or more of four methods, as summarized in Table 25-2.

Culture of virus from clinical specimens, using tissue culture cells, remains the standard diagnostic modality. However, it is labor-intensive, requires expertise in culture techniques and recognition of the effects of virus on cells, and is not always available except in large laboratories. Sending specimens out to reference laboratories is problematic, because many viruses tolerate such transportation poorly. Moreover, some viruses such as rhinovirus, hMPV, and some coronaviruses grow poorly in tissue cultures, and the results of viral culture take several days to become available. With all of these caveats, if a suitable specimen is available, culture should be attempted on samples obtained in patients suspected to have viral pneumonia. Shell vial cultures, especially when combined with immunofluorescent antibody staining of cells, has higher sensitivity than that of tube culture.

Serologic testing had been a mainstay in retrospective diagnosis of viral infections and remains an important epidemiologic tool. However, owing to the requirement for paired samples separated by 4 weeks to demonstrate a significant increase in IgG titers, serologic studies are now rarely used in clinical diagnosis of viral pneumonia.

Antigen detection can be performed in most respiratory secretions using direct fluorescent antibody (DFA) and enzymatic immunoassay (EIA) tests. DFA testing, performed by treating samples with a virus-specific antibody tagged with a fluorophore and a fluorescence microscope, often is used in conjunction with shell vial culture of viruses from respiratory secretions. EIAs are available for detection of influenza A virus in kit form

Table 25-2 Commonly Used Methods for Diagnosis of Viral Lower Respiratory Infection

Method	Tests	Specimen(s)	Comments
Culture	Inoculation of cultured human or primate cells; shell vial culture	NP wash, NP swab, sputum, BAL fluid, lung tissue	"Gold standard"; labor-intensive; some viruses grow poorly
Serologic testing	IgG and IgM assays; paired (acute and convalescent) IgG titers	Blood	Paired titers not useful in clinical diagnosis of acute infection
Antigen detection	DFA, EIA	NP wash, NP swab, BAL fluid, sputum; DFA with shell vial culture	Poor to moderate sensitivity, except for DFA with shell vial culture
Molecular methods	PCR assay; RT-PCR; real-time PCR analysis: NASBA	NP wash, NP swab, sputum, BAL fluid, lung tissue	Sensitivity better than that of culture; high specificity

BAL, bronchoalveolar lavage; DFA, direct fluorescent antibody test; EIA, enzymatic immunoassay; IgG, IgM, immunoglobulins G and M; NP, nasopharyngeal; PCR, polymerase chain reaction; RT-PCR, reverse transcriptase PCR.

(Rapid Influenza Diagnosis Test [RIDT]). Although highly specific (90% to 95%), these rapid tests have lower sensitivity (approximately 70%) compared with viral culture and molecular methods, especially when the viral load is low. A rapid antigen detection test is available for RSV; its sensitivity is very low compared with that of culture—only about 10%.

Molecular methods depend on detection of virus-specific genetic material. Reverse transcriptase PCR (RT-PCR), nucleic acid sequence–based amplification (NASBA), and real-time RT-PCR methods have been used. These methods have sensitivity (97% to 99%) and specificity (90% to 95%) similar to and often better than viral culture. Real-time PCR results are available the same day and can distinguish between strains such as H1N1 and H3N2. Commercially available tests using multiple primers, allowing testing for a panel of viruses, are becoming more common in large laboratories. The x-TAG RVP assay, approved by the U.S. Food and Drug Administration (FDA), tests for 12 viruses commonly implicated in respiratory illness. Even broader tests, using panviral gene microarrays, are being used as research tools and may soon be available for clinical use.

Patients suspected on clinical grounds to have influenza pneumonia should be tested for influenza using RIDT. If the result of this test is negative, viral culture of respiratory secretions (nasopharyngeal swab or wash sample, BAL fluid, endotracheal aspirate) should be performed. If available, a nucleic acid amplification test such as PCR assay should be performed on these specimens. In patients suspected to have other (or unknown) viral pneumonias, viral culture and, if available, a multiplex viral PCR assay are indicated.

TREATMENT

With pneumonias caused by the aforementioned viruses, effective treatment is available for those due to influenza A and B viruses, VZV, and possibly RSV. Available antiviral drugs are (1) adamantanes (amantadine and rimantadine); (2) neuraminidase inhibitors (oseltamivir, zanamivir, and, provided by the CDC on a case-by-case basis, peramivir); (3) ribavarin; and (4) acyclovir and its derivatives valganciclovir and famciclovir.

The adamantanes—amantadine and rimantadine—are no longer recommended for treatment of influenza owing to widespread resistance of the virus strains and should not be used in treatment of viral pneumonias. Of the neuraminidase inhibitors, oseltamivir is available orally only; zanamivir as an inhaled powder; and peramivir as an intravenous formulation. Ribavirin is available in oral formulation and as a liquid for aerosol administration and has been used intravenously in small series of patients.

The neuraminidase inhibitors are effective in reducing duration of symptoms for outpatients with influenza-related upper respiratory infection, when started within 48 hours of onset of symptoms. Efficacy against influenza pneumonia is unclear. A large Canadian study of adults hospitalized with seasonal influenza–related infections showed reduction in mortality and hospital stay when oseltamivir was started even later than 48 hours. The CDC currently recommends neuraminidase inhibitor treatment for all adults with severe influenza-related illness. It seems reasonable, therefore, to use one of these agents for any patient suspected to have influenza-related pneumonia, whatever the duration of symptoms, while etiologic investigations are under way. This approach also means that any patient with possible viral pneumonia during seasonal influenza season or during an influenza pandemic should receive oseltamivir while appropriate studies are undertaken to identify the specific etiologic agent of pneumonia.

Zanamivir is an alternative to oseltamivir. It is available only as an inhalant. Zanamivir can provoke wheezing and clog nebulizers (the CDC advises against using this agent in a nebulizer) and probably should be avoided in patients with respiratory compromise. Increasing resistance to oseltamivir is being reported in influenza A virus. These strains remain sensitive to zanamivir and peramivir. Oseltamivir is less active against influenza B virus than against influenza A virus; zanamivir is preferred if influenza B virus is known to be the etiologic agent, in the absence of contraindications to its use. The incidence of resistance to oseltamivir in the United States remains low, as reported by the CDC (less than 1% for H1N1 and H3N2) in April 2011 (http://www.cdc.gov/flu/weekly/).

In patients who do not respond to or who deteriorate while on oseltamivir, and if drug resistance is suspected, intravenous peramivir is available from the CDC. A recent uncontrolled case series shows promising results in such patients with use of intravenous peramivir. Drug sensitivity testing for cultured viral strains is available in reference laboratories and at the CDC.

Ribavirin is active against RSV. However, efficacy in RSV-related lower respiratory infections in adults is unproved. Limited evidence for efficacy comes from small case series of patients with immunocompromised states such as hematopoietic stem cell transplantation and patients undergoing chemotherapy for leukemia. Its use in adults critically ill with pneumonia and proven RSV infection should be considered carefully, with involvement of a physician who has some experience in using ribavirin in such situations. Ribavirin aerosol often is combined with intravenous immunoglobulin to treat severe RSV infections in immunocompromised patients. In addition, testing and, during the wait for results, initial treatment for bacterial pneumonias should be added. Ribavirin can cause hemolytic anemia. Aerosol use introduces hospital staffing problems, because this agent is teratogenic in animal experiments, and accidental exposure of women of reproductive age must be avoided. In VZV pneumonia, antiviral treatment with intravenous acyclovir should be given.

In every patient with suspected influenza-related lower respiratory infection, bacterial pneumonia due to *S. pneumoniae*, *H. influenzae*, or *S. aureus* including MRSA is a major consideration. Bacterial cultures should be performed, and antibiotics effective against these pathogens should be prescribed.

CONTROVERSIES AND PITFALLS

Probably the major reason for underdiagnosis of viral pneumonia is an inappropriately low level of clinical suspicion and corresponding lack of laboratory testing. During influenza season or a pandemic outbreak, the clinical management plan for every patient with pneumonia should include consideration of viral pneumonia. Similarly, any pneumonia in an immunosuppressed patient or elderly nursing home resident should raise suspicion for a viral cause. In patients with suspected influenza-related pneumonia, bacterial infection, especially due to *S. pneumoniae*, *H. influenzae*, or *S. aureus* including MRSA, should be a consideration in laboratory testing and initial treatment, because it is not possible to distinguish between viral and bacterial pneumonia with certainty on clinical examination alone.

Diagnosing viral lower respiratory infections using upper respiratory samples such as nasopharyngeal washings inevitably raises the question of whether the identified virus is involved in the lower respiratory infection. This remains an area to be explored. Pending further data, clinical judgment of whether the virus detected from upper respiratory samples might be responsible for pneumonia is necessary. When serious pathogens such as influenza virus are detected in a patient with pneumonia, the prudent approach is to assume that the patient has a viral and possibly a secondary bacterial pneumonia and treat accordingly. The situation is much less clear cut for less well-established lower respiratory tract pathogens such as hMPV, bocavirus, and rhinovirus. Recent evidence shows that high viral load in nasopharyngeal samples, as determined using quantitative PCR assay, correlates with an increased chance that the lower respiratory disease is due to the virus. Such tests are not commonly available.

Although good evidence supports the efficacy of antiviral drugs in treatment of influenza-related pneumonia, treatment of RSV infections in adults with ribavirin is controversial. There are no high-quality, controlled trials of ribavirin in adults to date. Based on small uncontrolled case series, expert opinion favors use of ribavirin and intravenous immunoglobulin in hematopoietic stem cell transplant recipients with RSV-related lower respiratory infections. Although it may be reasonable to extend this approach to patients with other serious immunocompromising conditions such as solid organ transplantation and prolonged steroid therapy, ribavirin use in elderly patients with no identified immunocompromising conditions is based on anecdotal reports and has to be approached on a case-by-case basis with advice from a physician who is experienced in treatment of RSV infections.

CONCLUSIONS

Advances in molecular methods of diagnosis have increased awareness and recognition of the role of viruses in causing pneumonia in immunocompetent as well as immunosuppressed adults. The list of viruses capable of causing such pneumonias is increasing. Although current therapeutic options are mostly limited to influenza infection, increasing recognition of viral pneumonias and underlying pathogenetic mechanisms would spur research and development of more effective and varied therapies.

Section 5
INFECTIOUS DISEASES

Chapter 26
Nonbacterial Infectious Pneumonia

William Graham Carlos III • Chadi A. Hage

Nonbacterial causes of infectious pneumonia are important diagnostic considerations in the evaluation of patients who are immunocompromised, who have recognized structural lung disease, or who do not respond to appropriate antibiotic therapy for presumed bacterial pneumonia. A detailed clinical history can assist the astute clinician in making the diagnosis of a nonbacterial cause of infectious pneumonia in these circumstances. Important information to gather includes travel history, geographic location, occupational history, and recreational activities. This chapter presents an overview of common fungal and parasitic causes of pneumonia, including clinical presentation, diagnostic considerations, and treatment options.

FUNGAL PNEUMONIAS

ASPERGILLOSIS

Aspergillus organisms are ubiquitous saprophytic fungi. They grow well in soil and decaying vegetation. These fungi also have been found in hospitals, ventilation and water systems, and dust associated with construction activity. Disease manifestations depend on the immune status and lung structure of the host. Clinical manifestations include allergic disease, airway colonization, aspergilloma formation, tracheobronchial disease, chronic necrotizing pneumonia, and invasive disseminating disease. Allergic disease generally is seen in immunocompetent patients and may encompass airway hyperreactivity, allergic bronchopulmonary aspergillosis (ABPA), and hypersensitivity pneumonitis. Airway colonization occurs in patients with impaired mucociliary clearance or distorted lung structure such as in bronchiectasis. Aspergillomas, or "fungus balls," thrive in cavitary lung lesions such as those associated with tuberculosis. Tracheobronchial aspergillosis and chronic necrotizing pneumonia (locally invasive aspergillosis) are manifestations found in patients with acquired immunodeficiency syndrome (AIDS), recipients of transplanted organs (especially lungs), and patients with obstructive lung disease who use inhaled or systemic steroids. Finally, invasive or disseminated aspergillosis develops in the context of profound and protracted granulocytopenia (Figure 26-1).

Fungal culture and histopathologic examination constitute the "gold standard" for the diagnosis of aspergillosis. The diagnosis has been simplified by the advent of the galactomannan detection assay, which confers a high degree of sensitivity and specificity. The treatment of aspergillosis is tailored to the disease manifestation. Allergic manifestations are managed with routine asthma care that includes avoidance of allergen exposures and maintenance bronchodilators. Steroids are reserved for severe cases. ABPA mandates treatment with corticosteroids initially and may require the addition of itraconazole. Aspergillomas can be followed clinically and generally remain dormant but can manifest with massive hemoptysis necessitating embolization or surgical resection. Voriconazole is the preferred agent for treatment of invasive aspergillosis. Liposomal amphotericin B, posaconazole, and echinocandins are reserved for salvage therapy.

HISTOPLASMOSIS

Histoplasmosis is the most prevalent endemic mycosis in North America. *Histoplasma capsulatum* is a dimorphic fungus existing as a mold in nature. It forms spores that become aerosolized, facilitating inhalation. After inhalation, *H. capsulatum* grows as yeast forms in the host.

The clinical manifestations of histoplasmosis are variable and depend on the intensity of exposure along with the immune status and underlying lung architecture of the host. The Mississippi and Ohio River valleys are highly endemic. Histoplasmosis also is endemic to parts of Central America, South America, Africa, and Asia. Moist soil is an ideal habitat for *Histoplasma*, especially when supplemented with bird or bat guano. Activities that can lead to infection include spelunking (caving), excavation, demolition, and cleaning of chicken coops or old buildings. After inhalation, the spores are converted into yeasts, which are phagocytosed by macrophages. The organism is able to survive and proliferate inside macrophages, allowing it to disseminate. Within 2 weeks, however, a protective cellular immune response usually develops, which contains the fungus by forming granulomas (often seen as calcified granulomas on chest radiographs). Most otherwise healthy persons infected with a low inoculum remain asymptomatic (i.e., the infection is subclinical) or are minimally symptomatic. Patients with impaired immunity that fails to contain the infection can develop progressive disseminated histoplasmosis, with involvement of the bone marrow, liver, spleen, adrenal glands, gastrointestinal tract, and central nervous system (CNS). This manifestation typically is seen in persons with AIDS or patients taking immunosuppressive medications such as prednisone, methotrexate, and anti-TNF-α agents. Common clinical manifestations of disseminated disease include fever, weight loss, hepatosplenomegaly, pancytopenia, meningitis, focal brain lesions, ulcerations of the oral mucosa, gastrointestinal ulcerations, and adrenal insufficiency. Disseminated histoplasmosis carries a high mortality rate unless promptly diagnosed and appropriately treated (Table 26-1).

Patients who inhale larger inocula of *Histoplasma* conidia during outbreaks or in an enclosed space may develop severe

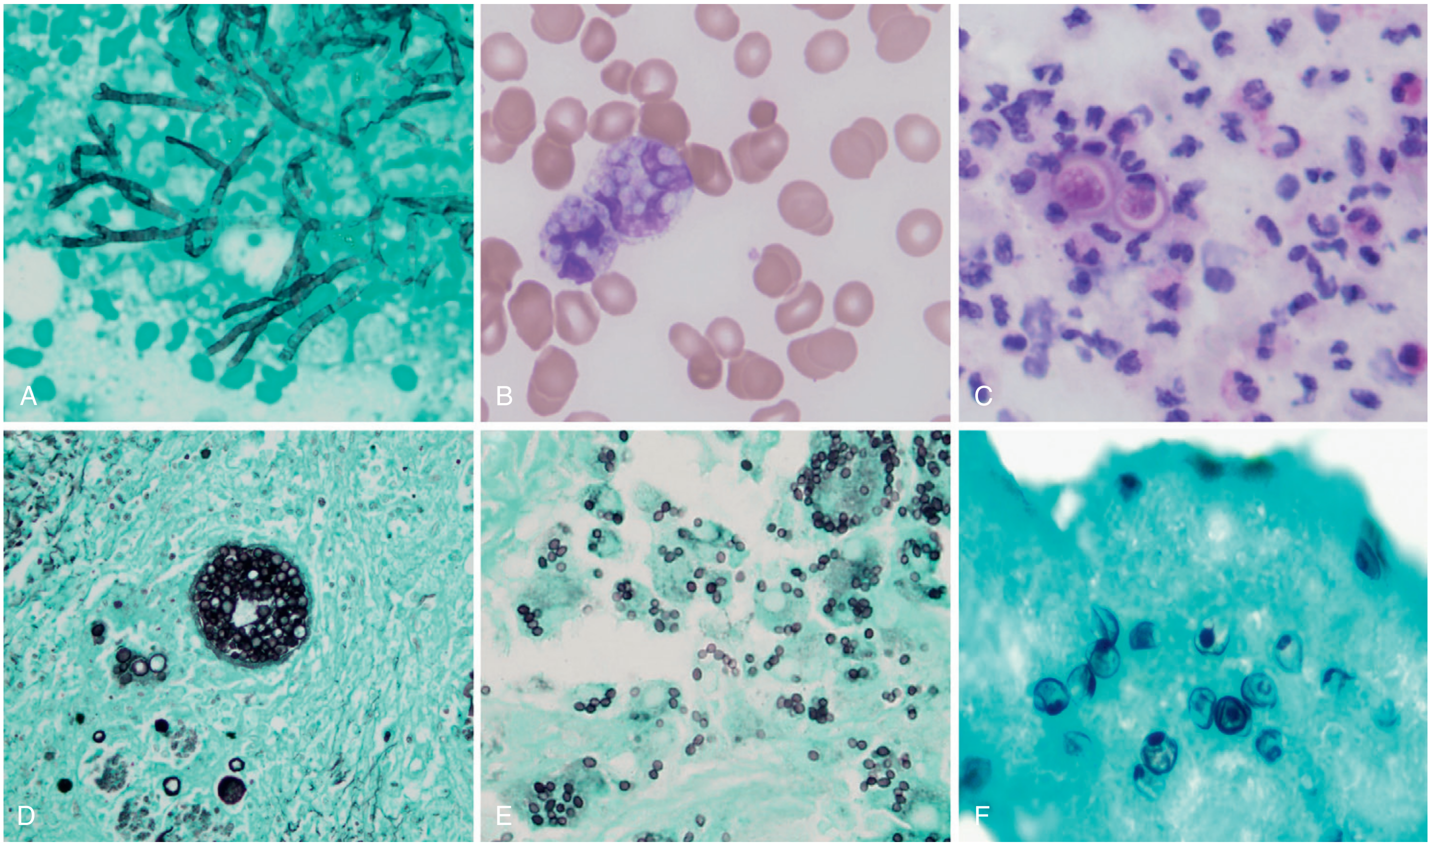

Figure 26-1 Examples of pulmonary fungal pathogens. **A,** *Aspergillus fumigatus* hyphae in BAL fluid from a neutropenic patient with invasive aspergillosis (Gomori methenamine silver nitrate [GMS] stain). **B,** *Histoplasma capsulatum* seen inside phagocytes on a peripheral blood smear from a patient with AIDS complicated by disseminated histoplasmosis (Giemsa stain). **C,** Large, broad-based budding *Blastomyces dermatitidis* yeasts in BAL fluid from a patient with pulmonary blastomycosis (Giemsa stain). **D,** *Coccidioides immitis* spherule containing numerous small spores in a lung biopsy specimen from a patient with acute pulmonary coccidioidomycosis. **E,** Cluster of narrow based-budding, small *Cryptococcus neoformans* yeasts, extracellularly located, in BAL fluid from a patient with AIDS complicated by disseminated cryptococcosis (GMS stain). **F,** Extracellularly located *Pneumocystis jiroveci* cysts (GMS stain) in BAL fluid from a patient with AIDS who presented with respiratory failure. *AIDS*, acquired immunodeficiency syndrome; *BAL*, bronchoalveolar lavage.

pulmonary disease with a flulike illness that can lead to respiratory failure. When the infection occurs in the context of structural lung disease (bullous emphysema), it may not be effectively contained, and patients can develop chronic cavitary histoplasmosis with upper lobe infiltrates, cavitations, and pleural thickening. Other late manifestations of histoplasmosis include fibrosing mediastinitis (a late complication associated with high morbidity), calcification of mediastinal nodes, and broncholithiasis.

Identification of *H. capsulatum* is accomplished using a combination of tests. Fungal culture remains the "gold standard." However, *H. capsulatum* may require up to 4 weeks to be grown in culture, limiting its utility in severe cases. Rapid diagnostic testing using antigen detection in serum or urine samples is useful in patients with moderate to severe disease. Antigen detection in bronchoalveolar lavage (BAL) fluid may help make the diagnosis of pulmonary histoplasmosis. Rapid diagnosis also can be achieved through cytopathologic examination, albeit with lower sensitivity than that attained with culture or antigen detection. *Histoplasma* serologic testing (immunodiffusion and complement fixation) is particularly useful in chronic (cavitary) and subacute disease, because detectable levels of antibody appear after 4 weeks of infection.

Treatment for histoplasmosis is reserved for patients with chronic pulmonary, disseminated, or acute moderate to severe disease. Liposomal amphotericin B followed by itraconazole is the preferred regimen for severe cases. Mild to moderate disease can be treated with itraconazole exclusively. Corticosteroids also may be useful in cases of severe, life-threatening acute pulmonary histoplasmosis. The duration of treatment for acute pulmonary histoplasmosis is 6 to 12 weeks, whereas that for disseminated and chronic pulmonary histoplasmosis is 12 to 18 months.

Fibrosing mediastinitis and broncholithiasis represent chronic reactions to past infection and do not respond to antifungal therapy. Treatment consists of endoscopic or surgical removal of partially or completely eroded broncholiths. Placement of endovascular stents may be required in advanced fibrosing mediastinitis causing obstruction of major mediastinal vessels. Obstruction of central airways or the esophagus also can occur and may necessitate balloon dilatation or stenting.

BLASTOMYCOSIS

Blastomyces dermatitidis is a dimorphic fungus that causes pulmonary and systemic disease. Most cases of blastomycosis have been reported in North America, where it occurs predominantly in the Midwestern states and Canadian provinces surrounding the Great Lakes. In the United States, the endemic region overlaps significantly with that of *H. capsulatum* along the Mississippi and Ohio River valleys. Cases have been reported from Africa and India as well. When outbreaks occur, they usually are associated with outdoor recreational activities or

Table 26-1 Types of Fungal Pneumonia

Fungal Disease	Pulmonary Manifestation(s)	Risk/Host Factor(s)	Diagnostic Test(s)	Treatment
Histoplasmosis	Acute and subacute pulmonary histoplasmosis	Normal host, occupational or recreational exposure	Serologic studies, antigen test, BAL fluid cytopathologic analysis	Itraconazole Amphotericin B
	Chronic cavitary pulmonary histoplasmosis	Emphysema	Serologic studies, sputum or BAL fluid culture	Itraconazole
	Progressive disseminated histoplasmosis	Immunosuppression (AIDS, anti-TNF, organ transplant recipients)	Antigen test, blood and BAL fluid culture, BAL fluid cytopathologic analysis	Amphotericin B Itraconazole
	Mediastinal histoplasmosis (granulomatous and fibrosing mediastinitis and broncholithiasis)	Normal host	Serologic studies	No antifungal therapy, antiinflammatory agent
Blastomycosis	Acute pulmonary blastomycosis	Recreational exposure, normal host	Antigen test, sputum cytopathologic analysis and culture	Itraconazole Amphotericin B
	Chronic pulmonary blastomycosis		Lung biopsy	Itraconazole
Coccidioidomycosis	Acute pulmonary coccidioidomycosis	Normal host, occupational or recreational exposure	Serologic studies, antigen test, sputum and BAL fluid culture, cytopathologic analysis	Fluconazole Amphotericin B Itraconazole
	Chronic cavitary pulmonary coccidioidomycosis		Serologic studies, sputum and BAL fluid culture	Fluconazole
	Disseminated coccidioidomycosis	Immunosuppression (AIDS)	Antigen test, serologic studies, BAL fluid culture, cytopathologic analysis	Amphotericin B Fluconazole
Aspergillosis	Invasive pulmonary aspergillosis	Neutropenic, leukemia, hematopoietic stem cell transplant recipient	*Aspergillus* galactomannan, BAL fluid cytopathologic analysis and culture	Voriconazole Amphotericin B Echinocandins
	Chronic necrotizing pneumonia	AIDS, COPD, chronic steroid use, solid organ transplant recipient	*Aspergillus* galactomannan, BAL fluid cytopathologic analysis and culture	Voriconazole Amphotericin B Echinocandins
	Tracheobronchial aspergillosis	COPD, inhaled steroids	Bronchoscopy, bronchial biopsy	Voriconazole Amphotericin B
	Allergic bronchopulmonary aspergillosis	Normal host	Serologic testing, peripheral eosinophilia	Itraconazole and systemic corticosteroids
	Mycetoma	Upper lobe cavitary lung disease	Radiographic diagnosis	No antifungal therapy
Pneumocystis infection	*Pneumocystis* pneumonia	Immunosuppression (AIDS)	BAL fluid cytopathologic analysis	Trimethoprim/ sulfamethoxazole, clindamycin-primaquine Pentamidine, dapsone, atovaquone

AIDS, acquired immunodeficiency syndrome; *BAL*, bronchoalveolar lavage; *COPD*, chronic obstructive pulmonary disease; *TNF*, tumor necrosis factor.

work around waterways. As with histoplasmosis, the mechanism of infection involves inhalation of the spores, which are then converted to the yeast form in the lung; however, polymorphonuclear cells are abundant in blastomycosis lesions, mimicking pyogenic infections.

Blastomycosis can manifest clinically in a variety of ways. The most common presentation is pulmonary disease, followed by involvement of the skin, bone, joints, and CNS. *Acute* pulmonary blastomycosis resembles community-acquired pneumonia and often is mistakenly treated for bacterial pneumonia before the correct diagnosis is made. Signs and symptoms include fever, chills, productive cough, and chest pain. Radiographic findings include consolidation, cavities, nodules, and miliary patterns. Mediastinal adenopathy and pleural effusions are uncommon. Acute blastomycosis can progress to acute respiratory distress syndrome (ARDS), even in immunocompetent patients. Risk factors for severe infection include diabetes and diffuse pulmonary involvement. *Chronic* pulmonary blastomycosis mimics lung cancer or tuberculosis and can be insidious in onset and progression and minimally symptomatic. Skin lesions often are mistaken for squamous cell carcinoma or pyoderma gangrenosum.

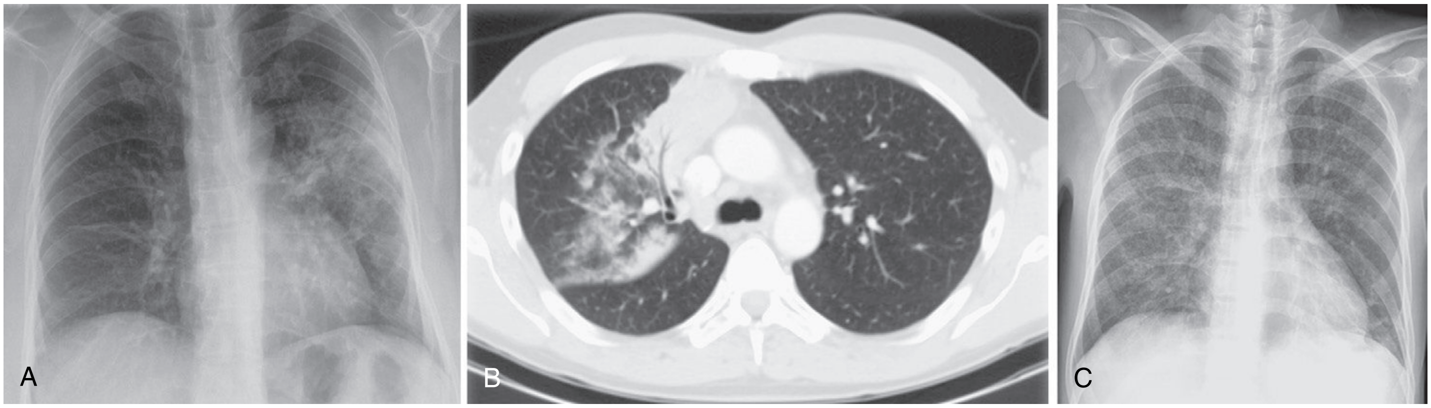

Figure 26-2 **A,** Acute pulmonary blastomycosis in a 51-year-old woman. The chest film shows a left upper lobe infiltrate. **B,** Acute pulmonary coccidioidomycosis in an otherwise healthy man. Chest computed tomography (CT) scan shows area of consolidation in the right upper and middle lobes. **C,** Progressive disseminated histoplasmosis in a 35-year-old patient with AIDS. The chest film shows bilateral reticulonodular interstitial infiltrates. *AIDS*, acquired immunodeficiency syndrome.

Definitive diagnosis requires growth of *Blastomyces* from sputum, BAL fluid, or biopsy material. Rapid identification is made by visualization of the characteristic broad-based budding yeast in clinical specimens. Typically, blastomycosis is diagnosed when a presumed community-acquired bacterial pneumonia fails to respond to antimicrobial therapy or if a mass suspicious for malignancy is detected. When the clinical presentation includes cutaneous manifestations, the diagnosis can be secured by skin biopsy. *Blastomyces* antigen can be found in the urine, serum, or BAL fluid, providing a reliable means for establishing a rapid diagnosis, especially in severe cases. The current antigen assays do not differentiate histoplasmosis from blastomycosis, as a consequence of cross-reactivity. Histopathologic and cytopathologic analysis can be helpful in differentiating histoplasmosis from blastomycosis and should be routinely ordered with invasive testing procedures.

In view of the cross-reactivity of the antigen assay, it is fortunate that the treatment for severe life-threatening blastomycosis is similar to that for histoplasmosis. Intravenous administration of amphotericin is the treatment of choice, and corticosteroids may be added in cases of ARDS. Non–life-threatening cases can be managed with itraconazole. In patients who are intolerant of itraconazole or who have CNS involvement, fluconazole can be used. Almost all patients with blastomycosis should be treated (Figure 26-2), although patients with self-limited disease may not require treatment.

COCCIDIOIDOMYCOSIS

Coccidioidomycosis, also known as “valley fever,” is caused by the dimorphic soil-dwelling fungus *Coccidioides*. It is endemic in the southwestern United States and northern Mexico. Recent surges in case numbers have been recently reported in Arizona, where 60% of the cases occur. The mechanism of infectivity is similar to that for histoplasmosis and blastomycosis, involving inhalation of spores, leading to neutrophilic inflammatory responses. Case clusters have occurred in patients 2 weeks after they were exposed to dust in endemic areas while excavating or rock hunting, or during a windstorm.

Most patients who become infected with *Coccidioides* are asymptomatic or have a self-limited illness. Patients who become symptomatic usually experience a flulike illness with symptoms including fever, chills, arthralgia, myalgia, and headaches. In addition, cough, pleuritic chest pain, dyspnea, and rarely hemoptysis may occur. Cutaneous manifestations often are reported with acute pulmonary coccidioidomycosis and may include maculopapular rash, erythema nodosum, and erythema multiforme. Chest radiographs initially show one or more areas of consolidation, with hilar or mediastinal lymphadenopathy. Fibrocavitary lesions can result from progressive disease. Areas of pneumonitis may heal by the formation of a coinlike lesion called a *coccidioidoma* that can persist for life.

Primary progressive coccidioidomycosis with diffuse pneumonia occurs in settings of intense environmental exposure or immunosuppression and often is associated with fungemia and respiratory compromise. Several months after the infection manifests, disseminated coccidioidomycosis may develop, with involvement of skin, bones, joints, genitourinary system, and the meninges. Risk factors for extrapulmonary dissemination include African American or Filipino ancestry, pregnancy during the second or third trimester, and depressed cellular immunity.

The gold standard for the diagnosis of coccidioidomycosis is culture or direct visualization of the fungus in tissue or respiratory secretions. Serologic testing plays an important role in establishing the diagnosis of coccidioidomycosis, in view of its speed and simplicity. Serologic studies are more likely to be positive in patients with disseminated disease and chronic disease. In contrast with *Histoplasma* and *Blastomyces*, *Coccidioides* grows within 3 to 7 days of culture.

The treatment of coccidioidomycosis is similar to that of histoplasmosis and blastomycosis and relies on triazoles (itraconazole or fluconazole) for diffuse pulmonary or nonmeningeal disseminated disease. Amphotericin B generally is reserved for immunocompromised patients with severe or disseminated disease unresponsive to triazoles as well as for pregnant women. For uncomplicated primary pneumonia in a normal host close observation often is all that is needed.

PARACOCCIDIOIDOMYCOSIS

Paracoccidioidomycosis, formerly named “South American blastomycosis,” is caused by a fungus endemic to South and Central America, *Paracoccidioides brasiliensis*. Paracoccidioidomycosis is highly endemic in Brazil, Colombia, Venezuela, and Ecuador, with reported infectivity rates as high as 50% to 75% in some areas. Like the other thermal dimorphic fungi, *P. brasiliensis* is inhaled and undergoes transformation in the alveoli. Most cases are subclinical, and only a minor proportion of hosts will develop signs or symptoms weeks after inhalation. Reactivation of disease can occur years after inoculation, and the condition may disseminate hematogenously to the adrenal glands, gastrointestinal tract, and other viscera.

Pulmonary disease frequently is seen in chronic paracoccidioidomycosis. Chest imaging typically reveals pulmonary opacities that can cavitate, in a pattern involving both medial pulmonary fields and resembling a "butterfly wing." The diagnosis of paracoccidioidomycosis can be reliably made by histopathologic examination of clinical specimens revealing characteristic yeast cells with multiple buds. Definitive diagnosis relies on culture of the organism. Serologic testing can suggest the diagnosis and monitor the response to treatment. In severe or disseminated cases of paracoccidioidomycosis, amphotericin B is recommended. Itraconazole is the drug of choice for milder disease.

CRYPTOCOCCOSIS

Cryptococcus neoformans is a yeast with a thick capsule. Two species of *Cryptococcus* are recognized to cause disease in humans: *Cryptococcus gattii* and *Cryptococcus neoformans*. *C. neoformans* has emerged as a leading cause of CNS infection in patients with AIDS. Recent outbreaks of *C. gattii* infection causing pulmonary disease in immunocompetent persons have been reported from the northwestern United States and neighboring Vancouver Island in Canada. The two species of *Cryptococcus* have geographic and clinical differences. Whereas *C. gattii* typically is associated with flowering eucalyptus trees, *C. neoformans* can be found around bird guano throughout the world. Overall, cryptococcosis is a rare infection and usually is asymptomatic and self-limited in immunocompetent patients. In those who have impaired cell-mediated immunity, it may cause lung infection and meningitis. Cryptococcosis is emerging as the third leading fungal infection behind candidiasis and aspergillosis in recipients of organ transplants.

The CNS is the most common site of disease activation. Symptoms of cryptococcal pneumonia include fever, malaise, cough, and chest pain. The chest radiograph may show large, nonspecific nodules or infiltrates, sometimes associated with lymphadenopathy. Pulmonary infections have a tendency toward spontaneous resolution and frequently are asymptomatic. Hematogenous spread to the brain can lead to lesions in gray matter and basal ganglia. CNS disease can manifest as meningoencephalitis with papilledema and high cerebrospinal fluid opening pressure. A patient with AIDS presenting with fever and headache should prompt consideration of a diagnosis of cryptococcal meningitis. Lumbar puncture with an increased opening pressure and India ink smear of centrifuged cerebrospinal fluid is useful in this scenario. In patients who do not have AIDS, levels of cerebrospinal fluid glucose are low, and protein levels are high and can correlate with a lymphocytic pleocytosis. Cryptococcal capsular antigen usually is detected in cerebrospinal fluid or serum by latex agglutination testing, with sensitivity and specificity approaching 90%.

Treatment of cryptococcosis is tailored to the site of involvement and severity. Severe pulmonary disease and CNS involvement require amphotericin B with flucytosine. Mild to moderate disease can be effectively treated with fluconazole.

PNEUMOCYSTIS

Pneumocystis jiroveci is a fungus known to cause pneumonia in patients that are immunocompromised. It is a ubiquitous organism. Commonly found in patients with human immunodeficiency virus (HIV) infection or AIDS, infection is rare in normal hosts. Infection with *Pneumocystis* should be considered in any immunocompromised patient presenting with bilateral infiltrates on chest radiographs. Computed tomography (CT) generally reveals ground glass shadowing in affected areas, and sparing of the pleural surfaces has been noted frequently. The diagnosis of pneumocystosis is readily made through demonstration of the organism using fungal stains. Diagnostic specimens typically are obtained by BAL. Rarely, dissemination can occur, causing renal disease, cutaneous popular skin lesions, choroiditis, and intestinal plaques.

The treatment of pneumocystosis depends on the severity of hypoxemia once the organism has been identified. Patients with a PaO_2 less than 70 mm Hg on room air require treatment with steroids in addition to intravenous trimethoprim-sulfamethoxazole or pentamidine. Mild cases can be treated with trimethoprim-sulfamethoxazole, dapsone, pentamidine, atovaquone, or clindamycin plus primaquine. Various prevention regimens are available for patients who are severely immunosuppressed (e.g., persons with AIDS whose $CD4^+$ counts are less than 200 cells/μL, patients on long-term immunosuppressants). They include trimethoprim-sulfamethoxazole, dapsone, and aerosolized pentamidine.

PARASITIC PNEUMONIAS

AMEBIASIS

Entamoeba histolytica is endemic in tropical developing countries, particularly Mexico, India, and nations of Central and South America, tropical Asia, and Africa. The disease is acquired predominantly after ingestion of contaminated food or water. After intestinal infection, trophozoites can invade intestinal vasculature and reach the liver through the portal venous system. From the liver, the infection may disseminate to the lungs or brain. Liver abscess is the hallmark of invasive disease. Peripheral liver abscesses can erode through the diaphragm, causing pleuropulmonary disease.

Symptomatic amebiasis is predominantly an intestinal infection causing diarrhea and abdominal cramps to dysentery or even intestinal perforation because of mucosal ulcerations. Pleuropulmonary signs and symptoms include cough, dyspnea, and pleuritic pain (usually right-sided) associated with fever and chills, diaphoresis, and weight loss. The chest radiograph may show elevation of the right hemidiaphragm, pleural effusion, atelectasis, lung consolidation (which usually affects the right lower lobe), or lung abscess. Hepatobronchial fistulas have been reported in patients who have pleuropulmonary complications of amebiasis; this finding is associated with the production of copious volumes of chocolate-colored sputum. Pericardial involvement also may be observed in such patients. The diagnosis can be readily established by demonstrating amebic cysts or trophozoites in the stool, pleural fluid, or bronchial secretions. Serologic tests are highly sensitive and specific in invasive disease. Metronidazole is the agent of choice for treatment of invasive amebiasis.

MALARIAL LUNG

Severe falciparum malaria often is complicated by noncardiogenic pulmonary edema, which can develop despite effective antimalarial therapy. This syndrome of malarial lung carries a high mortality rate. Pulmonary involvement is a manifestation of the cytokine storm that follows heavy infection and destruction of red cells. It often leads to ARDS, with capillary congestion, pulmonary edema, and alveolar hemorrhage. Bilateral pulmonary infiltrates and pleural effusions are seen on chest radiographs. It is commonly associated with cerebral disease and high levels of parasitemia. The diagnosis of malaria is established after demonstration of asexual forms of the parasite inside erythrocytes on peripheral blood smears stained with Giemsa or Wright stain. Besides quinine-based antimalarial therapy, exchange transfusion and supportive care with supplemental oxygen and mechanical ventilation are required for severe cases.

PULMONARY ASCARIASIS

Ascaris lumbricoides is the largest intestinal nematode parasite of humans. *Ascaris* is widely distributed in tropical and subtropical areas. Most infected persons are asymptomatic. After egg ingestion, larvae hatch in the jejunum, invade the mucosa, and migrate to the lungs, causing a pneumonitis 1 to 2 weeks after ingestion. The presentation is that of eosinophilic pneumonitis (Löffler-like syndrome), with cough, occasional hemoptysis, wheezing, dyspnea, and high-grade fever. The illness usually is self-limited. Abdominal symptoms and cutaneous reactions also may be present. The chest radiograph can show unilateral or bilateral patchy, migratory, peribronchial infiltrates. The diagnosis is easily established by demonstrating characteristic *Ascaris* eggs in stool. During the transpulmonary migratory phase (eosinophilic pneumonitis), larvae can be found in sputum or gastric aspirates before the eggs appear in the stool. Antihelmintic treatment usually is not required for pulmonary ascariasis, because it usually is self-limited. Symptomatic treatment with bronchodilators and oxygen therapy and potentially corticosteroids is appropriate.

STRONGYLOIDIASIS

Strongyloides typically is found in tropical climates and is especially common in Southeast Asia, sub-Saharan Africa, and Brazil. The southeastern United States has endemic regions as well. *Strongyloides stercoralis* is unique among helminths in that it is capable of replicating in the human host. This feature allows the worm to autoinfect the host, where it may persist for decades. Infection begins when the filariform larvae in contaminated soil penetrate the exposed skin of the host. The larvae migrate through the lymphatic and venous circulation and eventually settle in the capillaries and alveoli of the lungs. Eventually the larvae ascend the tracheobronchial tree to the larynx, are swallowed, and mature into adult egg-laying females. Eggs hatch in the mucosa and pass with feces into the soil. Eggs can transform within the intestine into filariform larvae, which can penetrate the bowel wall and reenter the circulation. These larvae can carry bacteria as they penetrate through the gastrointestinal tract, causing polymicrobial bacteremia, septicemia, or hyperinfection in immunosuppressed patients.

Strongyloidiasis may have a variety of clinical manifestations. Although uncomplicated disease may remain subclinical for years, some patients will develop mild pulmonary disease in the form of cough and bronchospasm, whereas others will progress to ARDS. Recurrent urticaria and larva currens, or "running larva," can cause raised skin lesions. Nonspecific abdominal pain and colitis can develop, as can bowel obstructions. Eosinophilia is common during parasitemia. Radiographic abnormalities can range from a diffuse pneumonitis to chronic migratory pulmonary opacities. Immunosuppressed persons (e.g., patients with AIDS, glucocorticoid users) are susceptible to hyperinfection, with ensuing gram-negative sepsis, pneumonia, or meningitis. In patients with massive infection, pulmonary involvement can be extensive, leading to respiratory failure and pulmonary hemorrhage. Pleural effusions, pulmonary cavitations, and abscesses also have been documented, usually in cases associated with higher burdens of organisms.

The diagnosis of strongyloidiasis can be readily established by demonstrating rhabditiform larvae in stool as well as in sputum, BAL fluid, or biopsy specimens in disseminated disease. Serologic testing may help establish the diagnosis in chronic cases. Even in asymptomatic patients, a diagnosis of strongyloidiasis warrants treatment, in view of the potential for autoinfection and the fatal hyperinfection syndrome. Ivermectin is the preferred therapeutic agent, given daily for 1 or 2 days or up to 7 days in cases of disseminated disease.

VISCERAL LARVA MIGRANS (TOXOCARIASIS)

Visceral larva migrans is caused by *Toxocara* spp. These nematodes are parasitic for nonhuman hosts but do not mature in humans. Consequently, most infections in humans remain subclinical. However, the larvae occasionally may travel through host tissues, where they can elicit profound eosinophilic inflammation, resulting in the syndrome of visceral larva migrans. All feline and canine species can carry *Toxocara*. Nursing mothers can pass larvae to suckling puppies, and pregnant bitches can infect their pups transplacentally. In puppies, the larvae can develop into adult worms, which produce eggs released in their feces. Humans (usually preschool children) acquire toxocariasis by ingesting soil contaminated by pup feces.

Although most infections are subclinical, the infection can progress as the larvae invade the liver, lungs, CNS, and other sites. In such cases, the ensuing intense eosinophilic granulomatous response may be associated with fever, malaise, cough, wheezing, and rashes. Radiographic manifestations consist of migratory infiltrates. Rarely, death results from severe neurologic, pulmonary, or cardiac involvement.

The diagnosis of toxocariasis is made by serologic testing or histologic examination of infected tissues. Stool examination is not helpful, because the larvae do not develop into egg-producing adults in humans. Although most infections with *Toxocara* are self-limited, requiring no treatment, steroids may be warranted for cases associated with severe inflammation. The anthelmintic albendazole given for 5 days appears to be effective in eradicating the organism.

TROPICAL PULMONARY EOSINOPHILIA

Tropical pulmonary eosinophilia develops after infection with lymphatic filarial species (*Wuchereria bancrofti* or *Brugia malayi*) that are found in tropical and subtropical areas. The infection is transmitted by mosquitos. Circulating filariae are cleared from the bloodstream by the lungs, releasing antigens that cause a pulmonary hypersensitivity reaction.

Clinical manifestations include paroxysmal cough and wheezing (usually nocturnal), weight loss, fever, adenopathy, and peripheral eosinophilia and elevated serum immunoglobulin E (IgE) levels. Chest radiographs may show bilateral interstitial infiltrates and vascular congestion. The diagnosis is based on clinical findings. The clinician must rule out similar entities such as asthma, Löffler syndrome, ABPA, Churg-Strauss syndrome, chronic eosinophilic pneumonia, and the idiopathic hypereosinophilic syndrome. Daily administration of diethylcarbamazine for 2 to 3 weeks is the standard therapy. Signs and symptoms usually resolve within 5 to 7 days after the initiation of therapy. Corticosteroids and antihistamines may also be used to control symptoms.

PARAGONIMIASIS

Paragonimus species such as *Paragonimus westermani* are hermaphroditic flukes that are endemic in Southeast Asia, South America, and South Africa. They are rarely found in North America and Europe. They infect humans who ingest undercooked crabs or crayfish that contain the encysted parasite. In many endemic regions, these crustaceans are consumed raw or pickled. The organisms penetrate the gut wall and travel to the lung by way of the peritoneal cavity, diaphragm, and pleural space. Mature flukes can be found in bronchioles surrounded by cysts. Parasite eggs are expectorated with sputum or swallowed and expelled with feces. The life cycle is then completed in snails or freshwater crustaceans.

Although some infections remain subclinical, the illness occurs during the first weeks of infection when the parasite is migrating from the intestine to the lung. Signs and symptoms include abdominal pain, diarrhea, hypersensitivity reactions (urticaria, eosinophilia, and fever), chest pain, cough, and hemoptysis. In most cases, however, no clinical manifestations emerge until the adult parasite begins to produce eggs in the lung, causing local inflammation with formation of cavities and cysts. Pulmonary signs and symptoms may include cough productive of rusty-brown sputum or frank hemoptysis. Sometimes the disease is mistaken for tuberculosis or lung cancer. Areas of fibrosis or pleural thickening are common. Pleural effusions are uncommon, but when they occur are characterized by high eosinophil counts in the pleural fluid. Of note, although eosinophilia is common in paragonimiasis, its absence does not rule out this disease.

The diagnosis is based on demonstrating eggs in bronchial secretions, pleural fluid, or feces. A number of serologic tests also are available. The preferred treatment is with praziquantel.

SCHISTOSOMIASIS

Pulmonary schistosomiasis develops when *Schistosoma* eggs are trapped in the pulmonary circulation, causing either pulmonary hypertension or formation of lung nodules. Skin is the portal of entry. The immature parasites migrate in the bloodstream and mature in venous plexuses. Eggs are then released and deposited in organs, where they cause a granulomatous reaction. Pulmonary hypertension is the most frequent and significant pulmonary manifestation of infection with *Schistosoma mansoni* or *Schistosoma japonicum*. The diagnosis is established by visualizing the characteristic eggs in organ biopsy specimens. Serologic tests also are available. Praziquantel is the preferred agent for treatment of schistosomiasis.

ECHINOCOCCOSIS

Echinococcosis is caused by the larval stage of *Echinococcus granulosus* or *E. multilocularis*, both of which may produce cystic lesions in any organ, mainly the liver and lungs. The infection is acquired through the ingestion of eggs. The parasite is transported in the bloodstream to the end organs. Pulmonary symptoms most often are related to compression of adjacent structures. Occasionally cysts may rupture into the airways or pleural space, causing an allergic reaction or superinfection. Chest CT typically shows sharply demarcated cysts with calcified borders and numerous smaller daughter cysts. The diagnosis is based on clinical and epidemiologic data. Serologic test findings are supportive, and aspiration of the cyst should be avoided, to limit the possibility of dissemination and associated hypersensitivity reactions. Surgical resection with complete removal of the cysts is the treatment of choice. Surgery should be done by experienced operators. Postoperative albendazole prophylaxis is recommended.

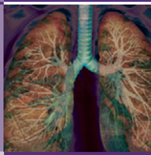
Section 5

INFECTIOUS DISEASES



Chapter 27

Nosocomial Respiratory Infections

Gianluigi Li Bassi • Miquel Ferrer • Antoni Torres

DEFINITIONS

The designation *nosocomial respiratory infection* refers to tracheobronchitis and pneumonia caused by pathogens highly prevalent in hospital settings and developing at least 48 hours after hospital admission. Nosocomial tracheobronchitis is characterized by signs of respiratory infection, such as an increase in the volume and purulence of respiratory secretions, fever, and leukocytosis, without radiologic infiltrates suggestive of consolidation on the chest film. Nosocomial pneumonia comprises pneumonia developing in nonintubated patients, ventilator-associated pneumonia (VAP), and health care–associated pneumonia (HCAP). VAP commonly develops in patients who receive invasive mechanical ventilation. HCAP is a more recently recognized clinical entity that is defined in the latest guidelines of the American Thoracic Society for the diagnosis and treatment of nosocomial pneumonia. HCAP develops in patients who are not hospitalized but are at risk for colonization by pathogens present in hospital settings, including multiple drug–resistant (MDR) microorganisms.

EPIDEMIOLOGY

INCIDENCE

Nosocomial tracheobronchitis occurs in 3% to 10% of tracheally intubated patients and often precedes the development of VAP. Nosocomial pneumonia is the second most common nosocomial infection and the leading cause of death from hospital-acquired infections in critically ill patients. Most recent studies report a VAP density rate of approximately 9 to 10 cases per 1000 ventilator days; nevertheless, those rates differ greatly according to the characteristics of the studied population. The risk of VAP is approximately 1% per day on mechanical ventilation and changes over time, being 3% the first 5 days on mechanical ventilation, 2% from days 5 to 10, and 1% for the remaining days.

IMPACT ON OUTCOMES

Nosocomial tracheobronchitis in hospitalized patients is associated with longer duration of mechanical ventilation and intensive care unit (ICU) stay. Indeed, tracheobronchitis is associated with increased sputum production, which often leads to weaning difficulties and extubation failure. Nevertheless, tracheobronchitis is not associated with worse survival.

The crude mortality rate for nosocomial pneumonia may be as high as 30% to 70%, although several cofactors influence mortality, making it extremely difficult to determine the true disease-attributable mortality. Indeed, the heterogeneity between patient populations, microbial patterns, antibiotic treatment, and diagnostic methods challenge precise estimate of mortality. Several case-matching studies have estimated that one third to one half of all VAP-related deaths are a direct result of the infection, with a higher mortality rate in cases caused by *Pseudomonas aeruginosa* or *Acinetobacter* spp. and associated with bacteremia. Higher mortality is associated in particular with late-onset VAP, specifically when the initial empirical antimicrobial therapy regimen is inadequate.

PATHOGENESIS

ROLE OF ENDOTRACHEAL TUBE

Pulmonary aspiration of colonized oropharyngeal secretions across the tracheal tube cuff is the main pathogenic mechanism for development of tracheobronchitis and VAP. The endotracheal tube (ETT), commonly used in the ICU for long-term mechanically ventilated patients, includes a high-volume, low-pressure (HVLP) cuff, which is approximately two to three times larger than the trachea; hence, when the cuff is inflated within the trachea, folds invariably form along the cuff surface, which leads to aspiration of oropharyngeal secretions. Several respiratory defense mechanisms are severely impaired after tracheal intubation: (1) The ETT completely bypasses the anatomic barrier provided by laryngeal structures, creating a direct conduit by which bacteria can be aspirated and reach lower airways; (2) presence of the tube hinders cough; and (3) inflation of the ETT cuff within the trachea drastically lowers mucociliary velocity.

Additionally, the ETT is commonly made of polyvinylchloride (PVC). With this material, bacteria easily adhere to the internal surface of the tube to form a complex structure called biofilm. Bacteria present within the biofilm have survival advantages and may be a source of persistent infection.

SOURCES OF COLONIZATION

Exogenous Versus Endogenous Sources

Patients can be colonized exogenously by contaminated respiratory equipment, the hospital environment, and the hands of the attending staff. Thus, health care personnel should be adequately trained in infection control and preventive strategies; strict sterilization protocols and hand washing with alcohol-based solutions should be implemented; and finally, lower patient-nurse ratios can be expected to promote optimal care with consequent lower colonization rates.

Nevertheless, endogenous colonization is believed to be the primary pathogenic mechanism for nosocomial respiratory infection development. In the hospitalized patient, the oral flora may shift to a predominance of aerobic gram-negative pathogens, *P. aeruginosa*, and methicillin-resistant *Staphylococcus aureus* (MRSA). After aspiration of bacteria-laden oropharyngeal secretions and colonization of the airways, the occurrence of respiratory infection depends on the size of the inoculum, the patient's functional status, and the competency of host defenses.

Stomach

According to the gastropulmonary hypothesis of colonization, the stomach of patients being treated in ICUs often is colonized by pathogens as a consequence of alkalinization of gastric contents by enteral nutrition and drugs. Continuous gastroesophageal reflux facilitates translocation of microbes into the oropharynx, which are then aspirated across the ETT cuff. Early studies have shown that in tracheally intubated patients, gastric pH higher than 4 is consistently associated with pathogenic colonization of the stomach. Conclusive evidence is still lacking, however, for an association of gastric colonization with increased risk of pneumonia, and some investigators have not found a relationship with bacteria causing lung infection as first originating in the stomach.

ETIOLOGIC AGENTS

Nosocomial respiratory infections may be caused by a variety of pathogens, and often more than one pathogen may be isolated. Microorganisms responsible for those infections differ according to the studied population, the duration of hospital stay, and the specific diagnostic methods used. Nosocomial respiratory infections are commonly caused by aerobic, gram-negative bacilli, such as *P. aeruginosa*, *Escherichia coli*, *Klebsiella pneumoniae*, or *Acinetobacter* spp., whereas *Streptococcus aureus* is the predominant isolated gram-positive pathogen. In a recent report by Esperatti and colleagues, the etiology of nosocomial pneumonia was investigated for invasively versus noninvasively ventilated patients managed in the ICU. Of interest, no significant differences were found, except for a higher proportion of *S. pneumoniae* in the noninvasively ventilated patients. These results imply that prevalence rates for nosocomial pathogens are similar in intubated and nonintubated patients, and that the use of empirical therapy likely to be active against them is warranted.

Underlying diseases may predispose patients to infection with specific organisms. For instance, patients with chronic obstructive pulmonary disease (COPD) are at increased risk for *Haemophilus influenzae*, *Moraxella catarrhalis*, *P. aeruginosa*, or *S. pneumoniae* infections; patients with acute respiratory distress syndrome (ARDS) are at higher risk for development of VAP caused by *S. aureus*, *P. aeruginosa*, and *Acinetobacter baumannii*. Finally, patients with traumatic injuries and neurologic disorders are at increased risk for *S. aureus*, *Haemophilus*, and *S. pneumoniae* infections.

Identification of pathogens resistant to multiple drugs is extremely important, in order to guide appropriate antibiotic treatment. Potential MDR pathogens are *P. aeruginosa*, MRSA, *Acinetobacter* spp., *Stenotrophomonas maltophilia*, *Burkholderia cepacia*, and extended-spectrum beta-lactamase–producing (ESBL-positive) *K. pneumoniae*. Conversely, *S. pneumoniae*, *H. influenzae*, methicillin-sensitive *S. aureus*, and antibiotic-sensitive Enterobacteriaceae organisms are not considered to be MDR pathogens. The incidence of MDR pathogens is closely linked to local factors and varies widely from one hospital to another. Accordingly, practitioners must be aware of the most prevalent microorganisms in their own clinical facilities and geographic regions to avoid the administration of initial inadequate antimicrobial therapy.

Legionella pneumophila as a cause of nosocomial pneumonia should be considered, particularly in immunocompromised patients. Anaerobes may potentially cause nosocomial infections, but often those pathogens are identified in association with aerobic pathogens, and their role is still considered controversial. Nosocomial infections are rarely caused by a fungus. *Candida* spp. and *Aspergillus fumigatus* are the most common isolated fungi, predominantly in immunocompromised patients. Finally, herpes simplex virus type 1 and cytomegalovirus (CMV) are the most common viruses identified as a cause of respiratory infections in hospitalized patients; of note, CMV pneumonia was found to be consistently associated with worse outcomes in patients managed in the ICU.

PREVENTION

Nosocomial respiratory infections are associated with high morbidity and mortality and constitute an important burden for the health care system; therefore, appropriate preventive strategies, summarized in Box 27-1, should be implemented to reduce overall incidence of those diseases. Approaches with proven efficacy in reduction of nosocomial respiratory infections should be grouped and implemented as a bundle, because together they are expected to result in a better outcome than when implemented individually.

Box 27-1 Preventive Strategies for Nosocomial Pneumonia

- Implementation, as a bundle, of nosocomial pneumonia–preventive strategies that have proven efficacy in reducing morbidity and mortality
- Implementation of educational programs for caregivers and frequent performance feedbacks and compliance assessment
- Strict alcohol-based hand hygiene
- Avoidance of tracheal intubation and use of noninvasive ventilation when indicated
- Daily sedation vacation and implementation of weaning protocols
- No ventilatory circuit tube changes unless the circuit is soiled or damaged
- Use of tracheal tube with cuff made of novel materials and shapes
- Use of silver-coated tracheal tube
- Application of low level of PEEP during tracheal intubation
- Aspiration of subglottic secretions
- Internal cuff pressure maintained within the recommended range and carefully controlled during transport of patients outside ICU setting
- Oral care with chlorhexidine
- Avoidance of stress ulcer prophylaxis in patients at very low risk for gastrointestinal bleeding, with use of sucralfate considered when indicated
- Semirecumbent patient positioning
- Continuous lateral rotation therapy
- Postpyloric feeding in patients who have impaired gastric emptying
- SDD for patients requiring mechanical ventilation for longer than 48 hours

ICU, intensive care unit; *PEEP*, positive end-expiratory pressure; *SDD*, selective digestive decontamination.

GENERAL PROPHYLACTIC MEASURES

Maintaining high levels of current knowledge on pathophysiology of nosocomial infections and preventive strategies in clinical health care personnel can be effective in reducing incidence of those diseases. Respiratory care practitioners and nurses should be the primary recipients of ongoing education programs, and frequent performance feedback and compliance assessment should be undertaken.

The World Health Organization (WHO) has endorsed hand hygiene as the single most important element of strategies to prevent health care–associated infections. Overall, most of the studies conducted in ICUs have shown consistent reduction in nosocomial infection rates through implementation of alcohol-based hand hygiene.

Daily interruption or lightening of sedation, as a strategy to avoid consistent impairment of respiratory defenses, as well as the avoidance of paralytic agents, is highly recommended.

Noninvasive Ventilation

Tracheal intubation and mechanical ventilation constitute the main risk for nosocomial respiratory infections and should be avoided whenever possible. Noninvasive ventilation is an attractive alternative for patients with acute exacerbations of COPD or acute hypoxemic respiratory failure, and for some immunocompromised patients with pulmonary infiltrates and respiratory failure.

Tracheal Tube Cuff

Novel ETT cuffs made of polyurethane, silicone, and latex have been developed and tested in laboratory and clinical trials. Particularly, the polyurethane cuff forms smaller folds on its inflation, so that the risk of aspiration of secretions above the cuff is less. The shape of the cuff may also play a role in prevention of aspiration. In comparison with standard cuffs with cylindrical shape, cuffs designed with a smooth tapering shape allow elimination of folds for a full section of the trachea-cuff contact zone, irrespective of the cuff material. Nevertheless, the clinical evidence on the efficacy of these novel tapered cuffs is still lacking.

It is important to maintain the internal pressure of the endotracheal tube cuff pressure between 25 to 30 cm H_2O, particularly when low levels of positive end-expiratory pressure (PEEP) are applied, in order to prevent both “macroleakage” of contaminated secretions into the lower airways and tracheal injury.

Tracheal Tubes Coated With Antimicrobial Agents

Coating the ETT with antimicrobial agents, such as silver, is a promising strategy to prevent biofilm formation within the tube with consequent VAP. The North American Silver-Coated Endotracheal Tube (NASCENT) randomized trial studied 2003 patients, expected to require mechanical ventilation for more than 24 hours, who were randomized to be intubated with either a silver-coated or a conventional tube. Use of the silver-coated ETT was associated with a lower incidence of microbiologically confirmed VAP, for a relative risk reduction of 35.9%.

Aspiration of Subglottic Secretions

Preventive aspiration of colonized subglottic secretions through dedicated ETTs reduces hydrostatic pressure exerted above the cuff, potentially preventing macroleakage across the cuff. Subglottic secretion drainage has been shown to reduce the incidence of VAP by nearly half, primarily by reducing both early- and late-onset pneumonia.

Body Position

Intubated patients are at higher risk for gastropulmonary aspiration when placed in the supine position (0 degrees) than in a semirecumbent position, particularly when they are enterally fed. The American and European guidelines strongly suggest that intubated patients should be preferentially kept in the semirecumbent position (30 to 45 degrees) rather than supine (0 degrees) to prevent aspiration, especially when the patient is receiving enteral feeding.

Stress Ulcer Prophylaxis in Intubated Patients

In the ICU, stress ulcer prophylaxis usually is achieved with either sucralfate, histamine type 2 receptor blockers (H_2 blockers), or proton pump inhibitors (PPIs). Sucralfate is the only agent that potentially prevents stress gastrointestinal ulceration without raising gastric pH. Clinicians must weigh the potential benefit of sucralfate (with potentially less VAP and more gastrointestinal bleeding) against that of H_2 blockers or PPIs (with potentially more VAP and less gastrointestinal bleeding) and probably should limit stress ulcer prophylaxis to high-risk patients.

Modulation of Oropharyngeal and Gastrointestinal Colonization

Extensive efforts have been devoted to modulate oropharyngeal flora of hospitalized patients and reduce the risk for aspiration of pathogens. Oropharyngeal decontamination with chlorhexidine effectively reduces VAP, particularly among patients managed in cardiothoracic ICUs. Results in noncardiac ICU populations are more uncertain, and significant reductions in VAP rates have been achieved only when chlorhexidine was used at concentrations of 2%.

Selective decontamination of the digestive tract (SDD) has been used as a preventive strategy against nosocomial pneumonia for almost 3 decades. The SDD regimen comprises a combination of nonabsorbable antibiotics active against gram-negative pathogens (e.g., tobramycin, polymyxin E), plus either amphotericin B or nystatin, administered into the gastrointestinal tract in order to prevent oropharyngeal and gastric colonization with aerobic gram-negative bacilli and *Candida* spp. while preserving the anaerobic flora. Some regimens include a short course of systemic antibiotics (most commonly cefotaxime) in addition to nonabsorbable gastrointestinal antibiotics. SDD reduces the incidence of VAP, and it is the only VAP-preventive strategy that has shown survival benefits in patients managed in the ICU. The long-term effects of SDD on emergence of bacterial resistance and risk of superinfections are still controversial.

DIAGNOSIS

Nosocomial pneumonia should be suspected in patients with a new or progressive infiltrate on lung imaging associated with at least two of the following clinical features:

- Fever
- Leukocytosis or leukopenia
- Purulent airway secretions

The presence of these clinical signs, without a new infiltrate on the chest film, suggests nosocomial tracheobronchitis. In patients managed in the ICU, clinical signs suggestive of pneumonia often are too nonspecific to be of diagnostic value. Moreover, the chest radiograph often is difficult to interpret in those

Table 27-1 Clinical Pulmonary Infection Score (CPIS)*

Criterion	Scoring Factor 0	1	2
Tracheal secretions	Absent	No purulent	Abundant and purulent
Infiltrates on chest radiograph	No	Diffuse	Localized
Temperature (°C)	≥36.5 and ≤38.4	≥38.5 or ≤38.9	≥39 or ≤36
Leukocytes (cells/µL)	≥4000 and ≤11000	<4000 or >11000	<4000 or >11000 + bands >50% or >500
Pa_{O_2}/F_{IO_2}	>240 or ARDS		≤240, no ARDS
Microbiology*	Negative		Positive

*CPIS of 6 or higher is considered positive for infection.

ARDS, acute respiratory distress syndrome.

patients; indeed, when infiltrates are evident, it is challenging to differentiate among cardiogenic and noncardiogenic pulmonary edema, pulmonary contusion, atelectasis, and pneumonia. Clinical variables often are evaluated as a group, to improve specificity of the clinical diagnosis. The Clinical Pulmonary Infection Score (CPIS) is based on clinical assessments, pulmonary radiographic findings, and semiquantitative culture of tracheal aspirate, each worth between 0 and 2 points (Table 27-1). A minimum value of 6 is the threshold to identify patients with pneumonia. Nevertheless, the value of CPIS remains to be validated in a large prospective study, especially in patients with bilateral pulmonary infiltrates.

The presence of bacteria in the lower airways of intubated patients is not sufficient to diagnose true lung infection, because the tracheobronchial tree of mechanically ventilated patients frequently is colonized by enteric gram-negative bacilli. Many sampling procedures are available, such as sputum collection, endotracheal aspiration, bronchoalveolar lavage (BAL), and protected specimen brush (PSB) procedures. In addition, several microbiologic techniques can be used, including Gram staining and intracellular organism count from specimens obtained by tracheal aspiration and BAL. Each diagnostic technique has advantages and limitations and provides different levels of diagnostic specificity and sensitivity.

Qualitative cultures of endotracheal aspirates yield a high percentage of false-positive results owing to frequent bacterial colonization of the proximal airways. Conversely, quantitative culture techniques of endotracheal aspirates may have an acceptable overall diagnostic accuracy. When patients develop pneumonia, pathogens are present in the lower respiratory tract secretions at concentrations of at least 10^5 to 10^6 colony-forming units (CFU)/mL, and contaminants generally are present at less than 10^4 CFU/mL. The current proposed VAP diagnostic threshold is 10^6, 10^4, and 10^3 CFU/mL for tracheal aspirates, BAL fluid, and PSB samples, respectively. Likewise, in a patient without radiographic pulmonary infiltrates, tracheal aspirates colonized at a concentration of at least 10^6 CFU/mL may suggest tracheobronchitis.

DIAGNOSTIC STRATEGIES FOR NOSOCOMIAL RESPIRATORY INFECTION

An ideal diagnostic strategy for patients suspected on clinical grounds to have nosocomial respiratory infection should achieve the following objectives:

- Accurately identify patients with true pulmonary infection and isolate the causative microorganisms, to allow prompt initiation of appropriate antimicrobial treatment and then optimization of therapy based on susceptibility studies of the pathogens
- Identify patients with extrapulmonary sites of infection
- Withhold and/or withdraw antibiotics in patients without infection

The diagnosis of nosocomial pneumonia begins with clinical suspicion triggered by suggestive findings. The presence of a new or progressively worsening radiographic infiltrate plus clinical criteria constitutes a firm basis for further investigation. Either of two diagnostic algorithms can be used: clinical or bacteriologic. The *clinical approach* recommends treating every patient suspected to have a pulmonary infection with new antibiotics even when the likelihood of infection is low (Figure 27-1). Nevertheless, samples of respiratory secretions such as endotracheal aspirate or sputum should be obtained before the initiation of antibiotic treatment. In this strategy, the selection of appropriate empirical therapy is based on risk factors and local resistance patterns. The etiology in each case of pneumonia is defined by semiquantitative cultures of endotracheal aspirates or sputum, often with additional microscopic examination of the Gram stain. Antimicrobial therapy is adjusted according to culture results or clinical response. Semiquantitative culture of tracheal aspirates has the advantage that no specialized microbiologic techniques are required, and the sensitivity is high. This clinical strategy provides antimicrobial treatment to a majority of the patients with suspected pneumonia and yields a low rate of false-negative results. Still, if the tracheal aspirate culture does not demonstrate pathogens and the patient has not received new antibiotics within the previous 72 hours, the diagnosis of pneumonia is unlikely. The main drawback of this strategy is that the high sensitivity of semiquantitative cultures of tracheal aspirates leads to overtreatment, with institution of unnecessary antibiotics in patients with false-positive results.

The *bacteriologic strategy* is based on the results of quantitative cultures of lower respiratory secretions (Figure 27-2). The procedure used to collect the samples (endotracheal aspirate, BAL fluid, or PSB) may be invasive (bronchoscopic) or noninvasive (blind procedures). The strategy reduces risks for overuse of antibiotics, because quantitative cultures yield fewer microorganisms above the threshold in comparison with

semiquantitative cultures. Among the disadvantages of the bacteriologic strategy is the possibility of obtaining false-negative results, which leads to delayed antibiotic treatment in patients with pneumonia. Moreover, results obtained using the microbiology strategy may lack reproducibility, and often no microbiologic information is available at the time of initiation of empirical antibiotic therapy.

PRACTICAL IMPLEMENTATION OF A DIAGNOSTIC STRATEGY IN SUSPECTED NOSOCOMIAL RESPIRATORY INFECTION

In practice, the development of local clinical guidelines can combine both clinical and bacteriologic strategies. In mechanically ventilated patients, the presence of an infiltrate on the chest radiograph differentiates between the possible presence of pneumonia and tracheobronchitis. The next step is to obtain samples from the lower respiratory tract, before initiation of antibiotic treatment or change in regimen, even though it should not delay the administration of antibiotic therapy, particularly for septic patients. When indicated, additional samples should be collected for microbiologic analyses, such as blood, pleural fluid, and, in case *L. pneumophila* or *S. pneumoniae* infections are suspected, urine should be obtained. With clinical findings suggestive of pneumonia, CPIS should be calculated, to improve objective assessment of the clinical parameters (see Table 27-1).

TREATMENT

Once the clinical decision to initiate antimicrobial therapy for nosocomial respiratory infection has been made, the following issues should be considered, both to achieve the best antimicrobial efficacy and to reduce overuse of antibiotics:

- The most likely etiologic microorganisms
- Choice of the empirical antimicrobials likely to be active against these microorganisms
- The adjustment of therapy after microbiologic results are in and with duration of treatment

An important point is that the indiscriminate administration of antimicrobial agents may contribute to the emergence of multiresistant pathogens and increase the risk of severe superinfections with increased morbidity and mortality, as well as exposing the patient to antibiotic-related adverse effects and higher costs. On the other hand, correct and prompt treatment of nosocomial respiratory infections results in better patient survival.

THE LIKELY ETIOLOGIC MICROORGANISMS

The selection of initial antimicrobial therapy needs to be tailored to the local prevalence of pathogens and antimicrobial patterns of resistance of the institution. The dynamics of change of oropharyngeal flora during hospital stay is depicted in Figure 27-3. Changes in oropharyngeal flora tend to occur progressively, so that the presence of microorganisms during one stage often overlaps with the next stage.

CHOICE OF THE EMPIRICAL ANTIMICROBIALS LIKELY TO BE ACTIVE AGAINST CAUSATIVE MICROORGANISMS

The latest guidelines of the American Thoracic Society and the Infectious Diseases Society of America (ATS/IDSA) for the management of adult patients with nosocomial pneumonia recommend that the selection of empirical antibiotic therapy for each patient should be based on the timing of onset and presence of risk factors for MDR pathogens—antimicrobial therapy in preceding 90 days; current hospitalization of 5 days or more; high frequency of antibiotic resistance in the community or in the specific hospital unit; hospitalization for 2 days or longer within the preceding 90-day period; residence in a nursing home or extended care facility; home infusion therapy (including antibiotics); chronic dialysis within 30 days; home wound care; MDR pathogen carrier status or infection in a family member; and immunosuppressive disease and/or therapy. The antibiotics recommended in the current ATS/IDSA guidelines are shown in Tables 27-2 and 27-3. Broad-spectrum empirical antibiotic therapy should be rapidly deescalated as soon as microbiologic data become available, to limit the emergence of resistance in the hospital.

Patients with Late-Onset Pneumonia or Early-Onset Pneumonia with Risk Factors for Multidrug-Resistant Bacteria

Patients with late-onset pneumonia or early-onset pneumonia with risk factors for MDR bacteria may be infected with resistant gram-negative bacilli. Priority should be given to treatment with a beta-lactam. Choice of the beta-lactam agent should take into account the following factors: (1) in vitro susceptibility of *P. aeruginosa* in the ICU, (2) the prevalence of Enterobacteriaceae organisms producing ESBL, (3) the results of previous cultures, and (4) antibiotics already received by the patient.

Table 27-3 Initial Empirical Antibiotic Treatment for Nosocomial and Ventilator-Associated Pneumonia of Late Onset or in Patients with Risk Factors for Infection by Multidrug-Resistant Pathogens and Any Degree of Severity

Probable Pathogen	Combined Antibiotic Treatment
Microorganisms from Table 27-2 PLUS: *Pseudomonas aeruginosa* *Klebsiella pneumoniae* (ESBL-positive)* *Acinetobacter* spp.* Other nonfermenting GNB Methicillin-resistant *Staphylococcus aureus* (MRSA) *Legionella pneumophila*[†]	Antipseudomonal cephalosporin (ceftazidime or cefepime)[‡] OR Carbapenem (imipenem, meropenem)[‡] OR Beta-lactam/beta-lactamase inhibitor (piperacillin-tazobactam)[‡] + Antipseudomonal fluoroquinolone (ciprofloxacin, levofloxacin)[§] OR Aminoglycoside[§] (amikacin) ± Linezolid or vancomycin[¶]

ESBL, extended-spectrum beta-lactamase; *GNB*, gram-negative bacilli; *ICU*, intensive care unit.

*If an ESBL-positive strain such as *K. pneumoniae*, or *Acinetobacter*, is suspected, a carbepenem is the agent of first choice.

[†] If *L. pneumophila* is the suspected pathogen, the combination antibiotic regimen should include a macrolide (e.g., azithromycin), or a fluoroquinolone (e.g., ciprofloxacin or levofloxacin) should be used rather than an aminoglycoside.

[‡] The choice of beta-lactam is made as follows: Patients who have not received any antipseudomonal beta-lactam within the last 30 days should be administered piperacillin-tazobactam or an antipseudomonal cephalosporin. Patients who have received these drugs should be given empirical therapy with a carbapenem. Patients with infection by ESBL-producing microorganisms should be treated with carbapenem regardless of the results of the antibiogram.

[§] For combined empirical therapy for multidrug-resistant GNB, an antipseudomonal fluoroquinolone should be given in cases of renal failure or with concomitant use of vancomycin. In other settings, combined empirical therapy with amikacin is initiated and maintained for a 5-day period.

[¶] Empirical therapy aimed against MRSA is initiated in patients with proven colonization, previous infection by this microorganism, or implementation of mechanical ventilation for more than 6 days. The antibiotic of choice is either vancomycin (except in persons allergic to this medication, those with serum creatinine values of 1.6 mg/dL or greater, or patients presenting with signs of empirical treatment failure after 48 hours of antibiotic therapy) or linezolid.

NOTE: For epidemiologic surveillance, nasal and perineal cultures should be performed on admission and at 1-week intervals thereafter during the ICU stay.

An antipseudomonal beta-lactam regimen would include a third-generation cephalosporin (ceftazidime or cefepime), piperacillin-tazobactam, or a carbapenem (imipenem or meropenem) (see Table 27-3).

ANTIMICROBIAL THERAPY IN SPECIAL SITUATIONS

The addition of antibiotics with activity against MRSA depends on the local prevalence of MRSA, the presence of risk factors for MRSA, and the severity of infection. In geographic areas with documented presence of community-acquired MRSA, severe pneumonia with radiologic images of cavitation and presence of gram-positive cocci in respiratory secretions, empirical treatment with linezolid or vancomycin may be appropriate. Infections by *L. pneumophila* serogroup 1 can be diagnosed by a *Legionella* urinary antigen test. A fluoroquinolone or a macrolide would be an appropriate agent for treatment of *L. pneumophila* infection.

MODIFICATIONS OF THERAPY AND DURATION OF TREATMENT

After 72 hours, treatment should be adjusted in accordance with the microbiologic results. The initial beta-lactam should be continued if the microorganism is susceptible to the empirical beta-lactam originally prescribed. If it is not, another beta-lactam, possibly a carbapenem, may be introduced. The empirical antibiotic active against MRSA should be discontinued if the presence of this pathogen is not confirmed by cultures. Discontinuation of the fluoroquinolone and especially the aminoglycoside should be considered after 3 to 5 days of treatment. The bactericidal activity of aminoglycosides and fluoroquinolones leads to a rapid reduction in the bacterial load during the first days of treatment. Thereafter, monotherapy may be sufficient. This approach would decrease emergence of resistant mutants and minimize nephrotoxicity caused by aminoglycosides.

A majority of infections can be effectively treated with regimens lasting up to 8 days. Four special situations may justify prolonged treatment: (1) infection by microorganisms that may multiply in the cellular cytoplasm, such as *Legionella* spp.; (2) the presence of biofilms or prosthetic devices; (3) the development of tissue necrosis, the formation of abscesses, or infection within a closed cavity, such as empyema; and (4) persistence of the original infection (such as with perforation or endocarditis). If the clinical course from the pneumonia is favorable within the first 3 to 5 days of antimicrobial therapy, treatment may be withdrawn after the completion of 8 days. In cases of pneumonia produced by nonfermenting gram-negative bacilli, the eradication of these microorganisms from the bronchial secretion can be achieved with a longer regimen of up to 14 days.

In patients originally suspected on clinical grounds to have ICU-acquired pneumonia but whose CPIS is lower than 6 on the third day of drug therapy, treatment may be withdrawn. In this setting, the patient probably did not have pneumonia, or the pneumonia was sufficiently mild that prolonged antibiotic treatment is not required (**Figure 27-4**).

IMPORTANT INSIGHTS FOR TREATMENT OF NOSOCOMIAL RESPIRATORY INFECTIONS

Studies have proved beneficial effects of antimicrobial treatment for patients with nosocomial tracheobronchitis being cared for in an ICU. In these patients, antibiotics can have an impact on ICU mortality rate, duration of mechanical ventilation, and ICU stay and ultimately hinder progression of the infection to VAP. Of importance, patients with airway colonization but without local and systemic signs of infection should not be treated. Additionally, aerosolized antibiotics can be a feasible option in such patients.

There is evidence that appropriate and timely antibiotic treatment can improve outcome in patients with VAP. Guidelines can play a significant role in accomplishing this aim. To achieve significant reductions in morbidity and mortality, however, two important principles should be followed: (1) the guidelines should be implemented in specific clinical settings, and (2) antibiotic treatment regimens should be tailored to specific risk factors for acquiring MDR pathogens. Although implementation of such guidelines is difficult, the available

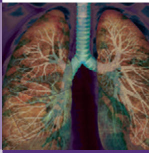
INFECTIOUS DISEASES



Chapter 28

Pneumonia in the Non-HIV-Infected Immunocompromised Patient

Jennifer Quint • Jeremy S. Brown

OVERVIEW

The respiratory tract is continually exposed to a range of microorganisms that normal immune responses generally prevent from causing infection. Hence, it is not surprising that patients with significantly impaired immunity frequently develop lung infections. Immunodeficient patients also frequently have several other risk factors that contribute to an increased risk for development of pneumonia, including low-level microaspiration of oropharyngeal contents, mucosal damage caused by cytotoxic therapy, underlying lung damage, and poor nutrition. As a consequence, lung infections are a common and frequently serious complication in patients with significant impairment of the immune system. Pulmonary infiltrates occur in 25% of patients with neutropenia developing after chemotherapy, and up to 5% of patients undergoing hematopoietic stem cell transplantation (HSCT) will die as a result of pneumonia. The range of potential pathogens causing lung infections in immunocompromised patients is much broader than for the usual pathogens causing community-acquired pneumonia and includes organisms such as *Aspergillus fumigatus* and human cytomegalovirus (CMV); the diagnosis of infections due to these microbes can be difficult, and the required therapies frequently are toxic. The large number of potential pathogens and the background disease together make management of lung infection in immunocompromised patients considerably more complex, and the use of invasive diagnostic tests such as bronchoscopy frequently is necessary. This chapter focuses on the common causative pathogens and the clinical approach to pulmonary infections in patients who have been severely immunocompromised by chemotherapy, organ transplantation, or hematologic disease (**Box 28-1**) but not human immunodeficiency virus (HIV) infection (discussed in Chapter 29). Pneumonia in patients with milder degrees of immunosuppression due to myeloma, low-dose cytotoxic therapy, or disease-modifying agents administered for rheumatologic conditions generally should be managed as community- or hospital-acquired pneumonia, but with recognition that the disease could be due to various opportunistic pathogens, as discussed in this chapter.

GENERAL PRINCIPLES OF THE CLINICAL APPROACH

Potential pathogens causing lung infection in the immunocompromised patient are listed in **Table 28-1**. Empirical therapy that is active against all these possible pathogens is not feasible, especially given the potential toxicity of some treatments. Hence, the challenge in managing these patients is to (1) reduce the scope of the differential diagnosis to include the most likely problems and thus allow relatively targeted empirical therapy and (2) identify when and which type of invasive diagnostic test(s) should be used to provide the most useful data. The likely potential causative pathogens can be defined by ascertaining the following:

- The clinical and radiologic presentation
- The speed of onset of the infection
- The type, duration, and severity of the patient's immune defect
- Positive results on microbiologic studies
- Associated factors of importance, including any recent local infective epidemics and the patient's prophylaxis regimen, ethnic background, and travel history

The exact type of immune defect is determined by a combination of the disease and the treatment received and, fortunately, can generally be predicted (**Table 28-2**). The three main categories of immune defect are absolute or functional neutropenia, defects in cell-mediated immunity, and deficiencies in antibody responses (a clinically less severely affected category). Each is associated with a particular range of pathogens (see Table 28-2). Patients with neutropenia are mainly at risk for infection with extracellular pathogens such as pyogenic bacteria and filamentous fungi. Defects in cell-mediated immunity tend to predispose affected patients to development of infections with intracellular pathogens such as viruses and mycobacteria, as well as some unusual extracellular infections such as *Pneumocystis* pneumonia (PCP). Deficiencies in antibody responses result in a high incidence of infections due to encapsulated bacteria such as *Streptococcus pneumoniae* and to herpesviruses. Individual patients may have a combination of these immune defects; for example, lymphoma can cause impairment of cell-mediated immunity that can be combined with neutropenia if the patient receives chemotherapy.

HSCT, especially for allograft recipients, is particularly associated with lung complications, including infections with a daunting range of pathogens. The immune defects associated with HSCT depend on the conditioning regimen and type of graft, and evolve with time. In phase I, the preengraftment phase (15 to 45 days after transplantation), prolonged neutropenia and breaks in the mucocutaneous barrier increase the risk of bacterial and fungal infections. Herpes simplex virus reactivation also can occur during this phase. In phase II, the

Box 28-1 Diseases and Conditions Associated With Severe Immunocompromise*

- Lymphoma/leukemia
- Hematopoietic stem cell transplantation (HSCT)
- Aplastic anemia
- Solid organ transplantation
- Other causes of neutropenia (fewer than 1500 cells/mL)
- Inherited disorders of immune function (e.g., chronic granulomatous disease, recent chemotherapy)
- High-dose corticosteroid treatment (greater than 30 mg prednisolone for 21 days or longer)
- Treatment with immunosuppressive therapy (e.g., tacrolimus, cyclosporine)
- Treatment with cytotoxic therapy (e.g., cyclophosphamide, mycophenolate)

*As defined in this chapter.

immediate post-engraftment phase at around 30 to 100 days after transplantation, infections relate primarily to impaired cell-mediated immunity and include those due to herpesviruses (particularly CMV) and PCP unless the patient is given prophylaxis. During phase III, the late phase (beyond 100 days), common pathogens again include herpesviruses, but there is also a marked increased incidence of infection with encapsulated bacteria such as *S. pneumoniae*, perhaps relating to impaired humoral immunity. Graft-versus-host disease also is associated with ongoing susceptibility to *Aspergillus* during phases II and III. For recipients of nonmyeloablative hematopoietic stem cell transplants, substantial differences may be observed during phase I, but susceptibility to infections during phases II and III is about the same. The risk of disease from community-acquired respiratory viruses is elevated in all three phases.

By combining the clinical pattern of presentation with knowledge of the patient's immune defect, a differential diagnosis of likely pathogens can be suggested. For example, infections developing rapidly over 1 to 3 days with a marked rise in serum inflammatory markers such as C-reactive protein (CRP), pronounced fever, and focal radiologic changes are very likely to be due to infection with pyogenic bacteria. In a patient with a defect in cell-mediated immunity, however, widespread ground glass infiltrations in both lungs developing over several days could represent CMV pneumonitis or PCP. In general, the more severe and prolonged the immune defect, the greater the range of possible causative pathogens and the less typical the clinical presentation for a particular pathogen, prompting the need for early invasive investigation if the initial therapy is failing to effect improvement. Furthermore the character of the disease can be dictated by the severity of the immune defect. For example, infections due to filamentous fungi such as *Aspergillus* progress faster with increasing severity of neutropenia, but may regress and become more focal when the neutrophil count recovers. Table 28-3 shows the common conditions that should be considered for different presentations of lung complications in immunocompromised patients. Many patients will be found to have dual pathologic processes, either involving two separate pathogens or with simultaneous noninfective (fluid overload being the most common) and infective problems, which will be responsible for separate elements of the clinical picture.

Table 28-1 Range of Pathogens Commonly Associated With Pneumonia in the Non-HIV-Infected Immunocompromised Patient

Pathogen	Cases (%)
Gram-Negative Pyogenic Bacteria	
Escherichia coli	6
Proteus, *Enterobacter*, *Serratia*, and *Citrobacter* spp.	2
Haemophilus influenzae	<1
Klebsiella pneumoniae	<1
Pseudomonas aeruginosa	8
Acinetobacter spp.	2
Stenotrophomonas maltophilia	<1
Gram-Positive Pyogenic Bacteria	
Streptococcus pneumoniae	2
Viridans streptococci	<1
Staphylococcus aureus	12
Enterococcus spp.	4
Other Bacteria	
Anaerobes	<1
Legionella pneumophila	2
Chlamydia spp.	2
Mycoplasma pneumoniae	<1
Mycobacterium tuberculosis	4
Nontuberculous mycobacteria	<1

Candida spp.	9
Aspergillus spp.	24
Rarer molds (e.g., *Mucor*, *Penicillium*, *Fusarium*)	2
Endemic fungi (e.g., *Histoplasma*, *Coccidioides*)	<1
Protozoa	
Toxoplasma gondii	<1
Helminths	
Strongyloides stercoralis	<1
Viruses	
Cytomegalovirus	6
Herpes simplex virus, varicella-zoster virus	2
Respiratory viruses (respiratory syncytial virus, adenovirus, influenza virus, parainfluenza virus, human metapneumovirus)	8

Modified from Rañó A, Agustí C, Jimenez P, et al: Pulmonary infiltrates in non-HIV immunocompromised patients: a diagnostic approach using non-invasive and bronchoscopic procedures, *Thorax* 56:379–387, 2001.

Previous results of microbiologic tests need to be reviewed, because these may provide a strong indication of the cause of the present lung infection. For instance, infected indwelling vascular and urinary catheters can form foci of infection that can metastasize to the lungs, and previous *Aspergillus* infection may recur during new episodes of immunosuppression. Knowledge of previous and present CMV status identifies patients at risk for development of CMV pneumonitis, and positive

Table 28-2 Type of Immune Defect According to Disease/Treatment and Range of Pathogens Commonly Associated With Infections in Patients with Such Immune Defects

Immune Defect	Cause	Associated Pathogens
Neutropenia/ functional neutrophil defects	Chemotherapy Early HSCT* Acute leukemia Chronic myelocytic leukemia Aplastic anemia Marrow infiltrations Azathioprine/ mycophenolate[†] High-dose corticosteroids[†] Chronic granulomatous disease[†] Other inherited phagocyte defects[†]	Pyogenic bacteria and anaerobes Filamentous fungi (*Aspergillus*, rarer molds) *Candida* spp.

*Allografts up to 1 month, autografts usually less than 14 days.

[†] Patients usually have a normal neutrophil count but have defects in their function and/or a poor response to infection.

HSCT, hematopoietic stem cell transplantation.

sputum surveillance cultures for methicillin-resistant *Staphylococcus aureus* (MRSA) or *Pseudomonas aeruginosa* may indicate likely causes of a new pneumonia. In addition, positive samples from other patients also may be helpful, because local epidemics of respiratory virus infections are not uncommon in hospitals, and more rarely, clusters of nosocomial *Aspergillus*, *Nocardia* (both of which may be associated with ongoing construction on the hospital site), or *Legionella* infection can occur.

Other important factors that need to be taken into account include the patient's present antibiotic prophylaxis regimen, travel history, and ethnic background. A patient compliant with co-trimoxazole prophylaxis will rarely develop PCP, and fluconazole prophylaxis predisposes to non-albicans *Candida* infection. Patients with certain ethnic backgrounds or a pertinent travel history are more at risk of TB, endemic mycoses such as histoplasmosis, or parasitic diseases such as disseminated strongyloidiasis. Finally, the patient's background lung structure and function should be considered, because existing structural abnormalities may make certain pathogens more likely. For example, bronchiectasis could predispose affected persons to pneumonia caused by *P. aeruginosa* (**Figure 28-1**), and preexisting lung cavities to *Aspergillus* infection.

CLINICAL ASSESSMENT AND DIAGNOSTIC PROTOCOLS

The combination of new respiratory symptoms and/or new radiologic findings with pyrexia suggests lung infection, although incidental radiologic or microbiology results may also identify active lung infection in an asymptomatic patient. The patient should undergo careful clinical assessment, including a review of previous laboratory and radiologic findings; the high mortality associated with lung infections in immunocompromised patients requires that this is initiated rapidly. The level of oxygenation will characterize the immediate risk to the patient and can also suggest likely pathogens as severe hypoxia is more likely with a bacterial lobar pneumonia, extensive PCP or viral infections. Chest radiographs are an essential first line investigation and are useful for monitoring progress. However, with the exception of lobar consolidation chest radiographs may not be sufficiently sensitive to make an accurate assessment of the pattern of lung shadowing. Ultimately a computed tomography (CT) scan of the thorax often is required. CT scans are approximately 20% more sensitive than chest radiographs at identifying lung involvement and also define whether new changes on a chest radiograph represent consolidation, nodules, ground glass infiltrates, or "tree-in-bud" changes.

All patients with suspected new lung infection require blood and sputum cultures, as well as routine blood tests, and in many cases nasopharyngeal aspirate studies for identification of viruses, assessment of CMV status, and serum testing for fungal antigens (galactomannan or β-D-glucan). An important question for the respiratory physician is when to utilize more invasive investigations, either bronchoscopy with bronchoalveolar lavage (BAL) and possibly transbronchial biopsy, percutaneous radiologically guided biopsy, or, on occasion, surgical biopsy, usually video-assisted thoracoscopic surgery (VATS). Which test should be used and when will depend to a large extent on the type of radiologic presentation—consolidation, diffuse ground glass infiltrates, tree-in-bud changes, and nodules—in accordance with the algorithms for each provided in Figures 28-2, 28-4, 28-6, and 28-7, respectively. These suggested protocols balance the likelihood and necessity of a positive yield against the clinical probability that a particular disease will be identified with the potential complications of the investigations. These protocols are for general guidance; atypical presentations and dual pathology are not uncommon, and an individual patient often will require a modified approach. Immunocompromised patients are also at high risk for development of a range of noninfective causes of lung disease, including pulmonary edema, idiopathic pneumonia syndrome (IPS), and diffuse alveolar hemorrhage (see Chapter 59). These conditions should always be considered in the differential diagnosis for new lung disease. The protocols are discussed in detail next.

INVESTIGATION OF CONSOLIDATION

Rapidly developing focal consolidation usually is due to bacterial pneumonia and initially can be treated empirically with broad-spectrum antibiotics (**Figure 28-2**). The most likely reason for a lack of improvement in the patient's condition within 48 to 96 hours is infection with bacteria resistant to

Table 28-3 Differential Diagnosis for Computed Tomography (CT) Pattern and Rate of Development of Clinical Problem

Predominant CT Pattern	Rate of Progression

†Usually focal patches.

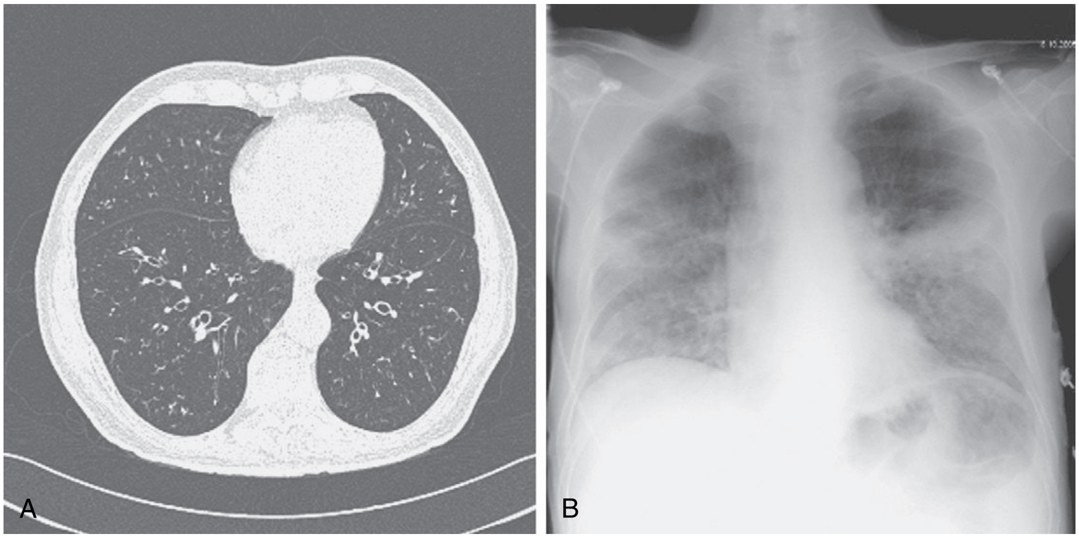

Figure 28-1 **A,** Computed tomography (CT) scan of thorax shows dilated, thick-walled bronchi, characteristic of bronchiectasis. The patient, who had a long history of chronic lymphatic leukemia and immunoglobulin deficiency, produced purulent sputum daily, culture of which grew *Pseudomonas aeruginosa*. **B,** A chest radiograph obtained in the same patient, whose clinical presentation included high fever, productive cough, and marked hypoxia, shows consolidation (most marked in the left middle zone) due to *P. aeruginosa* pneumonia.

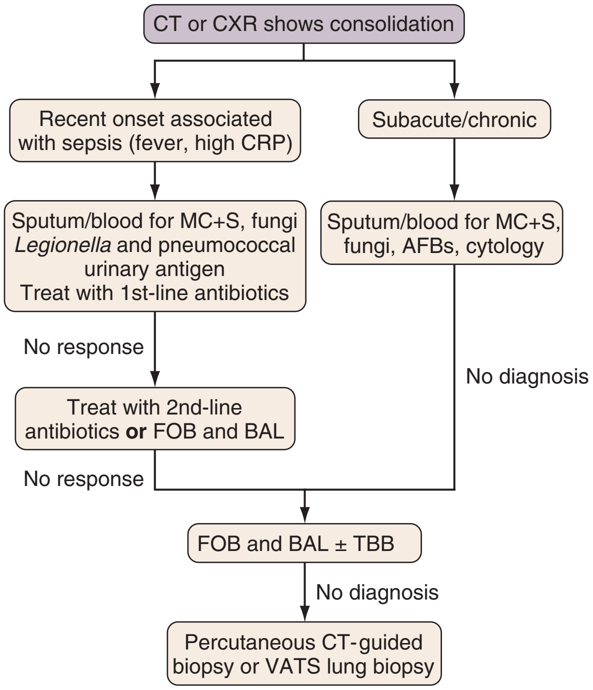
first-line antibiotics. At this point, treatment with second-line antibiotics effective against likely resistant organisms should be started. Consideration also should be given to starting antibiotics that are effective against MRSA and anaerobic pathogens if this has not been done already. In patients at high risk for invasive fungal infection, especially those with CT evidence of associated nodular disease or patchy or infarct-shaped consolidation, failure of first-line therapy warrants testing for fungal antigens (galactomannan or β-D-glucan) and either fiberoptic bronchoscopy (FOB) with BAL or percutaneous CT-guided biopsy (mainly for evaluation of dense consolidation adjacent to the pleura). These investigations also will be necessary in patients whose pneumonia fails to respond to second-line antibiotic therapy or those with subacute or chronic consolidation in whom sputum microbiologic or cytologic testing is nondiagnostic. With progressive disease and lack of a definitive diagnosis after the foregoing tests, surgical biopsy should be seriously considered.



CT or CXR shows consolidation
Recent onset associated with sepsis (fever, high CRP)
Subacute/chronic
Sputum/blood for MC+S, fungi *Legionella* and pneumococcal urinary antigen Treat with 1st-line antibiotics
Sputum/blood for MC+S, fungi, AFBs, cytology
No response
No diagnosis
Treat with 2nd-line antibiotics **or** FOB and BAL
No response
FOB and BAL ± TBB
No diagnosis
Percutaneous CT-guided biopsy or VATS lung biopsy

Figure 28-2 Investigation of consolidation in the immunocompromised patient. *AFBs*, acid-fast bacilli; *BAL*, bronchoalveolar lavage; *CRP*, C-reactive protein; *CT*, computed tomography; *FOB*, fiberoptic bronchoscopy; *MC+S*, microbial culture and sensitivity [testing]; *TBB*, transbronchial biopsy; *VATS*, video-assisted thoracoscopic surgery.

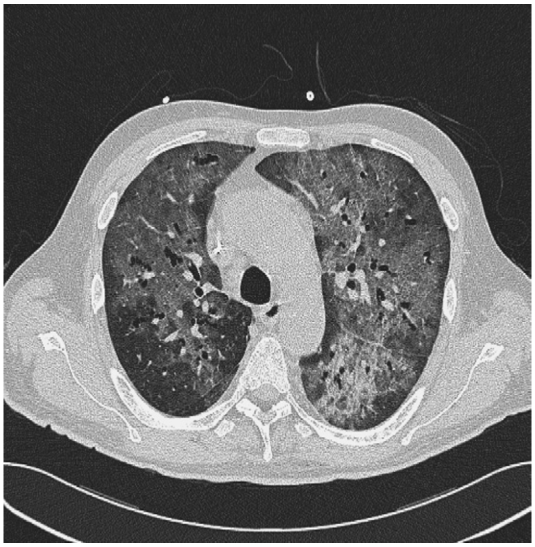


Figure 28-3 Computed tomography (CT) scan of thorax showing widespread bilateral ground glass infiltration in a hematopoietic stem cell transplant recipient. The differential diagnosis for this imaging appearance is broad in scope, including cytomegalovirus pneumonia, *Pneumocystis* pneumonia, drug reactions, and idiopathic pneumonia syndrome, and early invasive investigation typically is required even though with such widespread lung disease the patient is likely to have significant hypoxia.

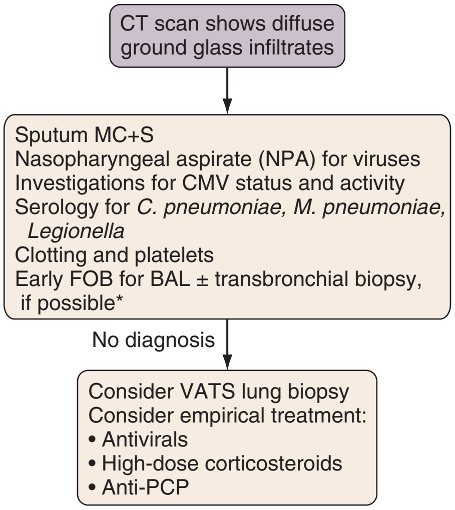

CT scan shows diffuse ground glass infiltrates
Sputum MC+S

Early FOB for BAL ± transbronchial biopsy, if possible*
No diagnosis
Consider VATS lung biopsy
Consider empirical treatment:
• Antivirals
• High-dose corticosteroids
• Anti-PCP

*Significant hypoxia often precludes FOB.

Figure 28-4 Investigation of diffuse ground glass infiltrates in the immunocompromised patient. *BAL*, bronchoalveolar lavage; *CMV*, cytomegalovirus; *FOB*, fiberoptic bronchoscopy; *MC+S*, microbial culture and sensitivity [testing]; *PCP*, *Pneumocystis* pneumonia; *VATS*, video-assisted thoracoscopic surgery.

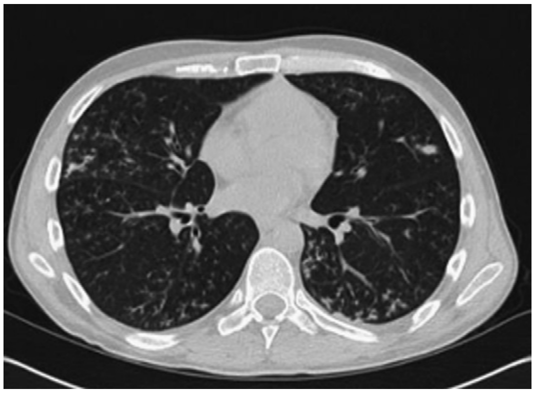

Figure 28-5 Computed tomography (CT) scan showing widespread bilateral "tree-in-bud" changes in a hematopoietic stem cell transplant recipient. This appearance is caused by marked small airway inflammation secondary to respiratory virus infection, bacterial bronchitis (e.g., *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Pseudomonas aeruginosa*, or *Haemophilus influenzae* infection), and, when more focal, *Aspergillus* tracheobronchitis or mycobacterial infection.

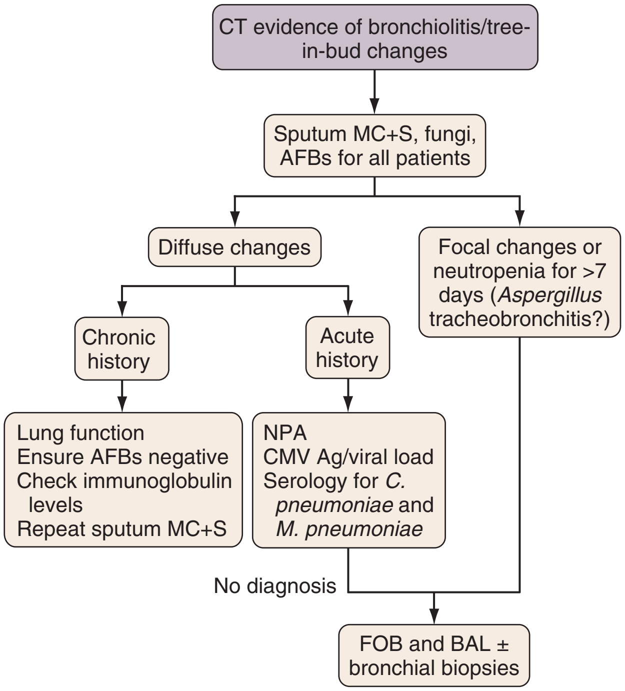
INVESTIGATION OF DIFFUSE GROUND GLASS INFILTRATION

The differential diagnosis for ground glass infiltrates and centrilobular nodules (Figures 28-3 and 28-4) is wide in scope and includes CMV infection, viral pneumonias, PCP, extensive bacterial infection, and noninfective causes such as acute respiratory distress syndrome (ARDS), drug toxicity, and IPS associated with HSCT (see Chapter 77). As a consequence, unless nasopharyngeal aspirate studies identify a respiratory viral infection, early FOB with BAL and, if possible, transbronchial biopsy should be attempted. Often, however, these patients are markedly hypoxic, increasing the risk associated with the procedure. Negative results on FOB do not exclude infective causes, and a decision then needs to be taken about empirical treatment versus VATS lung biopsy. CT-guided biopsy for investigation of diffuse lung disease carries a high risk of complications coupled with low diagnostic yield and therefore is not appropriate in this setting.

INVESTIGATION OF TREE-IN-BUD CHANGES

Tree-in-bud changes (Figures 28-5 and 28-6) suggest small airway pathology, which in immunocompromised patients is



CT evidence of bronchiolitis/tree-in-bud changes
Sputum MC+S, fungi, AFBs for all patients

Serology for *C. pneumoniae* and *M. pneumoniae*
No diagnosis
FOB and BAL ± bronchial biopsies

Figure 28-6 Investigation of "tree-in-bud" pattern associated with bronchiolitis in the immunocompromised patient. *AFBs*, acid-fast bacilli; *BAL*, bronchoalveolar lavage; *CMV*, cytomegalovirus; *CT*, computed tomography; *FOB*, fiberoptic bronchoscopy; *MC+S*, microbial culture and sensitivity [testing].

likely to be caused by respiratory virus infection, *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, or, especially if the changes are focal and associated with nodular changes, *Aspergillus* tracheobronchitis. Subacute or chronic changes also could reflect bacterial infection in bronchiectasis or nontuberculous mycobacteria infection. If results of nasopharyngeal aspirate studies are negative, then early FOB for BAL and bronchial biopsy of macroscopically inflamed bronchial mucosa should be performed. *Aspergillus* tracheobronchitis usually is obvious at FOB and is readily confirmed by culture and cytologic examination of bronchial washings and by bronchial biopsy. Infections due to respiratory viruses, *C. pneumoniae*, and *M. pneumoniae* often are difficult to diagnose but usually are either self-limiting illnesses or readily controlled with macrolide therapy.

INVESTIGATION OF PULMONARY NODULES

Considerations in the differential diagnosis for pulmonary nodules include infection with *Aspergillus* (or other invasive filamentous fungi), *Nocardia*, or mycobacteria (Figure 28-7). *Aspergillus* and *Nocardia* tend to cause a small number of nodules, whereas mycobacteria also can cause large numbers of small nodules. In addition, blood-borne spread of bacteria or *Candida* from infected indwelling devices can cause a variable number (often numerous) of pulmonary nodules. Serum testing for fungal antigens (galactomannan or β-D-glucan) should be performed. Nodules caused by pyogenic bacterial and viral pneumonia tend to be associated with other radiographic changes findings such as ground glass infiltrates or consolidation. The

Percutaneous CT-guided biopsy or VATS lung biopsy

*Neutropenia >7 days, high-dose steroids, GVHD, previous episode invasive aspergillosis. Even with halo or crescent signs present on the CT scan there should be a low threshold for performing BAL to identify the fungal species.

Figure 28-7 Investigation of pulmonary nodules in the immunocompromised patient. *AFBs*, acid-fast bacilli; *BAL*, bronchoalveolar lavage; *CMV*, cytomegalovirus; *CT*, computed tomography; *FOB*, fiberoptic bronchoscopy; *GVHD*, graft-versus-host disease; *MC+S*, microbial culture and sensitivity [testing]; *VATS*, video-assisted thoracoscopic surgery.

other major causes of nodules are underlying malignant disease and lymphoproliferative disorders secondary to prolonged immunosuppression. In the absence of CT signs suggestive of invasive filamentous fungal infection (the halo and crescent signs), nodules in patients with line infections or a positive blood culture may be treated empirically as for metastatic infection. For a majority of other patients with lung nodules, FOB with BAL is necessary, although for patients at high risk for infection with invasive filamentous fungi, if CT changes suggestive of *Aspergillus* infection are present, then empirical antifungal therapy is a reasonable alternative strategy, especially if the result of fungal antigen testing is positive. If FOB findings are unhelpful, the patient should progress to percutaneous CT-guided or VATS lung biopsy, because infections due to fungi, *Nocardia*, or mycobacteria are accompanied by specific histopathologic changes, and biopsy frequently is diagnostic.

BRONCHOSCOPY

Although many immunocompromised patients with pneumonia are hypoxic and have low platelet counts and/or abnormal clotting, FOB generally is safe and has a diagnostic yield of 30 to 50%. Exclusion of active infection is necessary to make a diagnosis of IPS after HSCT, so even a negative result can be useful. In our own experience, peroral FOB can be performed without significant bleeding in patients with a platelet count of 10,000/mL. BAL should be performed in patients with marked hypoxia or severe tachypnea only after careful consideration of risk versus benefit, because the procedure commonly reduces PaO_2 by 20 mm Hg and may precipitate the need for intubation and mechanical ventilation. Transbronchial biopsy improves the diagnostic yield of FOB by perhaps 5% to 10% but often is not possible, because the patient needs to be able to tolerate the potential complication of a pneumothorax and have a platelet count above 50,000/mL.

SPECIFIC CLINICAL ENTITIES

BACTERIAL PNEUMONIA

General Considerations

Pneumonia due to bacterial pathogens is the most common lung infection in the immunocompromised patient, causing about 40% to 50% of infective episodes. The main risk factor is neutropenia, but cell-mediated immune defects and functional defects in phagocyte responses due to cytotoxic or immunosuppressive therapy also will markedly increase the risk for development of pneumonia. Antibody deficiencies associated with lymphoproliferative disorders, myeloma, and HSCT predispose affected patients to development of pneumonia with encapsulated organisms such as *S. pneumoniae* and *Haemophilus influenzae*. Many cases of bacterial pneumonia are nosocomial infections in patients who have been hospitalized for long periods and who previously have been treated with antibiotics so that the normal oropharyngeal flora has been replaced mainly by gram-negative bacteria. As a consequence, the range of potential organisms causing bacterial pneumonia is very different from that seen in community-acquired pneumonia, with a high frequency of resistant organisms such as *P. aeruginosa* and MRSA (see Table 28-1).

Clinical Features and Diagnosis

Bacterial pneumonia often manifests with a clinical picture similar to that seen in immunocompetent patients, with new-onset fever, cough, chest and radiologic signs of lobar consolidation, and a rapid rise in the level of inflammatory markers such as CRP. However, a more insidious or diffuse presentation that is more difficult to differentiate from viral or fungal infection is not uncommon. CT scans showing dense focal consolidation with a lobar distribution are helpful in differentiating bacterial from fungal or viral pneumonia (**Figure 28-8**), and blood cultures will be positive in about 20% of cases. Antigen testing of the urine may identify *Legionella pneumophila* or *S. pneumoniae* infections. Patients with an atypical clinical presentation or those who do not respond to first- or second-line antibiotics should have FOB and BAL, which has a reasonably high diagnostic yield for bacterial pneumonia. Protected specimen brush procedures probably add little information over and above that obtained with directed BAL. Histologic examination is unlikely to reveal specific features, and lung biopsy is mainly used to exclude other causes of lung infiltrates.

Management

Oxygen therapy to maintain a normal PaO_2 is essential and may require continuous positive airway pressure (CPAP) support. Intubation may be necessary if the patient's underlying disease

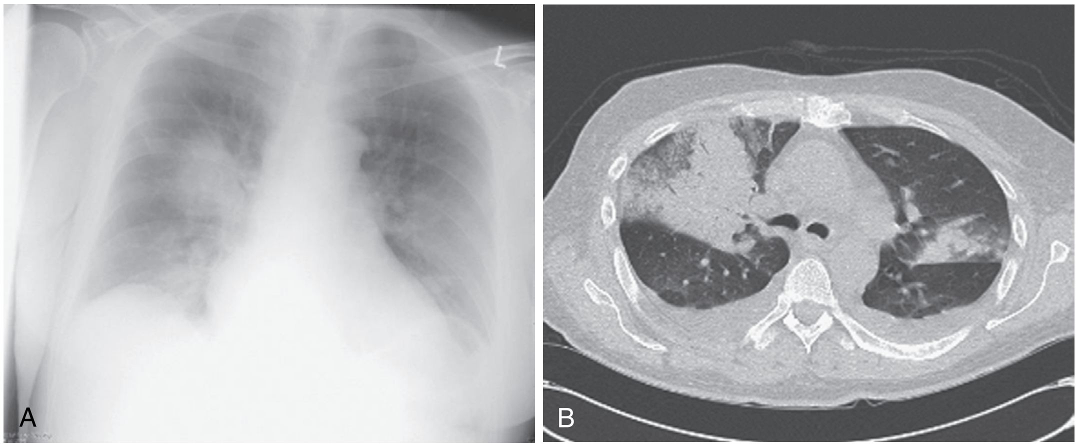

Figure 28-8 **A,** Chest radiograph showing a mass-like consolidation in the right middle lung zone in a patient with acute myeloid leukemia recently treated with chemotherapy and presenting with a high temperature but no respiratory symptoms after 9 days of neutropenia. **B,** Computed tomography (CT) scan of thorax in the same patient, showing that the shadowing is due to dense consolidation in the right upper lobe, with a smaller area of consolidation in the left upper lobe. The blood cultures grew *Escherichia coli*, and the patient improved rapidly on appropriate antibiotics, suggesting that the consolidation was a hospital-acquired pneumonia due to *E. coli.*

does not preclude mechanical ventilation but is associated with a poor prognosis in immunocompromised patients (up to a 95% mortality rate). Initial antibiotic therapy should be effective against the local pattern of hospital-acquired infections and will therefore probably include extended-range beta-lactams, aminoglycosides, or ciprofloxacin. Lack of response within 72 to 96 hours should prompt a switch to another broad-spectrum parenteral antibiotic (e.g., a carbapenem) in case the causative pathogen is resistant to first-line agents. Treatment for infections due to MRSA or other resistant gram-positive organisms also should be considered. Carbapenems and extended-range beta-lactams usually have good efficacy against anaerobic organisms.

Prevention

Antibacterial prophylaxis with a fluoroquinolone (e.g., levofloxacin) often is used during the neutropenic phase after HSCT. Prolonged antibiotic prophylaxis with penicillin V against encapsulated organisms is necessary for patients rendered functionally asplenic by their disease or therapy. Antibiotic prophylaxis also may be indicated in patients with chronic graft-versus-host disease, immunoglobulin deficiencies, and bronchiectasis. Vaccination against *S. pneumoniae* is recommended for all hematopoietic stem cell transplant recipients, and the conjugated vaccine probably should be used because of its stronger immunogenicity. Concern has emerged about the risk of whooping cough in recipients of hematopoietic stem cell transplants, who perhaps should receive vaccination against *Bordetella pertussis* and prophylaxis with azithromycin if exposed to an infected case.

MYCOBACTERIAL INFECTIONS

Mycobacterial infections usually are associated with defects in cell-mediated immunity and tend to develop subacutely. The risk for *Mycobacterium tuberculosis* infection is strongly dependent on the ethnic background and country of origin of the patient. Tuberculosis should be considered in at-risk patients with a cell-mediated immune defect or patchy or nodular lung shadowing, particularly those with a high-risk ethnic background. Nontuberculous mycobacterial infections (e.g., *Mycobacterium kansasii* or *Mycobacterium avium* complex [MAC]) are infrequent complications in immunocompromised patients. Exclusion of the diagnosis by negative culture takes too long to be clinically useful in patients with progressive disease. Therefore, with significant clinical suspicion of mycobacterial infection, invasive investigations are necessary to obtain material for a rapid diagnosis by identification of acid-fast bacilli, specific histopathologic changes, or possibly polymerase chain reaction (PCR) assay for samples obtained from sterile sites. Treatment is with the standard chemotherapy regimens.

NOCARDIAL INFECTIONS

Nocardia are gram-positive aerobic organisms found in soil and stagnant water. They grow relatively slowly as branching filaments. Immunocompromised patients should avoid gardening or occupations that result in exposure to soil and plants. Infection occurs through inhalation, so patients who wish to continue gardening may minimize exposure by wearing protective clothing such as an N-95 mask and gloves. The organisms most commonly causing human infection belong to the *Nocardia asteroides* complex, but other *Nocardia* spp. also can cause disease. Around 2% of lung infections in immunocompromised patients are due to *Nocardia*, and like mycobacterial infections, nocardial infections tend to affect patients with defects in cell-mediated immunity. In hematopoietic stem cell transplant recipients, the median time to onset is approximately 200 days after transplantation. Risk factors for disease also include corticosteroid use, active graft-versus-host disease, and concomitant opportunistic infections, especially with CMV.

Nocardia infection can manifest as a relatively acute pneumonia or as a more indolent disease similar to infection with *Mycobacteria* or *Aspergillus*. Radiologic changes include patches of consolidation, large nodules, often with cavitation, and pleural involvement in up to a third of cases. Hematogenous spread to other organs such as the brain, joints, and soft tissues occurs in up to 50% of patients. Microscopy or histologic examination can make the diagnosis rapidly through identification of characteristic beaded, branching, gram-positive and weakly acid-fast filaments. Respiratory and occasionally blood cultures can be positive but require prolonged aerobic culture. Most *Nocardia* strains are sensitive to co-trimoxazole as well as carbapenems, amikacin, third-generation cephalosporins, tetracyclines, and co-amoxiclav, but treatment needs to be very prolonged, lasting up to 12 months in immunocompromised patients. Mortality is high, reportedly up to 70%.

CYTOMEGALOVIRUS INFECTION

General Considerations

CMV infection is one of the most important complications in patients with defects in cell-mediated immunity such as transplant recipients and patients receiving potent immunosuppressive drugs such as fludarabine or alemtuzumab. CMV is the largest member of the Herpesviridae family of human double-stranded DNA viruses. It has a 230-kb genome that encodes over 200 products, which are expressed during replication in three overlapping phases over 24 hours termed immediate-early, early, and late.

Primary CMV infection is common in the general population, occurring mainly in children or young adults, but usually is asymptomatic or causes only mild disease. Previous infection is identified by serologic studies and leads to asymptomatic latent infection that can be reactivated in immunocompromised persons. Reactivation can be initiated by the cytokine tumor necrosis factor and stress catecholamines, so the virus often will be detected in transplant recipients 3 to 4 weeks after an infective episode involving another pathogen. Around 60% of immunocompromised patients with negative results on serologic testing for CMV who then receive transplants or blood products containing leukocytes from CMV-positive donors will develop CMV infection, which tends to be more severe than disease due to CMV reactivation. CMV-negative immunocompromised patients also can rarely develop primary infection after exposure to someone with active CMV infection.

Clinical Features and Diagnosis

The potential effects of CMV reactivation in immunocompromised patients are varied and include (1) clinically asymptomatic infection, which is common even in immunocompromised patients; (2) a CMV syndrome, defined as fever, a 50% fall in the leukocyte count, and a 2.5-fold increase in transaminases; (3) organ-specific infection, including the liver, central nervous system (CNS), gastrointestinal system, and lungs, often associated with more severe involvement of the transplanted organ; (4) accentuated rejection-related damage to the target organ (e.g., bronchiolitis obliterans in lung transplant recipients);

(5) impaired host immunity with increased incidence of opportunistic infections including pneumonia due to *Aspergillus*, *Pneumocystis jirovecii*, gram-negative bacteria, and *Nocardia*; and (6) increased incidence of EBV-associated lymphoproliferative disease.

CMV pneumonitis commonly manifests with insidious onset of fever, malaise, cough, and dyspnea with hypoxia. The chest radiograph may be normal in appearance or show nonspecific diffuse bilateral infiltrates. CT scan is more sensitive at identifying pulmonary infiltrates and classically shows bibasal symmetric ground glass opacities, septal line thickening, and multiple small centrilobular nodules (Figure 28-9). More asymmetric changes, consolidation, and effusions are not uncommon, however. The main considerations in the differential diagnosis are IPS, drug-induced pneumonitis, and, in patients not receiving effective prophylaxis, PCP. Serologic determination of either IgG or IgM has no place in the diagnosis of CMV disease, because these antibodies merely reflect previous exposure. However, CMV reactivation is nowadays readily detected by identifying significant viremia through either measuring the level of pp65 antigenemia or CMV DNA using PCR assay in the blood. CMV viremia usually is detectable 2 to 5 days before any clinical manifestations. Unfortunately, CMV viremia is not always present in patients with CMV pneumonitis; conversely, evidence of reactivation does not necessarily mean that new lung infiltrates are due to CMV pneumonitis. The chance that CMV infection is responsible for new lung infiltrates is proportional in part to the level of CMV in the blood, especially if the viral load increased rapidly. Definitive confirmation that CMV is causing pneumonia requires identification of CMV in the respiratory tract by FOB for BAL and preferably a transbronchial biopsy, or possibly a VATS lung biopsy. The presence of "owl's eye" intranuclear inclusions on cytologic examination is pathognomonic for CMV infection and although this modality is rapid, it is a relatively insensitive test. CMV can be cultured from respiratory samples using fibroblast cell culture to look for the distinctive cytopathogenic effect, but this takes at least a week and therefore is of little clinical benefit. The main diagnostic techniques for CMV pneumonitis are the relatively sensitive rapid tests for CMV antigens using BAL samples directly, or indirectly by probing cell cultures inoculated with the samples after 24 to 48 hours incubation (the shell vial or early antigen detection assays). Quantitative PCR assay on BAL fluid has been used to improve the predictive value for the diagnosis of CMV pneumonitis but requires further investigation. Despite this range of diagnostic techniques, a well-validated standard for identifying CMV pneumonitis is lacking, except for VATS biopsy.

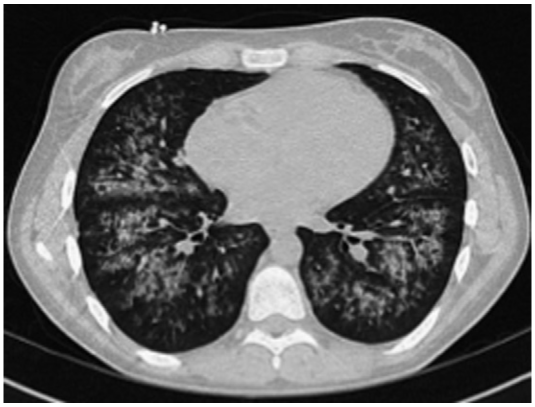

Figure 28-9 Computed tomography (CT) scan of thorax showing changes due to cytomegalovirus pneumonitis in a patient who had undergone hematopoietic stem cell transplantation for lymphoma 3 months previously.

Treatment

The currently available antiviral agents for treatment of CMV infection and disease are acyclovir, valacyclovir, ganciclovir, valganciclovir, foscarnet, and cidofovir (Table 28-4). A regimen based on the purine analogue ganciclovir is the preferred treatment; this agent, once phosphorylated within infected cells, competitively inhibits viral DNA polymerase. Ganciclovir has significant marrow-depressant effects and may be too toxic for use in hematopoietic stem cell transplant recipients or in patients with existing pancytopenia. Oral absorption is poor, but oral therapy with the valine ester valganciclovir has excellent bioavailability. The second-line agent foscarnet also inhibits the activity of viral DNA polymerase (by binding to the pyrophosphate-binding site). Foscarnet frequently causes significant renal toxicity. Alternatively, cidofovir has a broad activity against DNA viruses including CMV, acting as a competitive inhibitor of viral DNA polymerases. Cidofovir causes both myelosuppression and renal toxicity, and patients should be prehydrated and given probeniced before initiation of treatment. Patients with CMV disease also are frequently given hyperimmune intravenous immunoglobulin (IVIG) as passive vaccination therapy. Very few studies have compared these drugs for efficacy in CMV pneumonia. Treatment lasts from 14 to 21 days and should be guided by blood tests measuring the level of CMV viremia. Patients at risk for such infection often are given antiviral prophylaxis such as with valganciclovir. The mortality rate for established CMV pneumonia is up to 50% in hematopoietic stem cell transplant recipients but is less in other types of immunocompromised patients. Detection of CMV viremia frequently leads to preemptive therapy before symptomatic CMV infection develops, increasing the numbers of patients requiring treatment but improving overall outcome.

LUNG INFECTIONS DUE TO OTHER HERPESVIRUSES

Herpes simplex virus (HSV) and varicella-zoster virus (VZV) are rare causes of lung infection in immunocompromised patients, with a presentation similar to that for CMV pneumonia, but patients also may have the characteristic skin involvement. Microbiologic diagnosis relies on isolation of the virus from skin lesions or BAL fluid, and treatment is with high-dose acyclovir. Human herpesvirus type 6 (HHV6) may be an important pathogen causing infection after HSCT. Patients with HHV6 viremia have more CMV reactivation and unexplained fever and rash compared with patients without HHV6 viremia, and high-level HHV6 viremia (up to 25,000 copies/mL) has been associated with culture-negative pneumonitis.

INFECTIONS WITH RESPIRATORY VIRUSES

General Considerations

Lower respiratory tract infections with respiratory viruses are relatively common in immunocompromised patients. The common relevant viruses are respiratory syncytial virus (RSV), parainfluenza virus (PIV) (90% serotype III), influenza A virus, adenovirus, human metapneumovirus, coronavirus, and possibly rhinovirus. Infection is acquired by inhalation of infected respiratory droplets from other infected patients or mildly affected immunocompetent contacts. Consequently, immunocompromised patients should avoid contact with social

Table 28-4 Treatment Options for Viral Lung Infections

Treatment	Dose	Mode of Action	Viruses	Role/General Comments
Ganciclovir	2.5-5 mg/kg IV 2-3×/day	Inhibitor of viral DNA polymerase	CMV, HSV, HHV6	First-line agent; myelosuppressive; good efficacy
Valganciclovir	900 mg PO 1-2×/day	Prodrug of ganciclovir	CMV, HSV, HHV6	Better oral availability than ganciclovir
Foscarnet	60 mg/kg IV 3×/day	Inhibitor of viral DNA polymerase	CMV	Second-line agent; good efficacy; nephrotoxic
Acyclovir	10-15 mg/kg IV 3×/day	Inhibitor of viral DNA polymerase	HSV, VZV, HHV-6	Toxicity relatively uncommon
Cidofovir	1-5 mg/kg IV once weekly	Inhibitor of viral DNA polymerase	Adenovirus Possibly CMV	Third-line agent for CMV infection; efficacy against adenovirus unclear; nephrotoxic
Ribavarin	0.8 mg/kg inhaled	Nucleoside analogue	RSV, PIV, influenza virus, adenovirus, human metapneumovirus	Questionable benefit; nebulizer requires a scavenger tent because of potential toxicity; given over 12 to 18 hours
IVIG	E.g., 500 mg once daily	Passive vaccination	CMV, RSV	Combination treatment with antiviral agent
Palivizumab	15 mg/kg IV	Humanized anti-RSV monoclonal antibody	RSV	Efficacy unclear; used in combination with ribavarin
Amantidine	100 mg PO 2×/day	M2 inhibitor	Influenza A virus	Efficacy unclear; lowers incidence of progression to pneumonia?
Zanamivir	10 mg inhaled 2×/day	Neuraminidase inhibitor	Influenza virus	Probably reasonable efficacy
Oseltamivir	75 mg PO 2×/day	Neuraminidase inhibitor	Influenza virus	Probably reasonable efficacy

CMV, cytomegalovirus; *HHV-6*, human herpesvirus-6; *HSV*, herpes simplex virus; *PIV*, parainfluenza virus; *RSV*, respiratory syncytial virus; *VZV*, varicella-zoster virus.

contacts or members of the hospital staff clearly suffering from upper respiratory tract infections. Nosocomial epidemics of respiratory viruses readily occur, so infected patients should be effectively isolated. Respiratory viral infections are associated with defects in cell-mediated immunity and generally are a late complication after HSCT.

Clinical Features and Diagnosis

Respiratory virus lung infections often cause a bronchiolitis, manifesting with cough, fever, wheeze, and inspiratory squeaks. They frequently are preceded by a few days of coryzal symptoms. The chest radiograph may be normal in appearance, but a CT scan will show evidence of small airway involvement, with widespread tree-in-bud changes (Figure 28-10). The main considerations in the differential diagnosis in this clinical scenario are *Chlamydia* or *Mycoplasma* infection, extensive bacterial bronchitis (usually associated with bronchiectasis), and possibly *Aspergillus* tracheobronchitis. With more severe disease associated with significant pneumonitis, CT evidence will include small, poorly defined centrilobular nodules and usually bilateral patchy areas of peribronchial ground glass opacity and consolidation. The differential diagnosis in such cases is much broader in scope, including bacterial pneumonia, CMV pneumonitis, PCP, and noninfective causes of pneumonitis. In many patients, the diagnosis of respiratory viral infection can be rapidly confirmed by noninvasive testing using nasopharyngeal aspirate samples for either immunofluorescence for viral antigens or PCR assay for viral nucleic acids. A negative result on nasopharyngeal aspirate studies should lead to FOB, because these tests are more sensitive with BAL fluid than with nasopharyngeal aspirate samples. Respiratory viral infections in immunocompromised patients are often very prolonged but not too severe, with symptoms and positive results on nasopharyngeal aspirate studies persisting for several weeks.

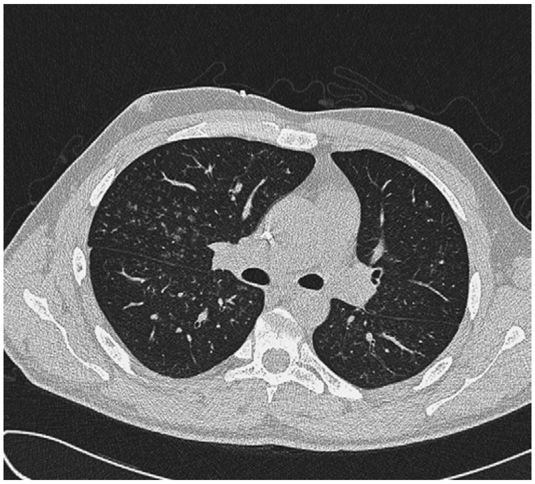

Figure 28-10 Computed tomography (CT) scan showing "tree-in-bud" changes (most obvious in the right upper lobe) due to PIV serotype 3 bronchiolitis in a patient with relapsed acute myeloid leukemia who had completed chemotherapy 25 days previously and presented with coryzal symptoms, cough, and a mild fever. *PIV*, parainfluenza virus.

Treatment and Special Considerations with Specific Viruses

With the exception of influenza, treatment options for respiratory viruses are limited and depend on the underlying virus (see Table 28-4). In the absence of pneumonia, the mortality associated with respiratory virus infection in immunocompromised patients is relatively low, and patients can be given supportive therapy only. By contrast, pneumonia due to respiratory viruses after HSCT is associated with significant mortality (up to 40%). Secondary infections are common, and patients frequently need concurrent treatment with antibiotics.

Influenza Viruses Infection after HSCT with influenza viruses is perhaps surprisingly less common than infection with RSV and PIV. First-line therapy is with neuraminidase inhibitors (zanamivir or oseltamivir), which do seem to be effective at limiting disease severity and duration. An alternative agent for treatment of influenza virus infection is amantidine, but its efficacy is not clear. Transplant recipients (and their family members or household contacts) should receive lifelong seasonal influenza vaccination with the trivalent inactivated vaccine. If an outbreak occurs with a nonvaccine influenza strain, chemoprophylaxis with zanamivir or oseltamivir should be considered.

Parainfluenza Virus Although infection with PIV probably is among the most common causes of respiratory viral infection after HSCT, currently data on effective treatments are scarce. Ribavarin and IVIG may have activity against PIV infection but have not yet been shown to be beneficial in clinical practice. No useful vaccine is generally available as yet.

Respiratory Syncytial Virus Hematopoietic stem cell transplant recipients, particularly those who are pre-engraftment and lymphopenic or those who have preexisting obstructive airway disease, are at highest risk for severe RSV pneumonia. Therapies for RSV infection include systemic or aerosolized ribavirin, passive immunization with high-RSV-titer immunoglobulin, and monoclonal antibody directed at the RSV F antigen (palivizumab). No randomized trial has been completed to test the efficacy of these strategies, and efficacy data are limited. Some centers provide monthly palivizumab prophylaxis for hematopoietic stem cell transplant recipients during the RSV season (November to April in the Northern Hemisphere), particularly for pediatric recipients. Preemptive aerosolized ribavirin may be effective in those transplant recipients with lymphopenia and preexisting impaired lung function who develop RSV upper respiratory tract infection before the emergence of evidence that the infection has spread to the lungs.

Human Metapneumovirus Human metapneumovirus (hMPV) is a relatively recently identified RNA paramyxovirus related to RSV. It has been increasingly associated with lower respiratory tract infection and pneumonia in hematopoietic stem cell transplant recipients, with mortality rates of up to 50%. IVIG and ribavirin have in vitro activity against hMPV, but no recommendations on treatment are currently available owing to lack of data.

Adenovirus Adenovirus infections can occur in patients with impaired cell-mediated immunity due to reactivation or de novo acquisition. Many different adenovirus serotypes exist, so pretransplant serology is not helpful. In HSCT, the risk of adenovirus infection is increased for allograft recipients, after T cell depletion or treatment with antithymocyte globulin (alemtuzumab), and for patients with graft-versus-host disease receiving systemic steroids. Clearance of adenovirus has been shown to be associated with recovery of adenovirus-specific T cell immunity. Few antiviral agents have in vivo activity against adenoviruses, and no randomized, placebo-controlled study of antiviral drug therapy for adenoviral infection has been performed. The available data suggest that cidofovir or ribavirin may have some efficacy.

Respiratory Viruses and Lung Allograft Syndromes

Respiratory viral infection early after hematopoietic cell transplantation can be a predictor for the development of alloimmune lung syndromes such as progressive airways obstruction due to bronchiolitis obliterans, perhaps as they sensitize the respiratory epithelium for lung involvement by graft-versus-host disease. Clinically, patients will present with rapidly progressive airway obstruction in the context of active respiratory viral infection and will require aggressive immunosuppression to prevent progression to respiratory failure.

INVASIVE ASPERGILLOSIS

General Considerations

Invasive infections with *Aspergillus* constitute a common and important cause of lung infection in immunodeficient patients. *Aspergillus* organisms are saprophytic filamentous fungi that are found ubiquitously in the environment. They propagate by dispersal of airborne spores, which are 2 to 3 μm in diameter and can therefore reach the distal airway. Exposure to airborne spores is essentially continuous, but this rarely causes a clinical problem unless the host's immune response is impaired. In a patient with impaired macrophage or neutrophil function, however, the spores can germinate and form a colony of branching multicellular hyphae that gradually expands and penetrates through host tissue, causing invasive pulmonary aspergillosis (IPA). The usual site of infection is the respiratory tract, including the sinuses, but blood-borne spread to internal organs (especially the CNS), bone, and skin is common. The most frequently isolated species causing infection are *A. fumigatus* (66% of cases), *Aspergillus flavus* (14%), *Aspergillus niger* (7%), and *Aspergillus terreus* (4%).

Clinical Features

IPA is mainly a disease that affects patients with hematologic malignancies receiving chemotherapy, persons with aplastic anemia, or transplant recipients in the early phase after HSCT. Significant persistent neutropenia is the strongest risk factor, with the incidence proportional to the depth and duration of neutropenia, so that more than 50% of patients with neutropenia lasting for over 4 weeks will develop IPA. Patients at high risk also include those receiving high-dose systemic corticosteroid therapy and/or have graft-versus-host disease (causing IPA in the late phase after HSCT), lung and liver transplant recipients, and patients with inherited disorders of phagocyte function such as chronic granulomatous disease (CGD), in which mutations in genes encoding the NADPH oxidase system impair the phagocyte oxidative burst. Various genetic polymorphisms affecting Toll-like receptors (TLRs) and cytokines seem to modify the risk of invasive aspergillosis for patients in the above risk groups.

The speed of development of IPA is proportional to the level of immunosuppression, but the disease usually evolves relatively slowly over days and weeks. Fever may be the only symptom of IPA, although cough, pleuritic chest pain, and hemoptysis are common. Chest radiographs show expanding patches of irregular consolidation (often infarct shaped) or nodules that can cavitate. CT scans are very helpful, because they will define the nodular nature of infiltrates, may show specific signs associated with IPA, and can identify the lung as

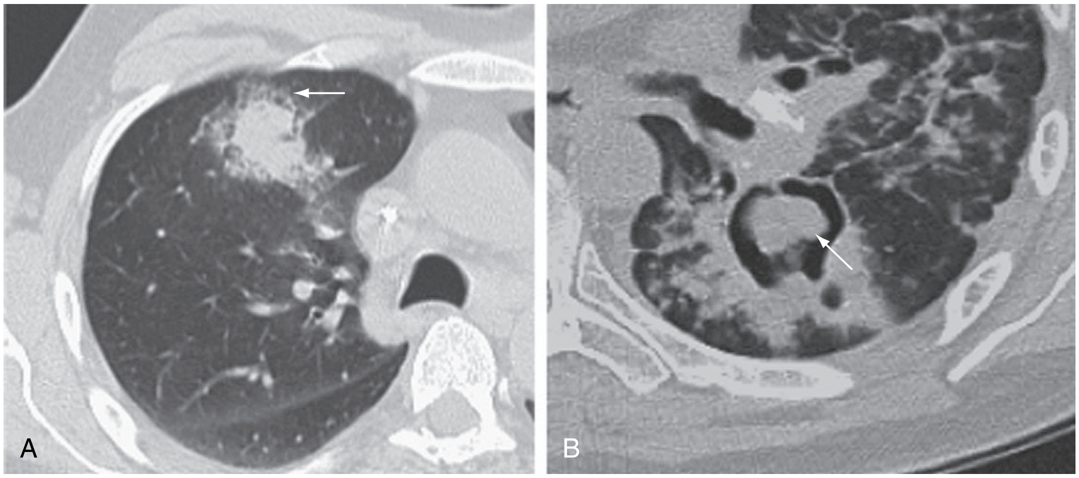

Figure 28-11 **A,** Computed tomography (CT) scan showing a nodule surrounded by an area of lower attenuation ground glass infiltration (the halo sign, indicated by the *white arrow*) suggestive of invasive aspergillosis. **B,** CT scan showing an area of invasive aspergillosis that has cavitated. Within the cavity, a mycetoma (*white arrow*) is evident.

the source of infection in patients with pyrexia and a normal chest radiograph. Specific CT appearances for IPA include the *halo sign*, an area of lower attenuation shadowing around a nodule or patch of consolidation reported in 50% of cases of IPA and usually occurring in the first week of infection (**Figure 28-11**); the *air crescent sign*, a partial cavity formed by infarcted necrotic lung, which is a very specific but later-onset sign occurring around the third week of infection; and an *intrapulmonary cavity containing a fungal ball*, especially associated with recovery of the patient's neutrophil count (see Figure 28-11). The halo sign may be detected in other infections, with neoplasms (adenocarcinoma, bronchoalveolar carcinoma, Kaposi sarcoma, and metastases), and in vasculitis. *Aspergillus* has a predilection for growing into blood vessels, and patients with IPA may suffer fatal massive hemorrhage. Other manifestations of invasive *Aspergillus* infections affecting the lung include *Aspergillus* tracheobronchitis, chronic necrotizing pulmonary aspergillosis (CNPA), and chronic cavitary pulmonary aspergillosis (CCPA).

With *Aspergillus* tracheobronchitis, infection is restricted to the tracheobronchial tree and manifests with a severe unremitting cough and pyrexia. CT scans may show focal areas of bronchial wall thickening and tree-in-bud small airway disease (**Figure 28-12**). FOB usually is diagnostic, with a distinctive macroscopic appearance of patchy, highly inflamed mucosa with necrotic white slough. *Aspergillus* can be found in cultures and/or cytology of bronchial washings, and there may be evidence of fungal invasion of the respiratory mucosa in bronchial biopsy specimens.

The more indolent forms of invasive aspergillosis such as CCPA or CNPA are increasing in incidence and are associated with milder degrees of immunosuppression, including steroid and cytotoxic therapies, chronic lung disease or cystic fibrosis. Affected patients present with a long history of cough and marked systemic symptoms of malaise, fatigue, and weight loss. On chest radiographs, CNPA manifests as an indolent patch of consolidation with or without cavitation that progresses over weeks or months (**Figure 28-13**), whereas CCPA manifests with an expanding upper lobe dry cavity with a thickened and irregular wall. There may be associated pleural thickening. *Aspergillus* infection also can cause a progressive upper lobe fibrosis.

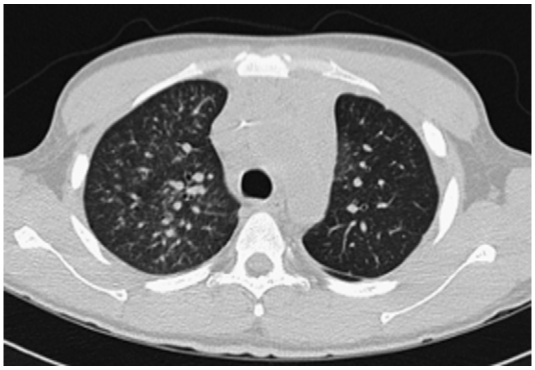

Figure 28-12 Computed tomography (CT) scan of thorax in a patient with acute lymphocytic leukemia treated with chemotherapy who presented with persistent cough and fever. The scan shows asymmetric "tree-in-bud" and nodular changes mainly affecting the right upper lobe, which were caused by *Aspergillus* tracheobronchitis.

Microbiologic Diagnosis

Investigations that can be helpful in making the diagnosis of IPA are described in **Table 28-5**. In high-risk patients with a compatible clinical syndrome and CT findings highly suggestive of IPA (halo and crescent signs), the diagnosis can be made clinically and may not require confirmation by invasive investigations. However, some *Aspergillus* species (e.g., *A. terreus*) are resistant to amphotericin B, and a clinical presentation similar to that in IPA can be caused by rarer filamentous fungi with drug sensitivities that differ from those demonstrated for *Aspergillus*. Hence, microbiologic confirmation is reassuring, because it ensures that appropriate treatment is given. A microbiologic diagnosis of IPA can be made by culture, cytologic, or histologic appearances in BAL or lung biopsy specimens, or by the detection of fungal cell wall antigen (galactomannan or β-D-glucan) or DNA (by PCR assay) in blood or BAL fluid. Isolation of *Aspergillus* from BAL in a high-risk immunodeficient patient is highly predictive of IPA but is relatively insensitive, identifying only 50% of cases of IPA. Culture from sputum is even less sensitive, and blood cultures are only rarely positive. Percutaneous CT-guided or VATS biopsy is highly sensitive, because

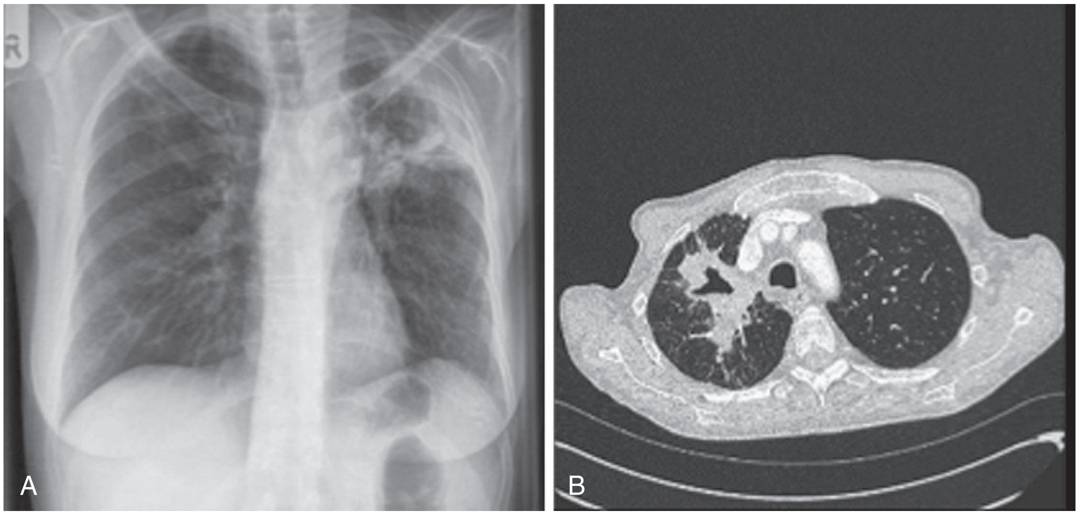

Figure 28-13 Slowly invasive aspergillosis in patients without severe immunosuppression. **A,** Chest radiograph showing a large irregular cavity in the left upper lobe with marked pleural thickening on a background of chronic obstructive pulmonary disease; the diagnosis was chronic cavitary pulmonary aspergillosis (CCPA), confirmed by surgical resection. **B,** Computed tomography (CT) scan showing a thick-walled dry cavity due to chronic necrotizing pulmonary aspergillosis (CNPA) in a patient with long-standing rheumatoid arthritis that was treated with a variety of immunosuppressive therapies. The diagnosis was confirmed by histologic identification of *Aspergillus* hyphae invading lung tissue in a biopsy sample obtained at video-assisted thoracoscopic surgery.

Table 28-5 Types and Roles of Diagnostic Tests for Invasive Aspergillosis

Test	Sample	Time Needed	Method	Role and General Comments
Culture	Sputum, BAL fluid, CSF, biopsy specimen	2-4 days	Culture on fungal media	Low sensitivity (50% for BAL) and does not necessarily improve invasive disease (can be colonizing the respiratory tract)
Cytologic examination	BAL fluid, biopsy specimen	6 hours	Microscopy for fungal elements	May not distinguish between fungal species
Histologic examination	Biopsy specimen	24-48 hours	Visualization of dichotomous branching septate hyphae	Fungal stains necessary; may not distinguish between fungal species
Antigen testing	Serum, BAL fluid	6 hours	Galactomannan detection	Cell wall antigen for *Aspergillus* and *Penicillium* spp.; sensitive; false positives occur
Antigen testing	Serum, BAL fluid	6 hours	β-D-Glucan detection	Cell wall antigen for *Candida*, *Aspergillus*, *Penicillium*, and *Pneumocystis* spp.; sensitive; false positives occur
PCR assay	Blood, BAL fluid	24 hours	Amplification of target DNA	Role not yet established, probably highly sensitive
CT appearance	—	Instant	Identification of halo or crescent sign, intracavitary mycetomas	Specific for invasive filamentous fungal infection but does not identify fungal species

BAL, bronchoalveolar lavage; *CSF*, cerebrospinal fluid; *CT*, computed tomography; *PCR*, polymerase chain reaction.

histopathologic examination of the sample can readily identify fungal hyphae infiltrating through lung tissue if fungal stains are used. Hence, strong consideration should be given to biopsy of lung nodules not responding to conventional antibacterial antibiotics, especially if BAL was nondiagnostic. To decrease mortality by allowing rapid identification of cases of IPA before the fungal load is high, several noninvasive tests have been developed. These include detection of galactomannan or β-D-glucan cell wall antigen in the blood (or BAL fluid if FOB has been performed), or PCR assay for *Aspergillus* DNA from the blood or BAL fluid. These tests are highly sensitive and when used as surveillance in high-risk patients could lead to preemptive antifungal therapy before clinically apparent disease has developed, leading to an improved mortality. However, detection of fungal DNA in a single sample of peripheral blood is a poor indicator of early invasive fungal infection, and galactomannan antigen is not specific for *Aspergillus* spp., frequently giving false-positive results (especially in patients treated with piperacillin-tazobactam or in young children). Despite these caveats, a negative galactomannan assay result makes active IPA infection unlikely. Serologic tests for antibodies to *Aspergillus* usually yield negative results in immunocompromised patients with IPA.

Diagnosing chronic forms of IPA in less immunocompromised patients often is difficult owing to lack of sensitivity of culture and the lack of data on the predictive values for antigen testing. CT-guided or VATS biopsy frequently is necessary to exclude malignancy and to confirm fungal invasion of lung tissue. *Aspergillus* IgG levels usually are raised in patients with CCPA, but not necessarily so in those with CNPA.

Treatment

The treatment options for invasive aspergillosis have been considerably improved by the introduction of new azoles, voriconazole and more recently posaconazole, and a new class of antifungal agents, the echinocandins, the first example of which is caspofungin. Doses, modes of action, and common toxicities for the different treatment options are given in Table 28-6. Voriconazole may be more effective than amphotericin B for treating IPA, but which drug is used depends on the patient's tolerance for that agent and any preexisting medical conditions (e.g., amphotericin B should be avoided in patients with renal problems, and azoles in patients with liver disease). Itraconazole is less efficacious and should be reserved for oral treatment in patients recovering from IPA after induction treatment with amphotericin B, caspofungin, or voriconazole or for the long-term treatment required for chronic forms of invasive aspergillosis. Drug levels probably should be monitored for patients receiving itraconazole, voriconazole, and posaconazole, at least for patients on prolonged therapy. The role of combination therapy remains unclear, but this strategy is potentially attractive in view of different mechanisms of action for the three effective classes of drugs. Urgent surgical resection should be considered in patients with major hemoptysis, because fatal bleeding is not uncommon. Elective resection can be used as primary therapy for single lesions due to IPA, especially those containing an intracavitary mycetoma that might lead to reactivation of IPA during subsequent immunosuppression. Treatment of IPA for several weeks often is necessary, followed by prophylactic therapy in cases with persisting radiologic changes. Treatment of CNPA and CCPA will need to be continued for months if not years (and even lifelong). Owing to a combination of uncontrolled infection and the underlying disease, the mortality rate for IPA is around 50%, and with chronic forms of aspergillosis, the infection rate remains as high as 33%. Azoles can be used for prophylaxis in at-risk groups, including hematopoietic stem cell transplant recipients. Fluconazole is not effective at preventing mold infections such as IPA, and despite its efficacy against *Aspergillus*, voriconazole seems to offer no clinical benefit over prophylaxis with fluconazole. However, prophylaxis with the newer extended-spectrum triazole posaconazole reduced the incidence of invasive aspergillosis in patients with prolonged neutropenia, from 7% to 1%. Acquired resistance of *A. fumigatus* to posaconazole has emerged during the course of therapy, which may potentially limit its use for prophylaxis.

OTHER FUNGAL INFECTIONS

Infections Due to Non-*Aspergillus* Filamentous Fungi

Although *Aspergillus* spp. dominate infections due to molds, other filamentous fungi can cause invasive pulmonary infections in immunocompromised patients, including *Fusarium*, *Zygomycetes*, *Scedosporium*, and *Penicillium*. These infections often are clinically similar to invasive aspergillosis but have a different spectrum of susceptibilities to antifungal agents. Hence, non-*Aspergillus* filamentous fungal infection needs to be considered in patients with a clinical diagnosis of IPA who are not responding to antifungal therapy. Diagnosis is made by culture from respiratory samples or lung biopsy, and mortality is very high. Galactomannan and β-D-glucan cell wall antigen test results are negative in patients infected with zygomycetes. Treatment is with surgical débridement combined with amphotericin and, for infections due to *Fusarium* and *Scedosporium* but not zygomycetes, voriconazole or posaconazole.

Infections Due to *Candida* Spp.

Infection with *Candida* rarely manifests as a pneumonia, but candidemia may lead to metastatic lung infection that causes

Table 28-6 Treatment Options for Invasive Aspergillosis

Treatment	Dose	Mode of Action	Role and General Comments	Toxicity
Amphotericin B	1-1.5 mg/kg IV once daily	Binds to ergosterol in the fungal cell membrane	Effective; cheap; withdrawn in a third of patients due to toxicity	Fever and chills; phlebitis; hypokalemia, hypomagnesemia; uremia; bronchospasm; gastrointestinal disturbance; muscle pain
Lipid formulations of amphotericin B	1-5 mg/kg per day IV	As above	Expensive; much improved toxicity profile	As above (much lower incidence)
Itraconazole	200 mg once daily or 2-3×/day IV or PO	Inhibits ergosterol biosynthesis	Poor efficacy in acute IPA; poor absorbance (check levels)	Gastrointestinal disturbance; elevated hepatic transaminases; fluid retention; neuropathy
Voriconazole	6 mg/kg 2× on day 1; then 4 mg/kg IV once daily 200 mg PO 2×/day	Inhibits ergosterol biosynthesis	Effective; expensive; good absorption	Elevated hepatic transaminases; visual and CNS disturbances
Posaconazole	200 mg 3×/day PO (no intravenous formulation)	Inhibits ergosterol biosynthesis	Effective; expensive; good absorption	Elevated hepatic transaminases; paresthesia; tremor; visual disturbances Availability maximized with fatty food
Caspofungin	70 mg loading dose; 50 mg IV once daily	Inhibits fungal cell wall synthesis	Expensive; effective	Generally well tolerated; flushing; gastrointestinal disturbance
Surgery	—	—	For life-threatening hemoptysis or removal of single lesions	Pleural dissemination of *Aspergillus* as well as the usual postoperative complications

CNS, central nervous system; *IPA*, invasive pulmonary aspergillosis.

pyrexia and is associated with radiologic evidence of lung nodules that often are peripheral in location and sometimes very large. Neutropenic patients with mucositis or indwelling lines are at risk for invasive candidemia, which usually is caused by dissemination of endogenous colonizing *Candida* spp. The frequent use of fluconazole for prophylaxis has led to increasing isolation of non-*albicans* species such as *Candida glabrata* and *Candida parapsilosis*. Treatment is with caspofungin, amphotericin, voriconazole, or posaconazole.

Infections Due to *Cryptococcus* and Endemic Fungi

Cryptococcus neoformans infections are acquired by inhalation of the fungal spores. Although respiratory infection often is asymptomatic, cryptococcal disease can cause multifocal consolidation and severe pneumonia in patients with defects in cell-mediated immunity and carries a mortality rate of 30%. The diagnosis is made by microscopic identification or culture of *C. neoformans* from respiratory tract samples. Treatment is with intravenous amphotericin B in combination with flucytosine, followed by oral fluconazole. Reactivation of latent infection with endemic fungi such as *Histoplasma* and *Coccidioides* should be considered in patients with defects in cell-mediated immunity presenting with multifocal lung shadowing who have lived in relevant geographic areas, especially if there is evidence of extrapulmonary involvement. Diagnosis generally requires identification of the fungus in tissues samples.

Pneumocystis jirovecii Infection

In addition to its close association with HIV infection, PCP is an important type of pneumonia in non–HIV-infected immunocompromised patients with defects in cell-mediated immunity or who are receiving systemic corticosteroid therapy equivalent to greater than 20 mg daily of prednisolone. The clinical presentation generally is insidious in onset, with cough and progressive dyspnea developing over weeks, but can be more fulminant. Impaired gas transfer and hypoxia on exertion with progression to respiratory failure are common. The chest radiograph usually shows bilateral infiltrates but may be normal in appearance. Generally the CT scan will show ground glass infiltrates, which classically mainly affect the upper lobes and spare the lung peripheries (Figure 28-14). On rare occasions, however, even the CT scan may show only minimal abnormalities. The diagnosis is made by recognition of the clinical picture in an at-risk patient and should be confirmed by cytologic identification of the characteristic *P. jirovecii* cysts in BAL fluid. Diagnosis can be improved using immunohistochemistry assay for *Pneumocystis* antigens, and perhaps by PCR analysis, although the latter will have a significant false-positive rate as a consequence of colonization in the absence of disease.

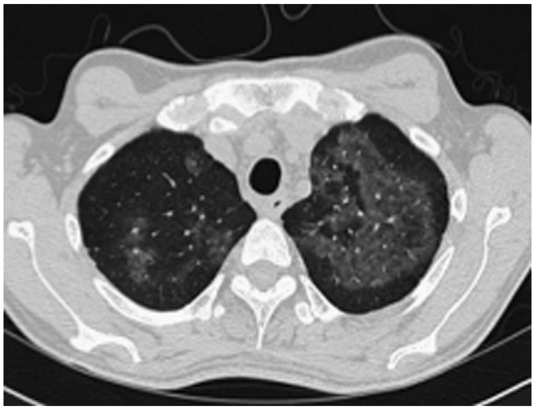

Figure 28-14 Computed tomography (CT) scan showing an upper lobe ground glass infiltrate with peripheral sparing. This pattern is highly suggestive of *Pneumocystis* pneumonia in patients with a defect in cell-mediated immunity.

First-line treatment is with high-dose co-trimoxazole and adjuvant steroids given according to the protocols used for PCP in HIV-infected patients. Myelosuppression due to co-trimoxazole means that many patients with hematologic disorders have to switch to second-line therapy with clindamycin and primaquine. In non-HIV immunocompromised patients, PCP is associated with intubation and mortality rates of around 30% each. PCP prophylaxis usually is prescribed for several months after allograft HSCT or organ transplantation, and occasionally longer in patients who continue to receive immunosuppressive drugs. Patients recovering from PCP should continue on chemoprophylaxis until their immunosuppression is resolved, although there are no clear parameters for defining this endpoint. Consensus is lacking on the requirement for PCP prophylaxis after autograft HSCT and for severe non–transplantation-related immunosuppression. Cotrimoxazole prophylaxis given either daily or three times per week is very effective (greater than 90% efficacy) and provides some protection against other pathogens, including *Toxoplasma*, *Nocardia*, and bacteria.

CONTROVERSIES AND PITFALLS

- Exactly when bronchoscopy should be used for diagnosing respiratory infections in immunocompromised patients remains controversial, with no clear consensus on early versus late bronchoscopy. The approach described in this chapter based on the type of lung shadowing aims to target bronchoscopy to the patients for whom it may be most helpful.
- CMV pneumonitis is an especially difficult diagnosis to confirm; the specific diagnostic tests often are inconclusive, and the clinician is left with presumptive evidence of involvement of CMV consisting of the combination of a pneumonitis with blood test results indicating reactivation of the virus.
- A major pitfall to avoid is failure to consider noninfective causes of respiratory problems in the non-HIV-infected immunocompromised patient; pulmonary edema, alveolar hemorrhage, ARDS, drug-related or idiopathic pneumonitis, and rapidly progressive airway obstruction due to lung graft-versus-host disease (often precipitated by respiratory viral infections) often need to be included in the differential diagnosis.
- Although most infective causes of lung problems in the non–HIV-infected immunocompromised patient generally have fairly characteristic presentations and affect selected risk groups, considerable overlap between clinical presentations for illnesses due to specific infectious agents is typical. This is especially true for the more severely immunosuppressed patient, in whom the usual clinical presentations become less characteristic.
- Finally, the clinician needs to remember that non–HIV-infected immunocompromised patients often have two simultaneous pathologic conditions (e.g., a bacterial pneumonia complicated by ARDS, or a respiratory viral infection with lung graft-versus-host disease).

EPIDEMIOLOGY, RISK FACTORS, AND PATHOPHYSIOLOGY

HUMAN IMMUNODEFICIENCY VIRUS INFECTION: BACKGROUND

It is now more than 30 years since the first report from Los Angeles, in the United States, of an “outbreak” of *Pneumocystis* pneumonia (PCP) among homosexual men that heralded the onset of the global human immunodeficiency virus (HIV) pandemic. Since the early 1980s, HIV infection has steadily spread throughout the world and caused an estimated 25 million deaths. At the end of 2009, according to the United Nations Program on HIV/AIDS (UNAIDS), 33.3 million people worldwide were HIV-infected, a majority of these living in resource-poor countries. In 2008, the Centers for Disease Control and Prevention (CDC) reported that in the United States, 1,178,350 persons 13 years of age or older were living with HIV infection, and more than 40,000 were newly infected each year. In the United Kingdom, the Health Protection Agency estimated that in 2009, 86,500 persons were living with HIV infection and 6630 were newly diagnosed. Over the previous 10 years, the proportion of U.K. residents older than 50 years of age who were living with HIV infection had increased from 1 in 20 to 1 in 5.

Current antiretroviral therapy (ART) regimens have the potential to suppress HIV replication for decades. In 2011, persons with newly diagnosed HIV infection living in nations such as the United States and the United Kingdom that provide access to treatment and care have an expectation that on ART their life expectancy will approach that for an age-matched HIV-uninfected population. Their clinicians now manage HIV-infected populations whose medical complications reflect age-related comorbidity. Unfortunately, these observations do not apply to a majority of people worldwide with HIV infection, who live in financially impoverished environments with little access to comprehensive health care prevention and treatment programs.

Respiratory disease remains an important contributor to morbidity and mortality, and more than two thirds of HIV-infected persons have at least one respiratory episode during the course of their illness. With relatively preserved immune responses, infectious agents are similar to those seen in the general population, although at a higher frequency. With progressive HIV disease, subjects are at an increased risk for opportunistic disease. For example, the North American Prospective Study of Pulmonary Complications of HIV Infection (PCHIS), a multicenter cohort drawn from all HIV risk groups at various stages of immunocompromise, revealed that over an 18-month study period, of approximately 1000 subjects who were not using ART, 33% reported an upper respiratory tract infection, 16% had an episode of acute bronchitis, 5% acute sinusitis, 5% bacterial pneumonia, and 4% developed PCP.

The immune dysregulation that arises from HIV infection means that bacteria, mycobacteria, fungi, viruses, and protozoa can all cause disease in patients with advanced infection. Box 29-1 shows the organisms that typically infect the lung in HIV disease. Of these, the agents of bacterial infections, tuberculosis, and PCP are the most important. In the West, 40% of diagnosed AIDS cases are due to PCP. This chapter provides a brief general overview of the epidemiology and pathogenesis of HIV infection, followed by a more detailed discussion of other important aspects of the disease and its infectious pulmonary complications.

It is reported that by the end of 2009, 33.3 million people worldwide had acquired HIV infection (Figure 29-1). Of these, over 40% are thought to have developed AIDS (for definition of AIDS, see Tables 29-1 and 29-2 and Box 29-2). Globally, 2.6 million people acquired HIV infection in 2009, and 1.8 million died of AIDS. The developing world has been most affected. Sub-Saharan Africa is the current epicenter of the pandemic (accounting for two thirds of all infections); here, nearly 6% of adults are HIV-infected. South and Southeast Asia are responsible for almost a fifth of the estimated HIV global burden. In Central-Eastern Europe and Central Asia, there are currently 1.4 million HIV-infected persons. In the developed world, North America and Western Europe account for approximately 1.5 million and 820,000 infections, respectively. The vast majority of these are spread through sexual contact, although vertical (mother-to-child) and blood-borne infections are common. In the developing world, heterosexual transmission is the norm. In North America and Europe, men who have sex with men constitute the largest group of HIV-infected persons.

VIROLOGY AND IMMUNOLOGY OF THE HUMAN IMMUNODEFICIENCY VIRUS

HIV was first isolated in 1983 from patients with symptoms and signs of immune compromise. Two subtypes, HIV-1 and HIV-2, have subsequently been identified. HIV-1 (hereafter referred to as HIV) is responsible for a majority of infections, is associated with a more aggressive clinical course, and is the focus of this chapter.

HIV is a human retrovirus belonging to the lentivirus family. Cell-free or cell-associated HIV infects through attachment of its viral envelope protein (gp120) to the CD4 antigen complex on host cells. The CD4 receptor is found on several cell types, although the T helper lymphocyte is the main site of HIV infection in the body. Additionally, HIV gp120 also must bind to the cell surface protein co-receptor chemokine receptor 5 (CCR5), or to other co-receptors, including CXCR4, depending on the host cell type. Polymorphisms in genes coding for CCR5 may affect disease progression by reducing the ability of HIV to enter and infect cells. At a population level, this effect appears to be small.

Box 29-1 Etiologic Agents of Human Immunodeficiency Virus (HIV)-Related Pulmonary Infections

Strongyloides stercoralis

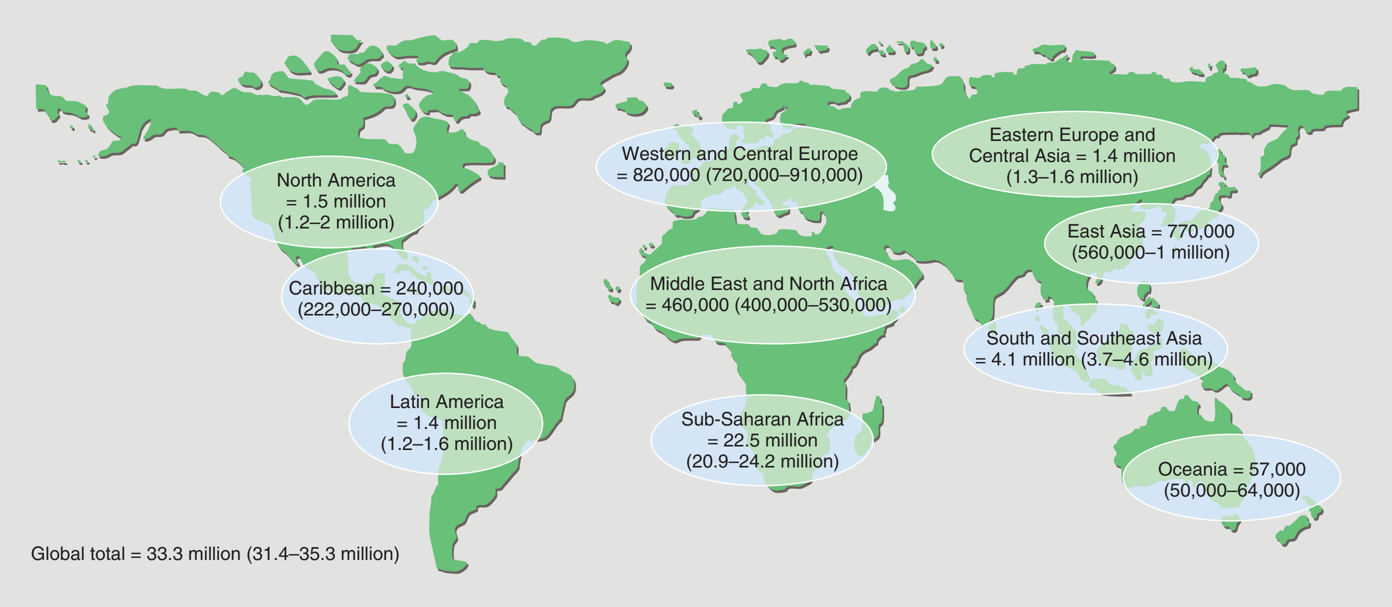
Viruses
Cytomegalovirus
Influenza A viruses

Once HIV is inside the cell, it uses the enzyme reverse transcriptase (RNA-dependent DNA polymerase) to transcribe its own RNA into a DNA copy that translocates into the nucleus and integrates with host cell DNA using its viral integrase. The virus (as proviral DNA) remains latent in many cells until the cell itself becomes activated. This may arise from cytokine or antigen stimulation. The viral genetic material is then transcribed into new RNA, which, in the form of newly created virions, bud from the cell surface and infect other host CD4-bearing cells.

HIV infection directly attacks the immune system, and in particular the T helper cells that underpin the coordinated immune response. This leads to progressive immune dysfunction, with an inability to react to opportunistic pathogens as well as persistent, unregulated immune activation. The etiopathogenic process is not well defined, although at the time of primary infection it is thought that HIV spreads to regional lymph nodes, circulating immune cells, and thymus. The result is a massive viral infection of the human host, which, despite a relatively potent immune response, targets specific memory T cells responsible for sustaining long-term protective immunity. Without therapeutic intervention, progressive immune failure is inevitable. This occurs through a combination of direct cell killing caused by HIV replicating within cells and the negative effects of chronic immune activation. Ultimately, in most cases the infection produces immune system destruction and dysfunction, which is reflected in a reduction in circulating absolute blood CD4$^+$ cell count, a decrease in the percentage of T cells expressing CD4 markers, and a fall in the CD4$^+$-to-CD8$^+$ T cell ratio. Patients present with clinical disease indicating profound immunodeficiency.

NATURAL HISTORY OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Intervention with ART, as well as specific preventive (prophylactic) therapy for opportunistic infections has changed the



North America = 1.5 million (1.2–2 million)
Western and Central Europe = 820,000 (720,000–910,000)
Eastern Europe and Central Asia = 1.4 million (1.3–1.6 million)
East Asia = 770,000 (560,000–1 million)
Caribbean = 240,000 (222,000–270,000)
Middle East and North Africa = 460,000 (400,000–530,000)
South and Southeast Asia = 4.1 million (3.7–4.6 million)
Latin America = 1.4 million (1.2–1.6 million)
Sub-Saharan Africa = 22.5 million (20.9–24.2 million)
Oceania = 57,000 (50,000–64,000)
Global total = 33.3 million (31.4–35.3 million)

Figure 29-1 Estimated number of adults and children with human immunodeficiency virus (HIV) infection (for December 2009) by regions of the world. *(From UNAIDS:* AIDS epidemic update: December 2009, *Geneva, World Health Organization, 2009.* www.unaids.org/en/dadataanalysis/epidemiology/2009aiddsepidemiologyupdate/, accessed 10/03/2012.)

clinical presentation of HIV disease in countries in which these interventions are available. Death rates for HIV-infected cohorts have fallen precipitously. In the absence of ART, in the developed world the median interval between HIV seroconversion and progression to AIDS is estimated to be 10 years and is shorter in cash-poor countries. Untreated, almost all cases of HIV infection progress to full-blown AIDS; without ART, 95% of affected patients will die within 5 years. Globally, in 2011 the main causes of death among HIV-infected patients (a majority of whom were not receiving ART) included tuberculosis, enteric bacterial infection, bacterial pneumonia, and PCP.

The clinical course of untreated HIV infection evolves in several reasonably distinct stages. First, acquisition of the virus, next, seroconversion, which (in the minority) may be associated with a clinical illness (primary HIV infection), then follows a clinically silent period lasting several months to years which leads to symptoms and signs indicating progressive HIV-induced immune compromise, ultimately resulting in AIDS (e.g., PCP).

Acute Primary Human Immunodeficiency Virus Infection

The time from acquisition of HIV infection to development of detectable antibodies (the “window” period) usually is about 6 to 8 weeks. For 30% to 70% of people who become infected, a seroconversion illness is typical. Antibodies to HIV antibody normally are detectable within 2 to 3 weeks of onset of these symptoms, though this can take longer. HIV RNA in peripheral blood is detectable before the appearance of antibodies and often is used to confirm infection.

The nonspecific features of primary “seroconversion” HIV infection usually are self-limiting, and the infection typically mimics a flu-like illness or glandular fever. Nearly all persons with primary HIV infection spontaneously recover within 4 weeks, irrespective of their acute symptoms. A small proportion develop persistent (symmetric) generalized lymphadenopathy. The prognosis for this group is no different from that for asymptomatic HIV-positive persons.

Table 29-1 CDC Classification of HIV Infection

Group	Infection
I	Acute primary
II	Asymptomatic
III	Persistent generalized lymphadenopathy
IV	Other disease
Subgroup A	Constitutional disease (e.g., weight loss >10% of body weight or >4.5 kg; fevers with temperatures >38.5° C for >1 month; diarrhea lasting >1 month)
Subgroup B	Neurologic disease (e.g., HIV encephalopathy, myelopathy, peripheral neuropathy)
Subgroup C	Secondary infectious diseases
Subgroup C1	AIDS-defining secondary diseases (e.g., *Pneumocystis jirovecii* pneumonia, cerebral toxoplasmosis, cytomegalovirus retinitis)
Subgroup C2	Other specified secondary infectious diseases (e.g., oral candidiasis, multidermatomal varicella zoster)
Subgroup D	Secondary cancers (e.g., Kaposi sarcoma, non-Hodgkin lymphoma)
Subgroup E	Other conditions (e.g., lymphoid interstitial pneumonitis)

AIDS, acquired immunodeficiency syndrome; *HIV*, human immunodeficiency virus.

Box 29-2 Adult AIDS Indicator Diseases*

Candidiasis of esophagus, trachea, bronchi, or lungs
Cervical carcinoma, invasive
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, with diarrhea for longer than 1 month
Cytomegalovirus disease (not in liver, spleen, or lymph nodes)
Cytomegalovirus retinitis
Encephalopathy caused by HIV (AIDS dementia complex)
Herpes simplex: ulcers for >1 month, or bronchitis, pneumonitis, esophagitis
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, with diarrhea for >1 month
Kaposi sarcoma
Lymphoma: Burkitt, or immunoblastic, or primary in CNS
Mycobacterium avium complex or *Mycobacterium kansasii*, disseminated or extrapulmonary
Mycobacterium tuberculosis, any site (pulmonary or extrapulmonary)
Mycobacterial infections due to other species or unidentified species, disseminated or extrapulmonary
Pneumocystis jirovecii pneumonia
Pneumonia recurrent within a 12-month period
Progressive multifocal leukoencephalopathy
Salmonella (nontyphoidal) septicemia, recurrent
Toxoplasmosis of brain
Wasting syndrome caused by HIV

*1993 data.
AIDS, acquired immunodeficiency syndrome; *CNS*, central nervous system; *HIV*, human immunodeficiency virus.
Centers for Disease Control: 1993 revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults, *MMWR* 41 (No.RR-17), 1992.

Table 29-2 CDC Classification System for Human Immunodeficiency Virus (HIV) Infection: Clinical Categories*

CD4$^+$ Count (cells/µL)	A: Acute (Primary) HIV Infection, Asymptomatic or With Persistent Generalized Lymphadenopathy	B: Symptomatic (not A or C)	C: AIDS Indicator Conditions
≥500	A1	B1	C1
200-499	A2	B2	C2
<200	A3	B3	C3

*Patients are stratified clinically (A-C) and immunologically (1-3). Category B consists of symptomatic conditions that are not included within AIDS indicator diseases (category C) but either can be attributed to or are complicated by HIV infection. Examples are persistent candidiasis, thrombocytopenia, and peripheral neuropathy.
AIDS, acquired immunodeficiency syndrome; *CDC*, Centers for Disease Control and Prevention.

Chronic Human Immunodeficiency Virus Infection

Although a proportion of HIV-seropositive persons remain completely well without ART for an extended period (approximately 20%, after 10 years), many infected persons have minor symptoms and signs suggesting immune dysfunction. Oral candidiasis and constitutional symptoms (e.g., malaise, idiopathic fever, night sweats, diarrhea, weight loss) are the strongest clinical predictors of progression to AIDS.

The term AIDS was originally created as an epidemiologic tool to capture specific clinical presentations, which early in the HIV epidemic appeared to suggest significant immune deficiency. Over the past 30 years, the definition has been modified to incorporate the expanding spectrum of diseases affecting HIV-infected patients, including cervical carcinoma and recurrent bacterial pneumonia (see Box 29-2). The 1993 CDC classification included an immunologic criterion for AIDS ($CD4^+$ count below 200 cells/μL or $CD4^+$ percentage less than 14% of total lymphocytes) regardless of clinical symptoms (see Table 29-2). These data are used to define a point at which the risk for severe opportunistic infection rises dramatically.

Apart from cervical carcinoma, AIDS indicator diseases differ little between men and women. Injection drug users in the United States and the United Kingdom have a high incidence of recurrent bacterial pneumonia and tuberculosis. Geographic differences occur that reflect the opportunistic pathogens present in the local environment (e.g., histoplasmosis or visceral leishmaniasis usually are found only in patients from endemic areas). In the developed world, survival differences after an AIDS diagnosis mainly arise from variation in ease of access to and provision of medical care. It is clear that better treatment outcomes are associated with specialist care provided by treatment centers with extensive experience in the management of HIV-infected persons.

In countries in which ART is available, the spectrum of HIV-related disease has changed over the past 30 years. In the HIV Outpatient Study (HOPS), a prospective multicenter observational study in the United States, between 1994 and 2007, opportunistic infections associated with very low $CD4^+$ counts (e.g., cytomegalovirus retinitis, *Mycobacterium avium* complex [MAC] infection) declined rapidly after introduction of ART and stabilized at low levels during the period 2003 to 2007. In the EuroSIDA cohort (a pan-European prospective study of HIV infection), between 1994 and 2004, opportunistic infections were observed less frequently over time, and malignant disease, such as non-Hodgkin lymphoma, increased as an AIDS-defining event.

Although death rates have fallen in ART-treated populations, there has been a rise in the proportion of non-AIDS deaths. In some series, this category accounts for a majority of events. Causes include liver disease (often due to viral hepatitides) and cancer, as well as cardiovascular disease and drug-related toxicity. In such circumstances, AIDS deaths usually occur among patients who have not accessed medical care regularly and who present with advanced HIV disease.

A new manifestation of opportunistic infection has been described in patients commencing ART. The immune reconstitution inflammatory syndrome (IRIS) (the pathogenesis of which is discussed later under treatment for tuberculosis) may cause severe if temporary clinical illness as the patient's immunity recovers. Patients appear to experience a relapse of their original (and often incompletely treated) disease. IRIS often is seen in MAC infection, tuberculosis, hepatitis B, CMV retinitis, and herpesvirus infection. In the developed world, metabolic complications of ART, such as ischemic heart disease, hypertension, diabetes, and cerebrovascular disease, are increasingly encountered by clinicians providing care. A significant number of persons receiving ART also experience drug toxicity. An increasing number of patients also are surviving to manifest symptoms associated with chronic hepatitis B and C virus infection. HIV-associated nephropathy (often with chronic kidney disease) is common among black Africans and is a significant cause of long-term morbidity.

PROGNOSTIC MARKERS

Laboratory markers and clinical symptoms (e.g., oral candidiasis or thrush) can independently reflect the immune changes that lead to serious disease. Staging systems have been developed that can predict the risk of progression to severe opportunistic disease (AIDS). The fall in absolute blood $CD4^+$ T lymphocyte count is the most widely used prognostic marker, although $CD4^+$ counts may be affected by a number of factors apart from HIV, including intercurrent infection, cigarette smoking, exercise, time of day, and laboratory variation. The percentage of $CD4^+$ cells and the ratio of $CD4^+$ to $CD8^+$ cells are more stable measures and may be used if the $CD4^+$ absolute counts appear to vary widely between routine clinical assessments.

Measurement of plasma HIV RNA "viral load" provides important prognostic information that can both guide therapy and suggest long-term outcome. It is of particular value in patients who have high $CD4^+$ counts but are clinically well, because it gives an indication of the expected speed of clinical progression.

PULMONARY IMMUNE RESPONSE DURING HUMAN IMMUNODEFICIENCY VIRUS INFECTION

It is clear from the frequency with which HIV-related respiratory disease occurs that the pulmonary immune response is profoundly compromised. Evidence from simian immunodeficiency virus (SIV)-infected primates indicates that within the lung acute retroviral infection causes a rapid increase, followed by a decline in SIV RNA. Intrapulmonary replication is "compartmentalized," in that plasma SIV levels correlate poorly with those in bronchoalveolar lavage (BAL) fluid. In humans, comparison of HIV replication in blood and in alveolar lining fluid indicates that little intrapulmonary HIV replication occurs when patients are asymptomatic. This process increases significantly with development of pulmonary disease, and in some instances, local HIV replication is greater than in plasma. Other studies, however, show no consistent change in HIV levels in BAL fluid as the patient's clinical status alters. Pulmonary memory $CD4^+$ cells are not as extensively infected by HIV compared with those within the gastrointestinal tract. Alveolar macrophages appear to carry a much lower HIV "viral load" than macrophages obtained from other body sites.

HIV affects both the humoral and cellular components of innate immunity. These alterations are apparent even in patients with (near) normal $CD4^+$ counts and undetectable HIV loads, and include a BAL $CD8^+$ lymphocytosis. HIV-induced impairment of innate immune function, particularly when there is additional $CD4^+$ cell depletion, likely contributes to the pathogenesis of opportunistic pulmonary infections, for example, the increased risk of *mycobacterium tuberculosis* infection and bacterial pneumonia.

Phagocytosis of bacteria by human alveolar macrophages does not appear to be influenced by HIV infection, suggesting that other mechanisms are important. In the general population deficiencies in signaling through Toll-like receptors (TLRs) are associated with an increased risk of, or an adverse outcome from, a number of infections. Activation of HIV-infected human macrophages by TLR4 results in impaired tumor necrosis factor-α release compared to that from uninfected macrophages; as interleukin (IL)-10 release is not impaired, this effect appears specific.

Intra-pulmonary immune responses after ART initiation are not as well described as those occurring during untreated HIV infection. Detection of HIV in BAL fluid is less likely in subjects on ART. Starting such therapy is associated with a delayed but significant decrease in the absolute number and percentage of alveolar $CD8^+$ lymphocytes. Successful virologic control leads to a reduction in activated intrapulmonary $CD8^+$ cells and increases in $CD8^+$-naive and central memory cells—implying that the intrapulmonary $CD8^+$ lymphocyte pool is repopulated from the peripheral circulation.

ART also induces a marked reduction in concentrations of proinflammatory cytokines and chemokines in BAL fluid. Despite this, both IFN-γ and IFN-γ inducible chemokines (inducible protein [IP]-10, monokine induced by IFN-γ [MIG]) remain detectable and appear to contribute to recruitment of memory cells into the lung.

On the basis of these findings, it is hypothesized that ART-naive patients have uncontrolled intrapulmonary HIV replication, which results in nonspecific cellular activation and augmented cytokine and chemokine expression. These changes promote an influx of inflammatory cells into the alveoli. With institution of ART, intrapulmonary HIV load and cellular activation are reduced and nonspecific cytokine secretion resolves, although persistent, low-level IFN-γ production from resident memory cells maintains IFN-γ–inducible chemokine levels. As a result, normal intrapulmonary trafficking of these cells occurs, resulting in more clear-cut evidence of innate and acquired immune control. The former includes ART reducing mononuclear cell chemokine production with a subsequent impact on TLR2-mediated signaling.

RISK FACTORS FOR RESPIRATORY DISEASE

An individual patient's risk for respiratory disease is determined by the medical history (e.g., receipt of effective preventive therapy or ART), place of residence and travel history (e.g., the influence of geography on mycobacterial and fungal disease), and immunity status. Falling blood $CD4^+$ counts or high plasma HIV RNA "viral loads" increase the chance of respiratory infection, with an increased spectrum of potential organisms associated with greater degrees of immunosuppression. For example, HIV-infected patients with a $CD4^+$ count below 200 cells/μL are four times more likely to have one episode of bacterial pneumonia per year than those with higher $CD4^+$ cell counts. More exotic organisms are found in subjects with very low $CD4^+$ counts. These include bacteria such as *Rhodococcus equi* and *Nocardia asteroides* and fungi such as *Aspergillus* spp. and *Penicillium marneffei*. Just as with *P. jirovecii*, this increased susceptibility reflects the importance of T cell depletion and macrophage dysfunction in the loss of host immunity (a process that has been confirmed by animal experiments).

Among HIV-infected patients, injection drug users are at greatest risk for development of bacterial pneumonia and tuberculosis. Persons who have had previous respiratory episodes (PCP or bacterial pneumonia) appear to be at increased risk for subsequent episodes of such disease. Whether this susceptibility relates to host or environmental factors is not certain, although structural lung damage and abnormal pulmonary physiology are likely to be contributing factors. This argument is supported by the increased rates of pneumonia in HIV-infected smokers compared with nonsmokers. Recent work has shown that chronic obstructive pulmonary disease (COPD) and lung cancer occur more frequently and at a younger age among HIV-infected patients, than in the general population. In view of the large number of HIV-infected persons who smoke heavily, targeting this population for smoking cessation obviously is a pressing need. This goal is reinforced by the association between smoking and an increased risk for bacterial pneumonia and more rapid progression to first AIDS illness and death.

CLINICAL FEATURES

BACTERIAL INFECTION

Bronchitis

The clinical presentation in bronchitis mimics that in bacterial exacerbations of chronic obstructive lung disease; most patients have a productive cough and fever. The pathogens commonly identified are similar to those in the general population (e.g., *Streptococcus pneumoniae* and *Haemophilus influenzae*). However, patients with advanced disease may be infected with *Pseudomonas aeruginosa* or *Staphylococcus aureus*. Response to appropriate antibiotic therapy in conventional doses is good, although relapses are common.

Bronchiectasis

Bronchiectasis is increasingly recognized in HIV-infected patients with advanced HIV disease and low $CD4^+$ lymphocyte counts. It probably arises secondary to recurrent bacterial, mycobacterial or *P. jirovecii* infections. The diagnosis most often is made by high-resolution (thin-section) computed tomography (CT) scanning (Figure 29-2). Its prevalence has not been accurately determined, although with improved survival from both opportunistic infections and HIV disease, it can be expected to be increasingly common in clinical practice. The pathogens isolated in patients with bronchiectasis are those seen in bronchitis. In addition, *Burkholderia cepacia* and *Moraxella catarrhalis* have been described.

Pneumonia

Community-acquired bacterial pneumonia occurs more frequently in HIV-infected patients than in the general population. It is especially common in HIV-infected injecting drug

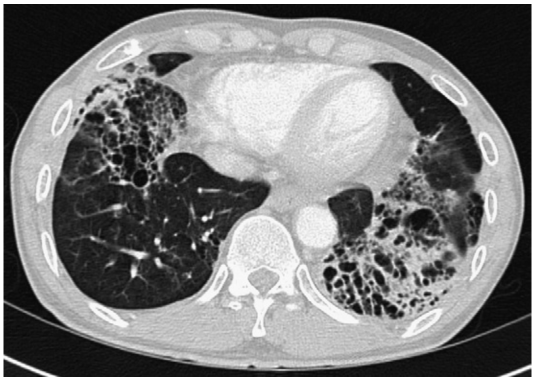


Figure 29-2 Computed tomography scan of thorax showing widespread bronchiectasis in a patient with a previous history of multiple episodes of bacterial pneumonia.

users. The spectrum of bacterial pathogens is similar to that in non–HIV-infected persons (see Box 29-1). *S. pneumoniae* is the most commonly identified pathogen, followed by *H. influenzae.* HIV-infected patients with *S. pneumoniae*–related pneumonia frequently are bacteremic. In one study, the rate of pneumococcal bacteremia in HIV-infected patients was 100 times that for an HIV-negative population. More recent work has confirmed this to be the case for all causes of HIV-related bacterial pneumonia. Typically, blood cultures have a 40-fold increased pick-up rate in HIV-positive patients. The widespread use of ART has led to some decrease in rates of bacterial pneumonia and bacteremia, although they are still considerably higher than in a non–HIV-infected population.

Bacterial pneumonia has a similar presentation in HIV-infected patients and in uninfected persons. Chest radiographs frequently are atypical in appearance, mimicking that in PCP in up to half of the cases (**Figure 29-3**). By contrast, radiographic lobar or segmental consolidation also may be seen in a wide range of bacterial organisms (**Figure 29-4**); these include *S. pneumoniae*, *P. aeruginosa*, *H. influenzae*, and *M. tuberculosis.* PCP also may manifest with lobar or segmental consolidation. In patients with more advanced HIV disease and low $CD4^+$ lymphocyte counts, *P. aeruginosa* and *S. aureus* also can cause pneumonia.

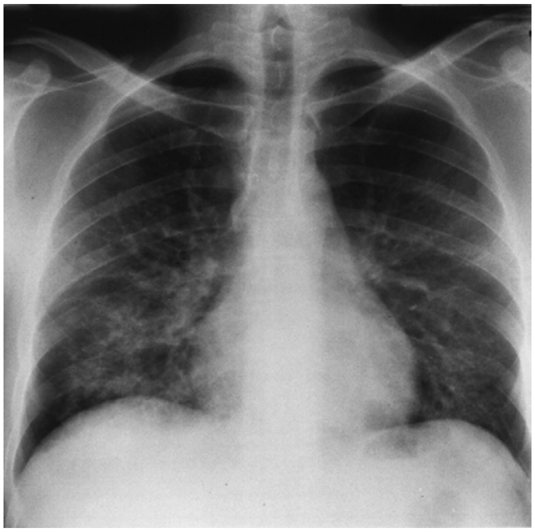

Figure 29-3 Chest radiograph showing bilateral, diffuse, interstitial infiltrates mimicking the changes of *Pneumocystis jirovecii* pneumonia. The etiologic agent was *Streptococcus pneumoniae.*

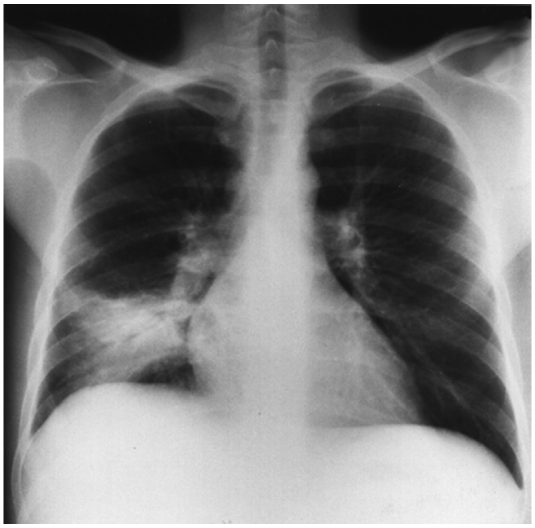

Figure 29-4 Chest radiograph showing lobar consolidation. The etiologic agent was *Salmonella choleraesuis*.

Complications of bacterial pneumonia are frequent, and pleural effusions are twice as likely in HIV infection (often occurring with *S. aureus* infection); empyema and intrapulmonary abscessation are present in up to 10% of patients. Inevitably, the mortality rate is high (approximately 10%).

Other Bacterial Infections

***Nocardia asteroides* Infection** *N. asteroides* has been reported as a cause of infection in patients with advanced HIV disease and low $CD4^+$ lymphocyte counts. The widespread use of trimethoprim-sulfamethoxazole (TMP-SMX) for prophylaxis against PCP may have reduced the incidence of infection due to this organism. The clinical presentation often is indistinguishable from that with other bacterial infections. Chest radiographic appearance may mimic that in tuberculosis (see later). The diagnosis is made by identification of the organism in sputum or BAL fluid or lung tissue.

***Rhodococcus equi* Infection** *R. equi* usually produces pneumonia in patients who have advanced HIV infection and have been in contact with farm animals or with soil from fields or barns where animals are housed. The presentation is subacute, with 2 to 3 weeks of cough, dyspnea, fever, and pleuritic chest pain. The chest radiograph typically shows consolidation with cavitation. Pleural effusions are common. The diagnosis usually is made by culture of sputum or blood; bronchoscopy with BAL or pleural aspiration may be necessary in some cases.

***Bartonella henselae* Infection** *B. henselae* is a gram-negative bacillus that causes bacillary angiomatosis in HIV-infected patients. Clinically, the cutaneous lesions may mimic Kaposi sarcoma, from which they may be distinguished by demonstration of organisms in tissue using Warthin-Starry silver stain. Bacillary angiomatosis also may infect the lungs, where it produces endobronchial red or violet polypoid angiomatous lesions, which may resemble those of Kaposi sarcoma. Biopsy is necessary to confirm the diagnosis.

MYCOBACTERIAL INFECTIONS

Tuberculosis

HIV infection is associated with a 20- to 40-fold increased risk for development of active tuberculosis disease in a person with latent tuberculosis infection (LTBI) over that in noninfected subjects. Taken together with its ability to infect both the immunocompromised and the immunocompetent, tuberculosis is perhaps therefore the single most important disease associated with HIV infection. It is estimated that each year, 1.1 million new cases of active tuberculosis occur in HIV-infected patients. Accordingly, tuberculosis is a major cause of HIV-related morbidity and mortality. It also is a clear driver in both resource-rich and poor countries for the current overall increase in tuberculosis rates. Where HIV infection is endemic, tuberculosis control at a population level is almost impossible if treatment for both infections is not available.

In the United Kingdom, many centers routinely offer HIV antibody testing to all patients with tuberculosis, regardless of risk factors for HIV infection. In the United States, the CDC now recommends HIV testing as a routine part of health care for all patients 13 to 64 years of age seeking medical services. The benefit of treating HIV co-infection is indisputable. Moreover, strategies that reduce high-risk behavior and cut ongoing HIV transmission can be introduced. Unfortunately, offering HIV testing in tuberculosis clinics has not been routine practice in many countries, and integration with HIV infection–related services is poor. This disconnect leads to both diagnostic delay of HIV infection and potentially suboptimal, uncoordinated care, with potentially disastrous outcomes.

Active tuberculosis can occur at any stage of HIV infection and, unlike almost every other HIV-related infection, may do so despite effective ART. In the United States, the United Kingdom, and most European countries, reporting of tuberculosis in both HIV-infected and non–HIV-infected patients is mandatory.

Clinical disease in HIV-infected patients may arise in several different ways: by reactivation of latent tuberculosis, by rapid progression of pulmonary infection, and by reinfection from an exogenous source.

Pulmonary disease is the most common presentation, and clinical manifestations are determined by the patient's level of immunity. For example, persons with reasonably well-preserved $CD4^+$ counts exhibit clinical features similar to those of "normal" adult postprimary disease (Table 29-3). Signs and symptoms typically include weight loss, fever with sweats, cough, sputum, dyspnea, hemoptysis, and chest pain. These patients may have no clinical features to suggest associated HIV infection. The chest radiograph frequently shows upper lobe consolidation, and cavitary change is common (Figure 29-5). If performed, the tuberculin skin test (TST), using purified protein derivative (PPD), usually gives a positive result, and the likelihood that spontaneously expectorated sputum or BAL fluid will be smear-positive for acid-fast bacilli is high.

In persons with advanced HIV disease (i.e., low $CD4^+$ lymphocyte counts and clinically apparent immunosuppression), it may be difficult to diagnose tuberculosis. The clinical presentation here often is with nonspecific symptoms. Fever, weight loss, fatigue, and malaise may be mistakenly ascribed to HIV infection itself. In this context, pulmonary tuberculosis is often similar to primary infection, with the chest radiograph showing diffuse or miliary-type shadowing (Figure 29-6), hilar or mediastinal lymphadenopathy, or pleural effusion; cavitation is unusual, with no upper zone chest radiographic predominance. In up to 10% of patients, the chest radiograph may appear normal; in others, the pulmonary infiltrate can be bilateral, diffuse, and interstitial in pattern, thus mimicking PCP. Hilar lymphadenopathy and pleural effusion also may be manifestations of pulmonary Kaposi sarcoma or lymphoma, with which *M. tuberculosis* may coexist. The TST result usually is negative, and spontaneously expectorated sputum and BAL fluid samples often are smear-negative (although they are culture-positive).

In addition to pulmonary tuberculosis, extrapulmonary disease occurs in a high proportion of HIV-infected persons with low $CD4^+$ lymphocyte counts (less than 150 cells/μL). Mycobacteremia and generalized lymph node infection (Figure 29-7) are common, but involvement of bone marrow, liver, pericardium, meninges, and brain also has been described.

Evidence of extrapulmonary tuberculosis should be sought in any HIV-infected patient with suspected or confirmed pulmonary tuberculosis, by culture of stool, urine, and blood or bone marrow. Traditional solid phase culture and speciation techniques may take 6 to 10 weeks. Liquid culture methods (e.g., BACTEC, Becton Dickinson, Towson, Maryland) that

Table 29-3 **Tuberculosis and Human Immunodeficiency Virus (HIV) Infection**

	Stage of HIV Disease	
Diagnostic Feature	**Reasonable Immunity**	**Impaired Immunity**
Chest radiographic appearance	Upper zone infiltrates and cavities (cf postprimary infection)	Lymphadenopathy, effusions, miliary or diffuse infiltrates (cf primary infection) Normal
Sputum or bronchoalveolar lavage "smear-positive"	Frequently	Less commonly
Disease site	Localized	Widely disseminated
Tuberculin test–positive	Frequently	Less commonly

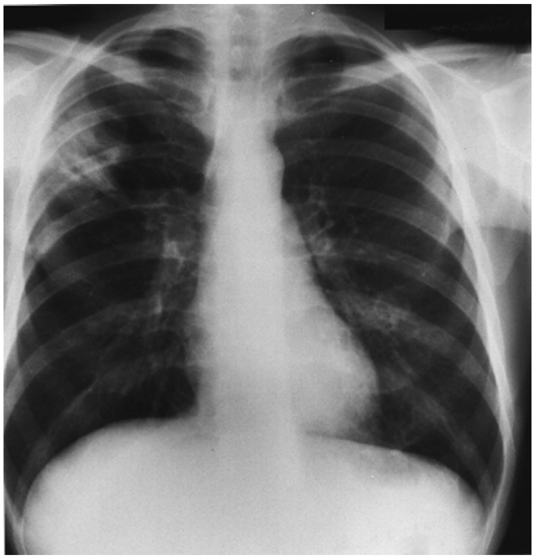

Figure 29-5 Chest radiograph showing pathologic changes of pulmonary tuberculosis in early-stage human immunodeficiency virus infection. Upper lobe infiltrates and cavities are seen.

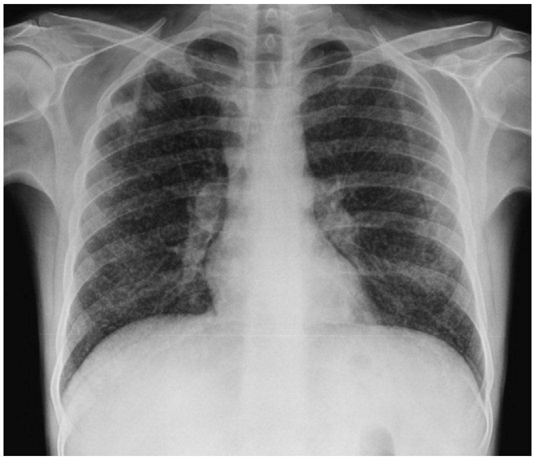

Figure 29-6 Chest radiograph showing pathologic changes of miliary tuberculosis. The patient's $CD4^+$ count was 80 cells/μL.

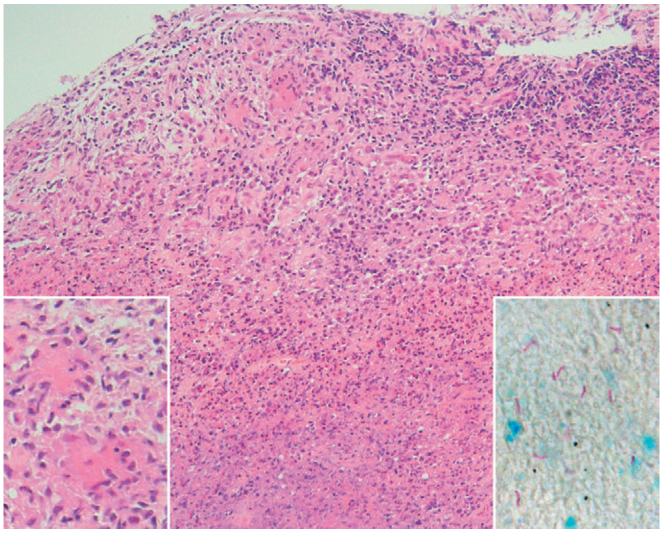

Figure 29-7 Photomicrograph of mediastinal lymph node showing necrotic tissue surrounded by areas of poorly developed granulomatous inflammation (*left inset*). A Ziehl-Neelsen stain showed numerous acid-fast bacilli (*right inset*). *(Reproduced from Miller RF, Shahmanesh M, Talbot MD, et al: Progressive symptoms and signs following institution of highly active antiretroviral therapy and subsequent antituberculosis therapy: immune reconstitution syndrome or infection?* Sex Transm Infect *82:111–116, 2006.)*

detect early growth provide a faster diagnosis (usually in 2 to 3 weeks). Molecular diagnostic tests using *M. tuberculosis* genome detection (e.g., by polymerase chain reaction [PCR]) offer the possibility of yet more rapid diagnosis (within hours). The original concerns that "high-tech" systems may not be practical in a field setting are now being challenged. The World Health Organization (WHO) has endorsed the Xpert TBRIF assay, which is portable and simple to use with sputum samples. This kit is expensive, however, although it may be of use in high-prevalence tuberculosis/HIV infection settings, in which prompt treatment initiation is critical to infection control. Current data suggest that such tests are of value, although less sensitive in HIV-infected subjects (in whom sputum samples generally have a lower bacterial load). The availability of simple but highly sensitive and specific methods that utilize the inoculation of large quantities of the sample (e.g., sputum) onto microscopic plates with subsequent rapid detection (in days) of both mycobacterial growth and resistance patterns (i.e., microscopic observation drug susceptibility [MODS] assay) is of great potential significance.

Until the results of culture and speciation are known, acid-fast bacilli identified in respiratory samples, biopsy tissue, an aspirate, or blood in an HIV-infected patient, regardless of the $CD4^+$ lymphocyte count, should be regarded as being *M. tuberculosis*, and conventional antituberculosis therapy should be commenced. If culture fails to demonstrate *M. tuberculosis* and instead another mycobacterium (see later) is identified, then the treatment regimen can be modified.

Drug-Resistant Tuberculosis

Multiple drug–resistant (MDR) tuberculosis—that is, disease caused by *M. tuberculosis* strains resistant to isoniazid and rifampicin (rifampin), with or without other drugs—is now an important clinical problem in HIV-infected patients in the United States, where it is responsible for approximately 3% of all cases of tuberculosis in this population. Outbreaks of MDR tuberculosis have occurred in both HIV-infected and non–HIV-infected persons in the United States in prison facilities, hostels, and hospitals. Similar incidents also have been documented among HIV-infected patients in Europe. Inadequate treatment (including case management and supervision of medication) of tuberculosis and poor patient compliance with antituberculosis therapy are the most important risk factors for development of MDR tuberculosis. Other cases have arisen through exogenous reinfection of profoundly immunosuppressed HIV-infected patients who are already receiving treatment for drug-sensitive disease.

Despite antituberculosis therapy, the median survival in HIV-infected persons with MDR tuberculosis initially was only 2 to 3 months. Recently this has improved, largely because of an increased awareness of the condition with early initiation of suitable therapy as determined by drug sensitivity testing.

The advances in molecular diagnostics are not confined to rapid mycobacterial speciation. Commercial kits are available which can detect the commonest mutations that confer rifampicin and isoniazid resistance with good sensitivity. These are of great potential value in infection control in tuberculosis-endemic areas. They can guide initial therapy, assess for resistance in unexpected poor clinical response and significantly improve treatment outcomes. Next generation tests will also incorporate drug resistance profiles for other important agents such as fluoroquinolones.

Extensively Drug-Resistant Tuberculosis

Extensively drug-resistant (XDR) tuberculosis—that is, *M. tuberculosis* resistant to isoniazid and rifampicin (rifampin), plus any fluoroquinolone and one or more of the three injectable second-line drugs (capreomycin, kanamycin, and amikacin)—is an increasing clinical problem. Originally described in South Africa in association with HIV infection, XDR tuberculosis has now been identified worldwide. The current picture mirrors early reports of MDR tuberculosis in HIV infection in that mortality is very high among HIV-infected patients: In the original South African study from KwaZulu Natal, survival was less than 3 weeks from the time of receipt of the first sputum sample. Earlier suspicion and prompt initiation of therapy have improved survival, although the outcome often is poor and treatment is extremely expensive.

Infections Due to Mycobacteria Other Than Tuberculosis

***Mycobacterium avium* Complex Infection** Before the widespread availability of ART, disseminated MAC infection developed in up to 50% of HIV-infected patients. It remains a problem in patients with advanced HIV disease who are not receiving such therapy and who have $CD4^+$ lymphocyte counts below 50 cells/μL. Clinical presentation is nonspecific and may be confused with the effects of HIV infection itself. Fever, night sweats, weight loss, anorexia, and malaise are common. Anemia, hepatosplenomegaly, abdominal pain, and chronic diarrhea are frequent findings. The diagnosis of disseminated MAC infection is based on culture of the organism from blood, bone marrow, lymph node, or liver biopsy specimens. Also, MAC frequently is identified in BAL fluid, sputum, stool, and urine, but detection of the organism at these sites is not diagnostic of disseminated infection. Evidence of pulmonary MAC infection is not usually obtained from a chest radiograph, which may be negative or show nonspecific infiltrates. Rarely, focal consolidation, nodular infiltrates, and apical cavitation (resembling the changes of *M. tuberculosis* infection) have been reported.

***Mycobacterium kansasii* Infection** *M. kansasii* infection is the second most common nontuberculous opportunistic mycobacterial infection in HIV-infected persons and usually appears late in the course of HIV infection in patients with CD4$^+$ lymphocyte counts below 100 cells/μL. The most frequent presentation is with fever, cough, and dyspnea. In approximately two thirds of persons with *M. kansasii* infection, the disease is localized to the lungs; the remainder have disseminated disease that affects bone marrow, lymph node, skin, and lungs. The diagnosis is made by culture of the organism from respiratory secretions or from bone marrow, lymph node aspirate, or skin biopsy. Focal upper lobe infiltrates with diffuse interstitial infiltrates are the most common radiographic abnormalities; thin-walled cavitary lesions and hilar adenopathy also have been reported.

***Mycobacterium xenopi* Infection** *M. xenopi* may occasionally be isolated from sputum or BAL fluid samples, but its significance is uncertain. Patients have low CD4$^+$ counts, and *M. xenopi* usually is accompanied by a copathogen such as *P. jirovecii*. Treatment of PCP is associated in most cases with resolution of symptoms. Some evidence suggests that starting ART prevents disease recurrence, provided that an adequate immune response is retained.

Pneumocystis jirovecii Pneumonia

The development of PCP is largely related to underlying states of immunosuppression induced by malignancy or treatment thereof, organ transplantation, or HIV infection. In 2011 in the United States, the United Kingdom, Europe, and Australasia, PCP was largely seen only in HIV-infected persons unaware of their serostatus or in those reported to be intolerant of or noncompliant with anti–*P. jirovecii* prophylaxis and ART.

P. jirovecii originally was regarded as a protozoan, as suggested by its morphology and the lack of response to antifungal agents such as amphotericin B. The organism is now thought to be a fungus. The demonstration of antibodies against *P. jirovecii* in most healthy children and adults suggests that infection is acquired in childhood and persists in the lungs in a dormant phase. Subsequent immunosuppression (e.g., as a result of HIV infection) allows the fungus to propagate in the lung, causing clinical disease. This "latency hypothesis," however, is challenged by several observations: *P. jirovecii* cannot be identified in the lungs of immunocompetent persons; "case clusters" of PCP in health care facilities suggest recent transmission; different genotypes of *P. jirovecii* are identified in each episode in HIV-infected patients who have recurrent PCP; genotypes of *P. jirovecii* in patients who have PCP correlate with place of diagnosis and not with their place of birth, suggesting infection has been recently acquired. Taken together, these data suggest that PCP arises by reinfection from an exogenous source.

The clinical presentation of PCP is nonspecific, with onset of progressive exertional dyspnea over days or weeks, together with a dry cough, with or without expectoration of minimal quantities of mucoid sputum. Patients often report an inability to take a deep breath, which is not due to pleurisy (Table 29-4). Fever is common, yet patients rarely complain of temperature-related signs and symptoms including sweats. In HIV-infected patients, the presentation usually is more insidious than in those receiving immunosuppressive therapy. The median time to diagnosis from onset of symptoms is more than 3 weeks in those with HIV infection, compared with less than 1 week in non–HIV-infected patients. In a small proportion of HIV-positive patients, the disease course of PCP is fulminant, with an interval of only 5 to 7 days between onset of symptoms and progression to development of respiratory failure. In others, it may be much more indolent, with respiratory symptoms that worsen almost imperceptibly over several months. Rarely, PCP may manifest as a fever of undetermined origin without respiratory symptoms.

Clinical examination usually is remarkable only for the absence of physical signs; occasionally, fine, basal, end-inspiratory crackles are audible. Features that would suggest an alternative diagnosis include a cough productive of purulent sputum or hemoptysis, chest pain (particularly pleural pain), and signs of focal consolidation or pleural effusion (see Table 29-4). Of note, infection with more than one pathogen occurs in almost one fifth of these patients, so symptoms may be related to infection with any of several agents.

The chest radiographic appearance in PCP typically is unremarkable initially. Later, diffuse reticular shadowing, especially in the perihilar regions, is seen and may progress to widespread alveolar consolidation that resembles that in untreated pulmonary edema or with presentation late in disease. At this stage,

Table 29-4 Clinical Presentation in *Pneumocystis jirovecii* Pneumonia

Examination	Typical Presentation	Atypical Presentation
Symptoms	Progressive exertional dyspnea over days or weeks	Sudden onset of dyspnea over hours or days
	Dry cough ± mucoid sputum	Cough productive of purulent sputum Hemoptysis
	Difficulty taking in a deep breath not related to pleuritic pain	Chest pain (pleuritic or "crushing")
	Fever ± sweats Tachypnea	
Signs	Normal breath sounds or fine end-inspiratory basal crackles	Wheeze, signs of focal consolidation or pleural effusion
Chest radiographic appearance	*Early*: perihilar "haze," or bilateral interstitial shadowing	Pleural effusion, lobar or segmental consolidation
	Late: alveolar-interstitial changes or "whiteout" (marked alveolar consolidation with sparing of apices and costophrenic angles)	
Arterial blood gases	PaO_2: *early*: normal; *late*: low	
	$PaCO_2$: *early*: normal or low; *late*: normal or high	

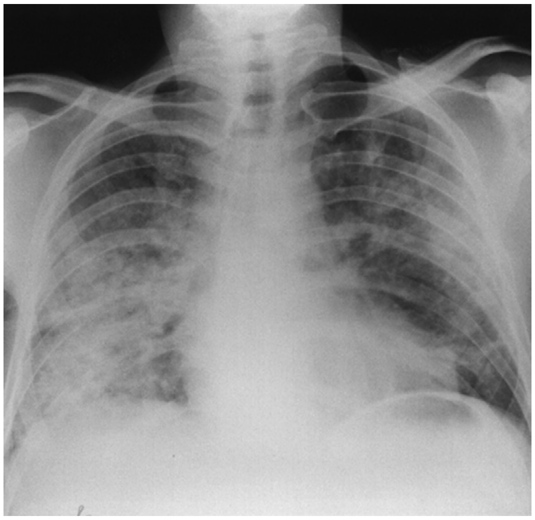

Figure 29-8 Chest radiograph showing diffuse bilateral interstitial infiltrates in a patient with severe *Pneumocystis jirovecii* pneumonia.

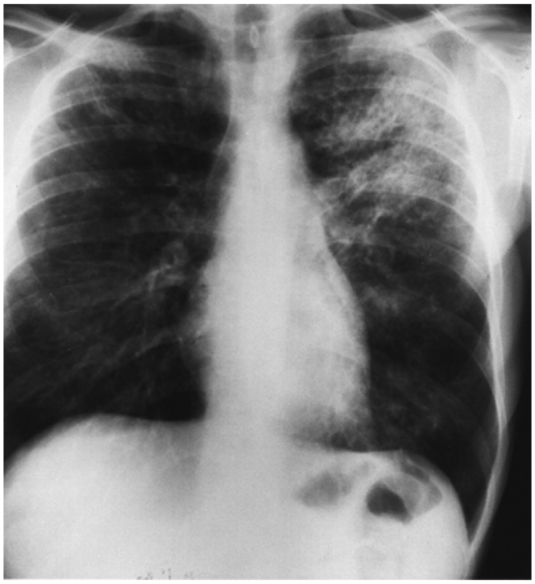

Figure 29-9 Chest radiograph showing upper lobe infiltrates in a patient with *Pneumocystis jirovecii* pneumonia. The patient had received nebulized pentamidine.

the lung may be grossly consolidated and almost airless (Figure 29-8). Up to 20% of chest radiographs are atypical in appearance, showing lobar consolidation, honeycomb lung, multiple thin-walled cystic air spaces (pneumatoceles), intrapulmonary nodules, cavitary lesions, pneumothorax, and hilar and mediastinal lymphadenopathy. Predominantly apical changes, resembling those of tuberculosis, may occur in patients with PCP that developed subsequent to anti–*P. jirovecii* prophylaxis with nebulized pentamidine (Figure 29-9). All of these radiographic changes are nonspecific; similar changes occur with other pulmonary pathogens, including pyogenic bacterial, mycobacterial, and fungal infection, as well as Kaposi sarcoma and nonspecific interstitial pneumonitis. Respiratory symptoms in an immunosuppressed, HIV-infected patient with a normal-appearing chest radiograph should not be discounted, however, because radiographic abnormalities may not appear until 2 to 3 days later.

The diagnosis of PCP is made by demonstration of the organism in induced sputum, BAL fluid, or lung biopsy material using histochemical or immunofluorescence techniques.

Molecular detection tests for *P. jirovecii* using a variety of primers have been reported using BAL fluid, induced sputum and oropharyngeal wash (OPW) specimens. In general PCR-based tests have increased sensitivity, but a reduced specificity when compared to visualization of the organism using histochemical stains. This reduced specificity results from the finding that *P. jirovecii* DNA may be detected in respiratory samples from HIV-infected patients who do not have PCP (such as with tuberculosis or bacterial pneumonia) but are colonized with the organism. One study compared two PCR-based assays; these had sensitivities of 97% and 98%, but specificities were only 68% and 66%. The sensitivity of molecular detection techniques is lower if OPW rather than BAL fluid is used.

FUNGAL INFECTIONS

Many fungal infections of the lung are confined to specific geographic regions, although with widespread travel they may occur in patients outside these areas. *Candida*, *Aspergillus*, and *Cryptococcus* spp. are ubiquitous and are found worldwide.

Candidal Infection

In contrast with infections of the oropharynx and esophagus, candidal infection of the trachea, bronchi, and lungs is rare in HIV-infected patients, as are candidemia, disseminated candidiasis, and deep focal candidiasis. The clinical presentation of pulmonary candidal infection has no specific features. Chest radiography is equally nonspecific—the radiographic appearance may be normal or show patchy infiltrates. Isolation of *Candida* from sputum may simply represent colonization and does not mean that the patient has candidal pneumonia. Indirect evidence may be obtained from positive cultures or rising antibody titers. However, in HIV-infected patients a high antibody titer alone is a less reliable indicator, and antibodies may be absent in proven cases of invasive candidal infection. Some correlation occurs between identification of large quantities of *Candida* species in BAL fluid and *Candida* spp. as the cause of pneumonia. Definitive diagnosis is made by lung biopsy.

Aspergillus Infection

Unlike in patients immunosuppressed and rendered neutropenic by systemic chemotherapy, infection with *Aspergillus* species is relatively rare in HIV-positive patients. Risk factors for aspergillosis are neutropenia, which commonly is drug-induced (e.g., in chemotherapy), and use of corticosteroids. Fever, cough, and dyspnea are the most common presenting manifestations, but pleuritic chest pain and hemoptysis are found in approximately one third of patients.

Patterns of pulmonary disease include cavitating upper lobe disease, focal radiographic opacities resembling bacterial pneumonia, bilateral diffuse and patchy opacities (nodular or reticular-nodular in pattern), pseudomembranous aspergillosis (which may obstruct the lumen of airways), and tracheobronchitis. Diagnosis of pulmonary aspergillosis is made by the identification of fungus in sputum, sputum casts, or BAL fluid in association with respiratory tract tissue invasion (Figure 29-10). Serum (1,3)-β-D-glucan levels may be elevated (see further on).

Cryptococcal Infection

Infection may manifest in one of two ways: either as primary cryptococcosis or complicating cryptococcal meningitis as part of disseminated infection with cryptococcemia, pneumonia, and cutaneous disease (umbilicated papules mimicking

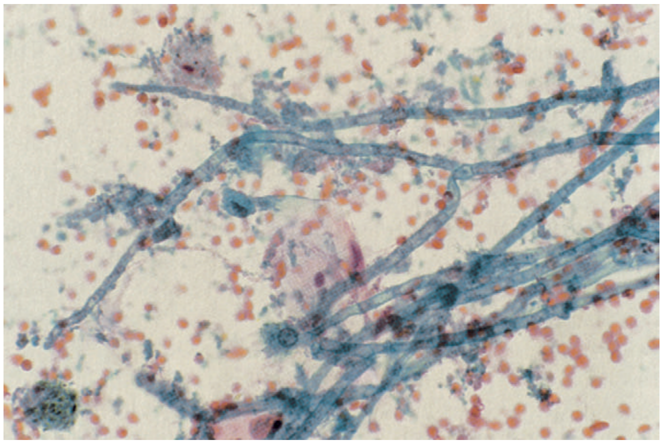

Figure 29-10 Bronchoalveolar lavage fluid containing *Aspergillus fumigatus* organisms.

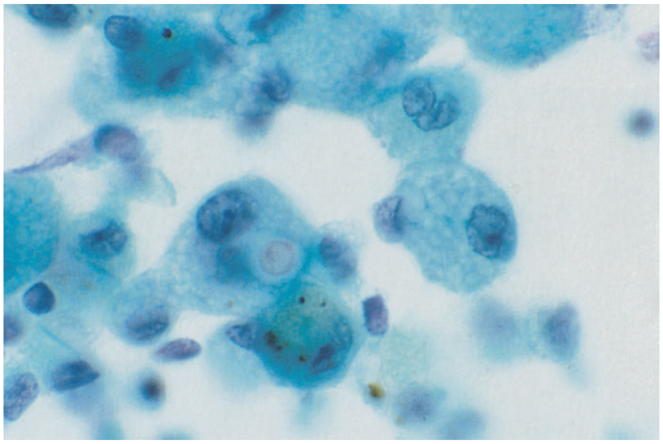

Figure 29-12 Bronchoalveolar lavage fluid containing *Cryptococcus neoformans* organisms.

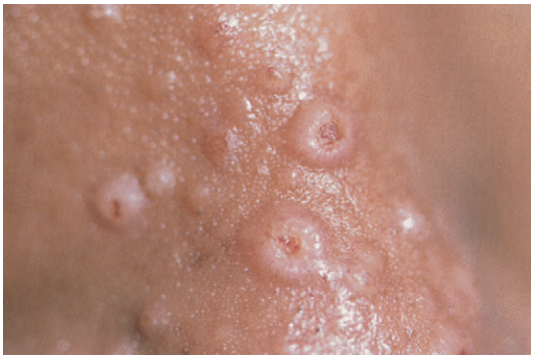

Figure 29-11 Skin changes in disseminated cryptococcosis. The multiple, umbilicated lesions resemble those of molluscum contagiosum.

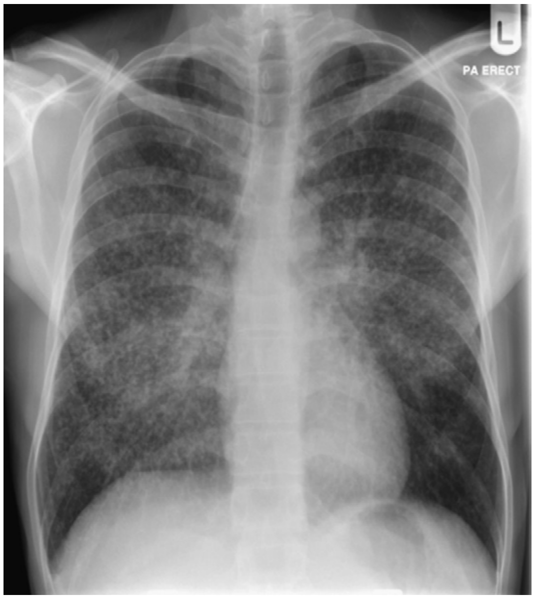

Figure 29-13 Chest radiograph showing pathologic changes of histoplasmosis.

molluscum contagiosum) (Figure 29-11). Primary pulmonary cryptococcosis presents in a very nonspecific way and is frequently indistinguishable from other pulmonary infections. In disseminated infection, the presentation frequently is overshadowed by headache, fever, and malaise (caused by meningitis). The time to onset may range from only a few days to several weeks. Examination may reveal skin lesions, lymphadenopathy, and meningism. In the chest, signs may be absent or crackles may be audible. Arterial blood gas analysis may reveal normal findings or show hypoxemia. The most common abnormality on the chest radiograph is focal or diffuse interstitial infiltrates. Less frequently, masses, mediastinal or hilar lymphadenopathy, nodules, and effusion are noted.

The diagnosis of cryptococcal pulmonary infection (Figure 29-12) is made by identification of *Cryptococcus neoformans* (by staining with India ink or mucicarmine, and by culture) in sputum, BAL fluid, pleural fluid, or lung biopsy tissue. Cryptococcal antigen may be detected in serum using the cryptococcal latex agglutination (CrAg) test. Titers usually are high but may be negative in primary pulmonary cryptococcosis, in which case BAL fluid (CrAg) is positive. In patients with disseminated infection, *C. neoformans* also may be cultured from blood and cerebrospinal fluid.

Endemic Mycoses

The endemic mycoses caused by *Histoplasma capsulatum*, *Coccidioides immitis*, and *Blastomyces dermatitidis* are found in HIV-infected patients living in North America (especially the Mississippi and Ohio River valleys). Histoplasmosis also is found in Southeast Asia, the Caribbean Islands, and South America. Coccidioidomycosis is endemic in the southwest United States (southern California), northern Mexico, and in parts of Argentina and Brazil. Blastomycosis has a similar distribution, with an extension north into Canada.

Histoplasmosis

Progressive, disseminated histoplasmosis in patients with HIV typically manifests with a subacute onset of fever and weight loss; approximately 50% of patients have mild respiratory symptoms with a nonproductive cough and dyspnea. Hepatosplenomegaly frequently is noted on examination, and a rash (similar to that produced by *Cryptococcus* spp.) may be seen. Rarely, the presentation may be rapidly fulminant, with clinical features of the sepsis syndrome including anemia or disseminated intravascular coagulation. The chest radiograph may be normal in appearance (in up to one third of patients), although characteristic abnormalities consist of bilateral, widespread nodules 2 to 4 mm in size (Figure 29-13). Other radiographic features are nonspecific and include interstitial infiltrates, reticular nodular shadowing, and alveolar consolidation. The diagnosis is made reliably by identification of the organism in Wright-stained peripheral blood or by Giemsa staining of bone marrow, lymph node, skin, sputum, BAL fluid, or lung tissue. It is important that identification be confirmed by detection of *H. capsulatum* var. *capsulatum* polysaccharide antigen by radioimmunoassay, which has a high sensitivity. False-positive results are possible in patients infected with *Blastomyces* and *Coccidioides* spp. Testing for *Histoplasma* antibodies by complement fixation or immunodiffusion techniques may give a negative result in immunosuppressed, HIV-positive patients. Serum (1,3)-β-D-glucan levels may be elevated (see further on).

Coccidioidomycosis

The clinical presentation of coccidioidomycosis is highly variable. The chest radiograph may show focal pulmonary disease with alveolar infiltrates, adenopathy, and intrapulmonary cavities or, alternatively, diffuse reticular shadowing. Diagnosis is made by isolation of the organism in sputum or BAL fluid. Disseminated disease is identified by isolating the fungus in blood, urine, or cerebrospinal fluid. Serologic tests also may be used for diagnosis.

Blastomycosis

Blastomycosis presents in patients who have advanced HIV infection, when CD4$^+$ lymphocyte counts are usually less than 200 cells/μL. Clinical signs and symptoms include cough, fever, dyspnea, and weight loss. Patients may present late in respiratory failure. Disseminated disease can occur with both pulmonary and extrapulmonary features. Involvement of multiple body systems including the skin, liver, brain, and meninges is common. Chest radiographic abnormalities include focal pneumonic change, miliary shadowing, or diffuse interstitial infiltrates. Diagnosis is made by culture from BAL fluid, skin, and blood. In this infection, early cytologic or histologic diagnosis is important, because culture of the organism may take 2 to 4 weeks. The mortality rate is high for disseminated infection.

Penicillium marneffei Infection

P. marneffei infection is particularly common in Southeast Asia. Most HIV-infected patients present with disseminated infection and solitary skin or oral mucosal lesions, or with multiple infiltrates in the liver or spleen, or bone marrow (leading to presentation with pancytopenia). Pulmonary infection has no specific clinical features, and chest radiographs may be normal-appearing or show diffuse, small nodular infiltrates. Diagnosis is made by identifying the organism in bone marrow, skin biopsy specimens, blood films, or BAL fluid. The differential diagnosis for *P. marneffei* infection includes both PCP and tuberculosis.

VIRAL INFECTIONS

Community-Based Respiratory Viral Infections

Influenza A

HIV-infected persons do not have a greater incidence of influenza A but may be at increased risk for more severe disease. This susceptibility is due to associated medical comorbid conditions.

HIV-infected patients with seasonal or H1N1 influenza typically present with an acute respiratory illness (e.g., coryzal symptoms) with fever, headache, and myalgia. Vomiting and diarrhea occur more often with H1N1 influenza than with seasonal influenza. Some patients with seasonal or H1N1 influenza may not have fever. Careful clinical assessment, together with awareness of local surveillance data on circulating influenza viruses and other community-prevalent respiratory pathogens, is important in the differential diagnosis for patients presenting with an influenza-like illness. In some HIV-infected patients, especially those with low CD4$^+$ cell counts (less than 100 cells/μL), the illness may progress rapidly (**Figure 29-14**) and can be complicated by secondary bacterial pneumonia. The diagnosis is made by detection of viral antigen or RNA, or by culture of nasopharyngeal aspirate or nasal swab.

CYTOMEGALOVIRUS INFECTION

CMV frequently is isolated from BAL fluid from patients with CD4$^+$ counts below 100 cells/μl; however, the role of CMV in causing disease in this context is unclear (see later).

In patients in whom CMV is the sole identified pathogen, clinical presentation and chest radiographic abnormalities (usually diffuse interstitial infiltrates) are nonspecific. Diagnosis of CMV pneumonitis is made by identifying characteristic intranuclear and intracytoplasmic inclusions, not only in cells in BAL fluid but also in lung biopsy specimens (**Figure 29-15**).

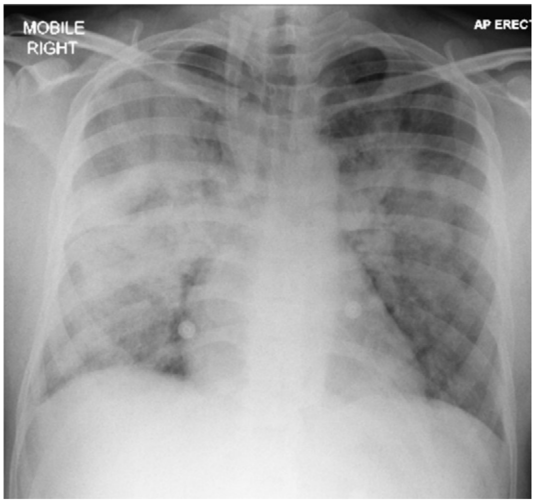

Figure 29-14 Chest radiograph showing pathologic changes of severe H1N1 influenza.

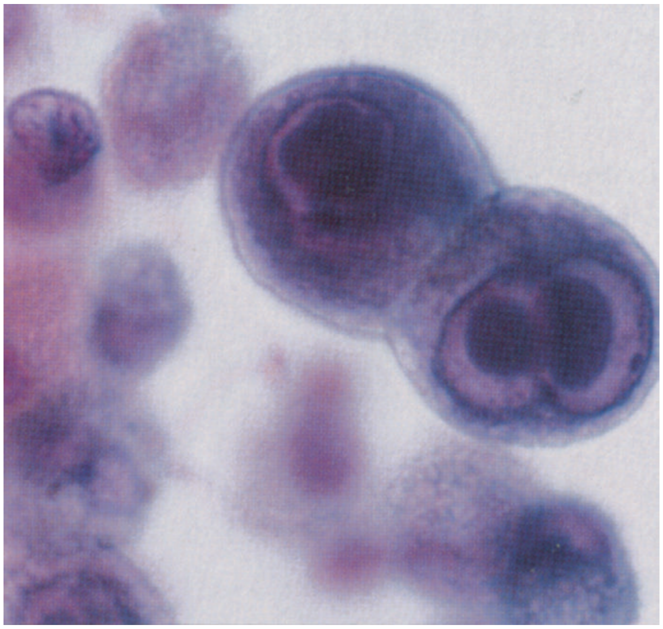

Figure 29-15 Bronchoalveolar lavage fluid containing cytomegalovirus inclusions.

PROTOZOAL INFECTIONS

Leishmaniasis

Pulmonary involvement with *Leishmania* spp. may rarely occur as part of the syndrome of visceral leishmaniasis in HIV-infected patients. Patients usually have advanced HIV disease with $CD4^+$ lymphocyte counts below 300 cells/μL and present with fever, splenomegaly, and leukopenia. Respiratory symptoms often are absent. Diagnosis of visceral leishmaniasis most often is made by staining and culture of splenic or bone marrow aspirate. Occasionally the parasite is found by chance in a skin or rectal biopsy specimen or BAL fluid taken for other purposes. The chest radiograph may be normal in appearance or show reticular-nodular infiltrates.

Toxoplasmosis

Toxoplasma gondii infection in HIV-infected patients usually occurs as a result of reactivation of latent, intracellular protozoa acquired in a primary infection. Toxoplasmic pneumonia frequently manifests with nonproductive cough and dyspnea. Chest radiographic abnormalities include diffuse interstitial infiltrates indistinguishable from those of PCP (Figure 29-16), as well as micronodular infiltrates, a coarse nodular infiltrate, cavitary change, and lobar consolidation. The diagnosis is made by hematoxylin-eosin or Giemsa staining of BAL fluid, which reveals cysts and trophozoites of *T. gondii*. Staining of BAL fluid is not always positive; the diagnostic yield is increased either by staining of transbronchial biopsy material or by performing PCR assay to detect *T. gondii* DNA in BAL fluid.

Strongyloidiasis

The nematode *Strongyloides stercoralis* is endemic in warm countries worldwide. In immunosuppressed patients, the organism has an increased ability to reproduce parthenogenetically in the gastrointestinal tract without the need for repeated exposure to new infection—so-called autoinfection. This enhanced reproductivity results in a great increase in worm load, and a hyperinfective state ensues; massive acute dissemination with *S. stercoralis* may occur in the lungs, kidneys, pancreas, and brain. Although infection with *S. stercoralis* is more severe in immunocompromised patients, it is no more common in patients who have HIV infection. Presentation with hyperinfection may be with fever, hypotension secondary to bacterial sepsis, or disseminated intravascular coagulation. The clinical features of respiratory *S. stercoralis* infection are very nonspecific. *S. stercoralis* in sputum or BAL fluid (Figure 29-17) may be identified in HIV-positive patients in the absence of symptoms elsewhere; this can predate disseminated infection and as such requires prompt treatment.

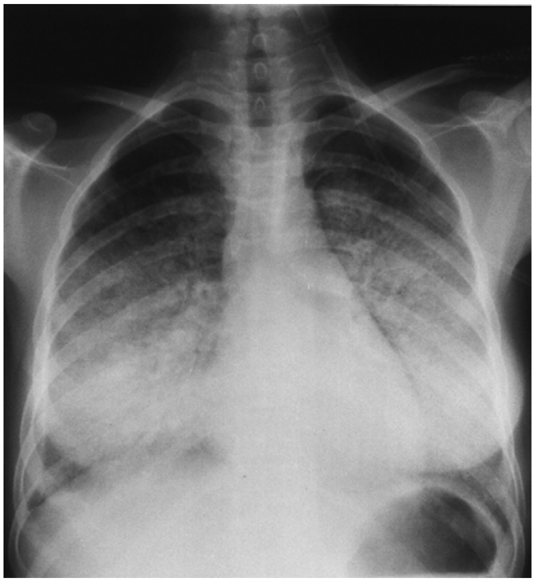

Figure 29-16 Chest radiograph showing pathologic changes of *Toxoplasma gondii* pneumonia. The diffuse bilateral infiltrates resemble those in *P. jirovecii* pneumonia. *(Reproduced from Miller RF, Lucas SB, Bateman NT: Disseminated* Toxoplasma gondii *infection presenting with a fulminant pneumonia*, Genitourin Med *72:139–143, 1996.)*

DIAGNOSIS

It is apparent from the foregoing discussion that HIV-related pneumonias of any cause may present in a very similar manner. A wide range of investigations are available to aid diagnosis. These are listed in Box 29-3. If the subject is producing sputum,

Box 29-3 Tests Available to Aid Diagnosis of Human Immunodeficiency Virus (HIV) Infection–Related Pneumonia

Physiologic
Transcutaneous pulse oximetry
Arterial blood gas analysis
Lung function testing

Radiologic
Chest radiography
Computed tomography scan of thorax

Histopathologic
Serologic studies (antigen or antibody testing)
Serum lactate dehydrogenase measurement
Microscopy and culture of body fluid/tissue (e.g., sputum, blood, bronchoalveolar lavage fluid, lung tissue) obtained by:
- Sputum induction
- Bronchoscopy and bronchoalveolar lavage
- Bronchoscopy and transbronchial biopsy
- VATS lung biopsy

Nucleic acid detection of specific organisms (e.g., by polymerase chain reaction assay for *Pneumocystis jirovecii* in bronchoalveolar lavage fluid or induced sputum)

VATS, video-assisted thoracoscopic surgery.

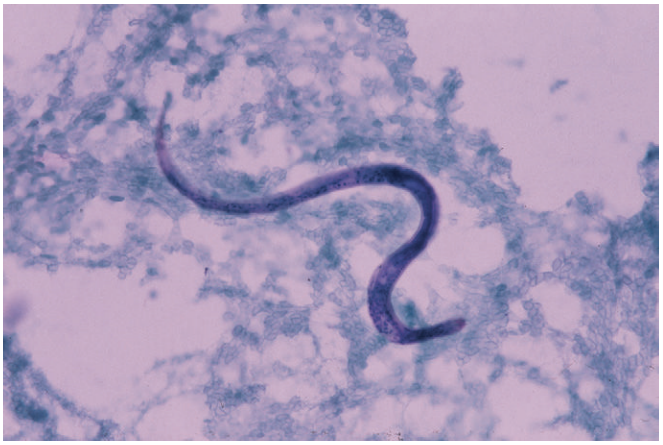

Figure 29-17 Bronchoalveolar lavage fluid sample containing an adult *Strongyloides stercoralis* roundworm.

it is important to obtain samples for bacterial and mycobacterial detection. In up to one third of cases, these will assist in diagnosis. Obtaining three samples on consecutive days (preferably either with overnight or early morning production) is the crucial first step in the diagnosis of pulmonary tuberculosis. This is considerably easier and safer for health care personnel than obtaining hypertonic saline–induced sputum or BAL fluid. Blood cultures also are important, because very high rates of bacteremia have been reported in both bacterial and mycobacterial disease (see earlier).

A patient who presents with symptoms and signs consistent with pneumonia should have chest radiography and arterial oxygen assessments performed at the first consultation. The question at this stage usually is whether this infectious episode is due to bacterial infection, tuberculosis, or PCP. In general, alveolar and interstitial shadowing is taken as evidence for PCP, although important caveats apply.

Until tuberculosis has been ruled out, the patient should be segregated from other people in hospital and community environments and should be made aware of personal infection control measures such as "cough hygiene."

ARTERIAL OXYGEN ASSESSMENTS

Transcutaneous pulse oximetry and arterial blood gas analysis are useful tests for hypoxemia. They can be used to distinguish an alveolar condition (i.e., PCP) from bacterial pneumonia. The alveolitis produces a greater impairment of oxygen transfer (especially during exercise), such that for a given clinical situation there will be more hypoxemia and a wider alveolar-arterial oxygen gradient (i.e., $PO_2[A–a]$) in those with PCP. With use of pulse oximetry, this manifests as low oxygen saturation at rest that decreases further with exercise. In general, more information can be obtained from arterial blood gas analysis, although this advantage is offset by the need for direct arterial puncture.

Of patients with PCP, fewer than 10% have a normal PaO_2 and a normal $PO_2(A–a)$. These measures are sensitive, although not particularly specific for PCP, and similar results may occur with bacterial pneumonia, pulmonary Kaposi sarcoma, and *M. tuberculosis* infection. The diagnostic value of identifying exercise-induced desaturation, measured by transcutaneous oximetry, has been validated only in HIV-infected patients who have PCP and a normal or near-normal appearance on the chest radiograph. The test's value has not been confirmed in patients with radiographic abnormalities due to PCP or other pathogens. Exercise-induced desaturation may persist for many weeks after treatment and recovery from PCP, even in the absence of active pulmonary disease.

LUNG FUNCTION TESTING

Abnormalities of lung function are well documented with HIV infection. The most common of these relate to tests measuring gas exchange, rather than the size of the conducting airways. In general, an overall reduction in diffusing capacity for carbon monoxide (DLCO) occurs at all stages of HIV infection, with the largest changes found in HIV-infected patients with PCP. A normal DLCO in a patient with symptoms but a normal-appearing or unchanged chest radiograph makes the diagnosis of PCP extremely unlikely. Data from the North American Pulmonary Complications of HIV Infection Study (PCHIS) suggest that patients with rapid rates of decline in DLCO are at an increased risk for development of PCP. A recent cross-sectional study of HIV-infected patients showed 47% had respiratory symptoms. Almost two thirds of patients had diffusion impairment, which was associated with a history of past or present smoking ("ever smoking") and receipt of PCP prophylaxis. Approximately 21% had irreversible airway obstruction. This finding was associated with pack-years smoked and injection drug use and with receipt of ART.

COMPUTED TOMOGRAPHY SCANNING

High-resolution (thin-section) CT scanning of the chest may be helpful when the chest radiographic appearance is normal, unchanged, or equivocal. The characteristic appearance of an alveolitis (i.e., areas of ground glass attenuation through which the pulmonary vessels can be clearly identified) may be present, which indicates active pulmonary disease (**Figure 29-18**). This feature, however, is neither sensitive nor specific for PCP, although its sensitivity can be improved if evidence for reticulation or small cystic lesions is added. Hence, a negative test result implies an alternative diagnosis.

BIOCHEMICAL ASSAYS

Lactate Dehydrogenase

In an HIV-infected patient who presents with an acute or subacute pneumonitis, an elevated serum lactate dehydrogenase (LDH) level is strongly suggestive of PCP. In interpreting such results, it is important to recognize that other pulmonary disease processes (e.g., pulmonary embolism; nonspecific pneumonitis; fungal, bacterial, and mycobacterial pneumonia) and extrapulmonary disease (Castleman disease and lymphoma) also may cause elevations of LDH and may need to be considered in the correct clinical context.

Plasma or Serum *S*-Adenosylmethionine

The rationale behind use of the plasma or serum *S*-adenosylmethionine (SAM or AdoMet) assay is that *Pneumocystis* was thought to be unable to metabolize SAM, because it lacks a SAM synthetase and therefore scavenges this from its host. According to this hypothesis, patients with PCP might be expected to have low SAM levels. Some studies have shown that plasma AdoMet levels can be used to distinguish HIV-infected patients with PCP from those with other-cause pneumonia (e.g., bacterial pneumonia or tuberculosis) and found no

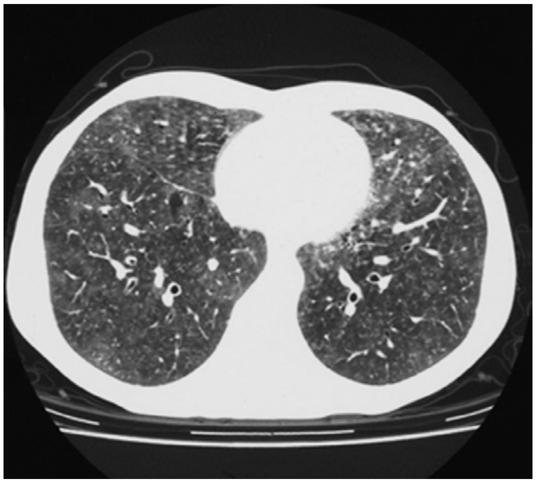

Figure 29-18 Computed tomography scan of thorax showing diffuse bilateral ground glass shadowing typical of *Pneumocystis* pneumonia.

overlap in AdoMet levels between those with and those without PCP. Another study that measured serum AdoMet reported overlapping levels in HIV-infected patients with PCP and other-cause pneumonia. Currently measurement of serum or plasma AdoMet is not used for diagnosis of PCP.

Serum (1,3)-β-D-Glucan

In all fungi, including *Pneumocystis,* (1,3)-β-D-glucan is a cell wall component. Serum (1,3)-β-D-glucan levels are higher in patients with PCP (with or without underlying HIV infection) when compared to patients without PCP. The sensitivity and specificity of this assay are maximal using a cutoff of 100 pg/mL (for diagnosis of PCP). Because serum (1,3)-β-D-glucan levels may be elevated in pneumonia caused by several fungal pathogens, this test does not permit discrimination among potential etiologic disorders (e.g., PCP, *Aspergillus* infection, histoplasmosis). Additionally, case reports of false-positive results in patients with pulmonary infection due to *P. aeruginosa* further limit diagnostic utility. Among patients with confirmed PCP, use of serum (1,3)-β-D-glucan levels to monitor response to therapy requires further evaluation.

From the preceding discussion, it is evident that noninvasive tests cannot reliably distinguish the different infecting agents from each other but may be useful in excluding acute opportunistic disease. Thus, the clinician is left with either proceeding to diagnostic lung fluid or tissue sampling (using either induced sputum collection or bronchoscopy and BAL with or without transbronchial biopsy) (Table 29-5) or treating an unknown condition empirically. ART also has altered the investigation of respiratory disease. The numbers of invasive procedures performed are falling, and such procedures tend to be used in patients not taking antiretroviral drugs (usually to exclude PCP), or in whom no response to empirical antibiotic therapy (regardless of the CD4$^+$ count) has been observed.

INDUCED SPUTUM

Spontaneously expectorated sputum is inadequate for diagnosis of PCP. Sputum induction by inhalation of ultrasonically nebulized hypertonic saline may provide a suitable specimen (see Table 29-5). The technique requires close attention to detail and is much less useful when samples are purulent. Sputum induction must be carried out away from other immunosuppressed patients and health care workers, ideally in a room with separate negative-pressure ventilation, to reduce the risk of nosocomial transmission of tuberculosis. Although very specific (at a rate greater than 95%), the sensitivity of induced sputum varies widely (55% to 90%), and therefore a negative result for *P. jirovecii* prompts further diagnostic studies. The use of immunofluorescence staining enhances the yield of induced sputum compared with standard cytochemistry.

BRONCHOSCOPY

Fiberoptic bronchoscopy with BAL commonly is used to diagnose HIV-related pulmonary disease. When a good “wedged” sample is obtained, the test has a sensitivity of greater than 90% for detection of *P. jirovecii* (Figure 29-19). Just as with induced sputum, fluorescent staining methods increase the diagnostic yield, which makes bronchoscopy the procedure of choice in most centers. More technically demanding (both of the patient and of the operator) than induced sputum collection, bronchoscopy and BAL have the advantage that direct inspection of the upper airway and bronchial tree can be performed and, if necessary, biopsy specimens taken. Transbronchial biopsy may marginally increase the diagnostic yield of the procedure. This is relevant for the diagnosis of mycobacterial disease, although the relatively high complication rate in HIV-infected persons (pneumothorax and the possibility of significant pulmonary hemorrhage in up to 10%) outweighs the advantages of the technique for routine purposes.

Samples of BAL fluid are examined for bacteria, mycobacteria, viruses, fungi, and protozoa. Inspection of the cellular component also may provide etiologic clues—cooperation of a pathology department with experience in opportunistic infection diagnosis is vital. The drug interactions associated with antiretroviral protease inhibitor therapy mean that special care should be exercised with use of sedation with either benzodiazepine or opiate drugs. Prolonged sedation and life-threatening arrhythmias have been reported.

A diagnostic strategy therefore includes sputum induction and, if results are nondiagnostic or if the test is unavailable, bronchoscopy and BAL. If this approach does not yield a result, consideration is given to either a repeat bronchoscopy and BAL

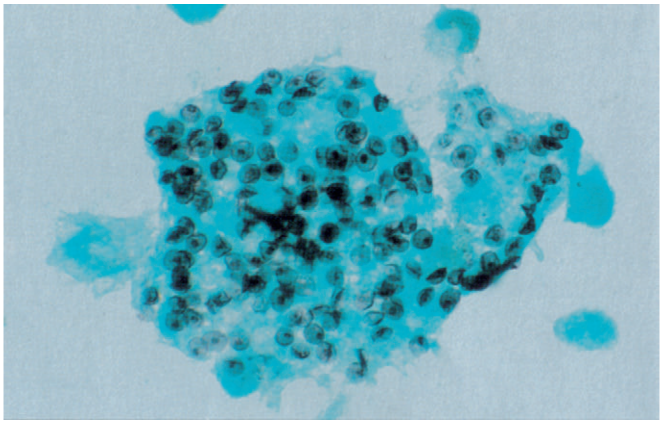

Figure 29-19 Bronchoalveolar lavage fluid containing *Pneumocystis jirovecii* organisms. (Grocott silver stain.)

Table 29-5 Induced Sputum, Bronchoalveolar Lavage, and Surgical Biopsy in Diagnosis of *Pneumocystis jirovecii* Pneumonia

Technique	Ease of Procedure	Diagnostic Sensitivity (%)	Cost	Comments
Induced sputum	Simple—once technique established	50-90	Low	Requires dedicated health care worker(s) and facility Risk to health care workers from expectorated aerosol
Bronchoalveolar lavage	Moderate	90->95	Moderate	Risk of deterioration after procedure Risk to health care workers from coughed secretions Sensitivity may be increased by two-lobe lavage
Surgical biopsy	Complex	>95	High	Requires health care workers with surgical expertise

with transbronchial biopsy or video-assisted thoracoscopic surgery (VATS) for biopsy.

EMPIRICAL DIAGNOSIS AND THERAPY

Although empirical therapy usually is reserved for the management of presumed bacterial pneumonias and initially may appear unwise when the underlying disease may be an opportunistic infection, in reality PCP is almost invariably a diagnosis of exclusion, and certain clinical and laboratory features may guide the assessment of an HIV-infected patient's risk for this condition. The likelihood that *P. jirovecii* is the causative organism increases if the person is not taking effective anti-*Pneumocystis* drug prophylaxis or has a previous medical history with clinical or laboratory features suggestive of systemic immunosuppression (i.e., recurrent oral thrush, long-standing fever of unknown cause, clinical AIDS, or blood CD4^+ count less than 200 cells/μL). Hence, some centers advocate use of empirical therapy for HIV-infected patients who present with symptoms and chest radiographic and blood gas abnormalities typical of mild PCP, without the need for bronchoscopy. Invasive measures are reserved for patients with an atypical radiographic presentation, those who fail to respond to empirical therapy by day 5, and those who exhibit clinical deterioration at any stage.

Most clinicians in the United States and the United Kingdom would seek to obtain a confirmed diagnosis in every case of suspected PCP. In practice, both strategies discussed above appear to be equally effective, although a number of caveats should be borne in mind when empirical treatment is given for PCP. Patients who have PCP typically take 4 to 7 days to show clinical signs of improvement, so a bronchoscopically proven diagnosis ensures that the treatment being given is correct, particularly in the first few days of therapy, when the drug regimen may not be well tolerated. In addition, the diagnosis of PCP has implications for the infected person, because it may influence the decision to start either ART or anti-*Pneumocystis* prophylaxis. Finally, empirical therapy requires the patient to be maximally adherent with treatment, because nonresolution of symptoms may be seen as a failure of therapy, rather than of compliance.

TREATMENT

Persons infected with HIV, compared with the non–HIV-infected general population, have an increased likelihood of adverse reactions to therapeutic agents. Such agents include TMP-SMX (see later on) and other antibacterial and antimycobacterial agents. In addition, complex drug interactions with other medications, particularly components of ART, have been reported. Before institution of therapy for any infectious complication in an HIV-infected patient, it is important to consult with a physician experienced in the care of such patients and to seek advice from a specialist pharmacist.

TREATMENT OF BACTERIAL PNEUMONIA

The main organisms causing pneumonia in HIV-infected persons are similar to those found in the general population with community-acquired pneumonia. Thus, bacterial pneumonia in HIV-infected patients should be treated in a manner similar to that in HIV-negative persons, using published American Thoracic Society (ATS) and British Thoracic Society (BTS) guidelines. In addition, expert advice on local antibiotic resistance patterns should be sought from infectious disease or microbiology colleagues, because treatment usually is begun on an empirical basis before the causative organism is identified and antibiotic sensitivities are known. The same clinical and laboratory prognostic indices that are described for the general population apply to HIV-infected patients and should be documented on presentation.

Response to appropriate antibiotic therapy usually is rapid and is similar to that seen in the non–HIV-infected person. Early relapse of infection after successful treatment is well described. Those HIV-infected patients who have presumed PCP and are being treated empirically with high-dose TMP-SMX, and who have infection with either *S. pneumoniae* or *H. influenzae*, rather than *P. jirovecii*, also may improve. In addition, in those patients who are treated with benzylpenicillin for proven *S. pneumoniae* pneumonia but do not respond, and penicillin resistance can be discounted as the cause, it is important to consider the possibility of a second pathologic process, such as PCP. Copathogens are reported in up to 20% of cases of pneumonia.

TREATMENT OF PNEUMOCYSTIS JIROVECII *PNEUMONIA*

Before institution of treatment, assessment of the severity of PCP should be performed, to include a thorough history, physical examination, arterial blood gas analysis, and chest radiography. On the basis of the findings, patients can then be stratified into those with mild, moderate, or severe disease (Table 29-6).

Table 29-6 **Grading Severity of *Pneumocystis jirovecii* Pneumonia**

	Disease Severity		
Clinical Feature	**Mild**	**Moderate**	**Severe**
Symptoms and signs	Dyspnea on exertion with or without cough and sweats	Dyspnea on minimal exertion and occasionally at rest; cough and fever	Dyspnea and tachypnea at rest; persistent fever and cough
Oxygenation			
Pao_2 on room air, at rest (mm Hg)	>83	61-83	≤8.0; ≤60
Sao_2 on room air	>96	91-96	<91
Sao_2 with exercise	>90	<90	<90
$\text{Po}_2\text{(A–a)}$ (mm Hg)	<35	35-45	>45
Chest radiographic appearance	Normal or minor perihilar shadowing	Diffuse interstitial shadowing	Extensive interstitial shadowing with or without diffuse alveolar shadowing

This classification is important, because some drugs are of unproven benefit and others are known to be ineffective for the treatment of severe disease. In addition, adjuvant glucocorticoid therapy may be given to patients with moderate or severe pneumonia. Before (or as soon as feasible after) starting therapy with TMP-SMX, dapsone, or primaquine, patients should be tested for glucose-6-phosphate dehydrogenase deficiency, because these drugs increase the risk of hemolysis.

Trimethoprim-Sulfamethoxazole

Several drugs are effective in the treatment of PCP. TMP-SMX is the drug of first choice (Tables 29-7 and 29-8). Overall, it is effective in 70% to 80% of patients when used for first-line therapy. Adverse reactions to TMP-SMX are common and usually become apparent between days 6 and 14 of treatment. Neutropenia and anemia (in up to 40% of patients), rash and fever (up to 30%), and biochemical abnormalities of liver function (up to 15%) are the most frequent adverse reactions. Hematologic toxicity induced by TMP-SMX is neither attenuated nor prevented by coadministration of folic or folinic acid. Furthermore, the use of these agents may be associated with reduced therapeutic success. During treatment with TMP-SMX, monitoring with full blood counts, liver function testing, and measurements of urea and electrolytes at least twice weekly is indicated.

It is not known why HIV-infected patients, especially those with higher CD4$^+$ counts, experience such a high frequency of adverse reactions to TMP-SMX. The optimal strategy for management of an HIV-infected patient who has PCP and who becomes intolerant of high-dose TMP-SMX has not been

Table 29-7 **Treatment of *Pneumocystis jirovecii* Pneumonia According to Disease Severity**

	Effective Agent or Regimen		
Regimen Category	**Mild Disease**	**Moderate Disease**	**Severe Disease**
First choice	Trimethoprim-sulfamethoxazole	Trimethoprim-sulfamethoxazole	Trimethoprim-sulfamethoxazole
Second choice	Clindamycin-primaquine OR Trimethoprim-dapsone OR Atovaquone	Clindamycin-primaquine OR Intravenous pentamidine OR Trimethoprim-dapsone	Clindamycin-primaquine OR Intravenous pentamidine
Adjuvant corticosteroids	Benefit not proven	Benefit proven	Benefit proven

Table 29-8 **Treatment Schedules for *Pneumocystis jirovecii* Pneumonia***

Drug	**Dosage**	**Comments**
Trimethoprim-sulfamethoxazole (TMP-SMX)	Trimethoprim 15-20 mg/kg IV q24h plus sulfamethoxazole 75-100 mg/kg IV daily in divided doses, q6h or q8h	Give IV for moderate to severe disease, can change to oral formulation after clinical improvement
	Same daily dose of TMP-SMX as above, given in divided doses q8h for 21 days OR 1920 mg (two TMP-SMX double-strength tablets) PO q8h for 21 days	Given for mild disease
Clindamycin-primaquine	Clindamycin 600-900 mg IV q6h-q8h plus primaquine 15-30 mg PO q24h for 21 days OR Clindamycin 300-450 mg PO q6h-q8h plus primaquine 15-30 mg PO q24h for 21 days	Methemoglobinemia less likely if primaquine dose of 15 mg PO q24h is used
Pentamidine	4 mg/kg IV q24h for 21 days	Diluted in 250 mL of 5% dextrose in water and infused over 60 minutes 3 mg/kg IV q24h for 21 days used by some clinicians to reduce toxicity
Trimethoprim-dapsone	Trimethoprim 15 mg/kg PO q24h in divided doses q8h plus dapsone 100 mg PO q24h for 21 days	
Atovaquone	750 mg PO q12h for 21 days	Give with food to increase absorption
Glucocorticoids	Prednisolone 40 mg PO q12h on days 1-5, then 40 mg PO q24h on days 6-10, then 20 mg PO q24h on days 11-21 OR Methylprednisolone IV at 75% of dose given above for prednisolone	Regimen recommended by CDC/NIH/IDSA; widely used in United States
	Methylprednisolone 1 g IV q24h on days 1-3, then 0.5 g IV q24h on days 4-6, then prednisolone 40 mg PO q24h, tapered to 0 over days 7-16	Regimen widely used in United Kingdom

*NOTE: None of these regimens for adjuvant glucocorticoids therapy have been compared in prospective clinical trials.
CDC, Centers for Disease Control and Prevention; *NIH*, National Institutes of Health; *IDSA*, Infectious Diseases Society of America.

established. Many physicians advocate "treating through" minor rash, often adding an antihistamine and a short course of oral prednisolone (30 mg every 24 hours, tapering to zero over 5 days).

Other Therapeutic Agents

If treatment with TMP-SMX fails, or is not tolerated by the patient, several alternative therapies are available (see Tables 29-7 and 29-8).

Clindamycin-Primaquine

The combination of clindamycin and primaquine is widely used for treatment of PCP whatever the severity. The combination is as effective as oral TMP-SMX and oral trimethoprim-dapsone for the treatment of mild and moderate-severity disease. As a second-line treatment it is effective in up to 90% of patients. Methemoglobinemia due to primaquine occurs in up to 40% of patients. If a once-daily dose of 15 mg rather than 30 mg of primaquine is used, the likelihood of methemoglobinemia is reduced. Diarrhea develops in up to 33% of patients receiving clindamycin. In such instances, stool samples should be analyzed for the presence of *Clostridium difficile* toxin.

Trimethoprim-Dapsone

This oral combination is as effective as oral TMP-SMX and oral clindamycin plus primaquine (see earlier) for treatment of mild and moderate-severity PCP. The combination has not been shown to be effective in patients who have severe PCP. Most patients experience methemoglobinemia (caused by dapsone), which usually is asymptomatic. Up to one half of patients have mild hyperkalemia caused by trimethoprim.

Atovaquone

Atovaquone is licensed for the treatment of mild and moderate-severity PCP in patients who are intolerant of TMP-SMX. In tablet formulation (no longer available), this drug was less effective but was better tolerated than TMP-SMX or intravenous pentamidine for treatment of mild or moderate-severity PCP (see Tables 29-7 and 29-8). There are no data from prospective studies that compare the liquid formulation (which has better bioavailability) with other treatment regimens. Common adverse reactions include rash, fever, nausea and vomiting, and constipation. Absorption of atovaquone is increased if it is taken with food.

Intravenous Pentamidine

Intravenous pentamidine is now seldom used for the treatment of mild or moderate-severity PCP because of its toxicity. Intravenous pentamidine may be used in patients who have severe PCP, despite its toxicity, if other agents have failed (see Tables 29-7 and 29-8). Nephrotoxicity develops in almost 60% of patients given intravenous pentamidine (indicated by elevation in serum creatinine), leukopenia develops in approximately half, and up to 25% have symptomatic hypotension or nausea and vomiting. Hypoglycemia occurs in approximately 20% of patients. Because of the long half-life of the drug, this effect may emerge up to several days after the discontinuation of treatment. Pancreatitis also is a recognized side effect.

Caspofungin

The echinocandin caspofungin inhibits (1,3)-β-D-glucan synthase and is effective against *Aspergillus* and *Candida*. Case reports and small case series show that a regimen of caspofungin, used alone or in combination with other therapy, may be effective therapy for PCP in patients not responding to or tolerating first-line therapy. It has not been prospectively evaluated against TMP-SMX or other therapeutic agents for first-line therapy.

Adjuvant Glucocorticoids

For patients who have moderate and severe PCP, adjuvant glucocorticoid therapy reduces the risk of respiratory failure by up to half, and the risk of death by up to one third (see Tables 29-7 and 29-8). Glucocorticoids are given to HIV-infected patients with confirmed or suspected PCP who have a PaO_2 less than below 70 mm Hg or a $PO_2(A–a)$ greater than greater than 33 mm Hg. Oral or intravenous adjunctive therapy is given at the same time as (or within 72 hours of starting) specific anti–*P. jirovecii* therapy. Clearly, in some patients treatment is commenced on a presumptive basis, pending confirmation of the diagnosis. If glucocorticoids are started at a later time, the benefits are less clear, although most clinicians would use these agents in patients with moderate or severe PCP. In prospective studies, adjuvant glucocorticoids have not been shown to be of benefit in patients with mild PCP. However, it would be difficult to demonstrate this, given that survival in such cases approaches 95% with standard treatment.

General Management of *Pneumocystis jirovecii* Pneumonia

Mild PCP may be treated on an outpatient basis with oral TMP-SMX if the patient is able to manage at home, is willing to attend the outpatient clinic for regular review, and exhibits clinical and radiographic evidence of recovery. If the patient is intolerant of oral TMP-SMX despite clinical recovery, either the drug is switched to an intravenous formulation or the regimen may be changed to oral clindamycin plus primaquine. All patients with moderate and severe PCP should be hospitalized and given intravenous TMP-SMX or intravenous clindamycin and oral primaquine (plus adjuvant steroids). Patients with moderate or severe disease who show clinical and radiographic response by days 7 to 10 of therapy may be switched to oral TMP-SMX to complete the remaining 14 days of treatment. If the patient has failed to respond within 7 to 10 days or deteriorates before this time, while receiving TMP-SMX, then treatment should be changed to clindamycin and primaquine, or intravenous pentamidine.

Deterioration in the Patient with *Pneumocystis jirovecii* Pneumonia

Deterioration in a patient who is receiving anti–*P. jirovecii* therapy may occur for several reasons (**Table 29-9**). Before deterioration is ascribed to treatment failure necessitating a change in therapy, these alternatives should be evaluated carefully. It also is important to consider treating for any copathogens present in BAL fluid and to perform bronchoscopy if the diagnosis was made empirically, and to repeat the procedure or carry out open lung biopsy to confirm that the diagnosis is correct.

Prognosis

The prognosis for patients with severe PCP with respiratory failure requiring admission to the ICU has improved over the last decade. This improvement probably is due to better management of respiratory failure and ARDS, rather than to specific improvements in PCP care or to use of ART (see further on). Factors associated with poor outcome include increasing patient

Table 29-9 Causes of Clinical Deterioration in a Human Immunodeficiency Virus (HIV)-Infected Patient with *Pneumocystis jirovecii* Pneumonia

Cause	Comments
Severe progressive pneumonia	
Side effects of therapy	Drug-induced anemia Drug-induced methemoglobinemia
Iatrogenic	Pulmonary edema due to fluid overload
Postbronchoscopy	Sedation Pneumothorax
Pneumothorax	Spontaneous
Copathology in lung	Bacterial infection CMV infection Intercurrent pulmonary embolism
Wrong diagnosis	When diagnosis of PCP is empirical and is in fact bacterial pneumonia
Inadequate therapy	Wrong dose or route of administration Adjuvant glucocorticoids omitted in moderate or severe disease

CMV, cytomegalovirus; *PCP*, *Pneumocystis* pneumonia.

age, need for mechanical ventilation, and development of a pneumothorax. The last factor reflects both the association between this complication and PCP and the subsequent difficulty in successful mechanical ventilation of such patients.

Timing of Initiation of Antiretroviral Therapy in a Patient with *Pneumocystis* Pneumonia

The optimal timing of initiation of ART after PCP remains to be determined; some clinicians start ART immediately, whereas others prefer to see a clinical response to PCP treatment. One randomized trial of patients with opportunistic infection, approximately two thirds of whom had PCP, demonstrated that ART was associated with a significant reduction in mortality but no evidence of increased IRIS when ART was initiated early (within 2 weeks) compared with deferred therapy (i.e., at 4 weeks or later after initiation of treatment for the opportunistic infection. Although this study supports early ART, it does not show whether immediate treatment at time of PCP diagnosis or waiting for a response to PCP treatment (usually within 4 to 7 days) is the best strategy. Furthermore, the study excluded those with severe laboratory abnormalities and required patients to be able to take oral medication, so mechanically ventilated patients were not studied, suggesting possible selection bias in favor of less sick patients.

TREATMENT OF MYCOBACTERIAL DISEASES

Treatment of Tuberculosis

The treatment of HIV-related mycobacterial disease is complex. Not only do patients have to take prolonged courses of relatively toxic agents, but also these antimycobacterial drugs have side effects similar to those of other prescribed medications, especially those used for ART. Drug-drug interactions also are extremely common.

Overlapping Toxicity

In the developed world, isoniazid-related peripheral neuropathy is rare in HIV-negative subjects taking pyridoxine. The nucleoside reverse transcriptase inhibitors (RTI) didanosine and stavudine, which are now less rarely used in the United States and the United Kingdom, but which frequently are seen in the developing world can also cause a painful peripheral neuropathy. This complication develops in up to 30% of patients if stavudine and isoniazid are coadministered. Rash, fever, and biochemical hepatitis are common adverse events with rifamycins, pyrazinamide, and isoniazid (occurring more frequently in patients with tuberculosis who have HIV infection with hepatitis C coinfection). The non-nucleoside RTI drugs (e.g., nevirapine) have a similar toxicity profile. If treatment for both HIV and tuberculosis is coadministered, then ascribing a cause may be problematic.

Drug-Drug Interactions

Drug-drug interactions between medications used to treat tuberculosis and HIV infection occur because of their common pathway of metabolism, through the hepatic cytochrome P-450 enzyme system. Rifampin is a potent inducer of this enzyme (rifabutin less so), which may result in subtherapeutic levels of non-nucleoside RTI and protease inhibitor antiretroviral drugs, with the potential for inadequate suppression of HIV replication and the development of resistance to HIV. In addition, the protease inhibitor class of antiretroviral drugs inhibits the metabolism of rifamycins, which leads to increases in their plasma concentration and is associated with increased drug toxicity. The non-nucleoside RTI drugs are inducers of this enzyme pathway. Coadministration of rifabutin with efavirenz requires an increase in the dose of rifabutin to compensate for the increase in its metabolism induced by efavirenz (see later). The newer classes of ART such as integrase inhibitors (e.g., raltegravir) or second-generation non-nucleoside RTI (e.g., rilpivirine) also are significantly affected by rifamycins.

Type and Duration of Therapy for Tuberculosis

The optimal duration of treatment of tuberculosis, using a rifamycin-based regimen, in a patient who has HIV infection is unknown. Current recommendations from the BHIVA and the ATS/CDC/Infectious Diseases Society of North America (IDSA) are to treat tuberculosis in HIV-infected patients in the same way as for the general population (i.e., for 6 months for drug-sensitive pulmonary tuberculosis). In addition, ATS/CDC/IDSA guidelines recommend that treatment be extended to 9 months in patients who have cavitation on the original radiograph, continuing clinical signs, or a positive culture after 2 months of therapy.

Risk for development of rifampin monoresistance in HIV-infected patients receiving the drug has been reported. This association is especially strong if intermittent regimens are used and may be related to a lack of efficacy of the other drugs present in the combination (e.g., intermittent isoniazid). Hence, daily medication regimens are recommended and should be closely supervised in all HIV-positive patients. In clinical practice, rifabutin usually is given thrice weekly with ritonavir-boosted protease inhibitors. This regimen appears generally to achieve adequate rifamycin levels, although therapeutic drug failure and rifamycin resistance have recently been reported in patients who demonstrated appropriate adherence to prescribed treatment. Some clinicians now routinely prescribe daily rifabutin at its thrice-weekly dose and monitor drug levels. Little additional toxicity is reported, although the regimen is more expensive and has not been fully evaluated.

Directly observed therapy (DOT) is an important although fairly labor-intensive strategy that has the support of the WHO.

It is of undoubted value in populations at risk for nonadherence, such as substance abusers, the homeless, and people with mental health problems, and can be integrated with addressing other health care needs. This approach can help to offset what might appear punitive to persons in DOT programs.

Timing of Initiation of Antiretroviral Therapy for Tuberculosis

Recent data are available that can guide the optimal time to start ART in patients being treated for tuberculosis. Initial decision analysis showed that early treatment with antiretroviral therapy led to a marked reduction in further opportunistic disease. Against this was balanced the risk of needing to discontinue antituberculosis therapy or ART because of drug toxicity or drug-drug interactions. IRIS was reported to be more likely if these treatments were started at the same time.

These findings have now been confirmed in several studies from around the world, predominantly in developing nations. In essence, deferred ART (i.e., given at least 8 weeks after starting antituberculosis therapy) was associated with significantly increased mortality, when compared to treatment started within 4 weeks. Although IRIS was several times more frequent in the latter population, its morbidity generally was manageable and mortality was low. The survival benefit of early treatment was most pronounced in post hoc analyses in subjects with the lowest $CD4^+$ counts (that is, less than 50 cells/μL).

Delaying the start of antiretroviral therapy can simplify patient management and may reduce or prevent adverse drug reactions and drug-drug interactions; plus also reduce the risk of IRIS. Based on current guidance for general ART initiation, patients with $CD4^+$ counts above 350 cells/μL, who are at low risk of HIV disease progression or death during 6 months of treatment for tuberculosis, could defer ART until treatment for tuberculosis is completed or well under way. In these patients, the $CD4^+$ count should be closely monitored. In patients who have $CD4^+$ counts of 349 to 100 cells/μL, many centers currently delay starting ART until after the first 2 months of treatment for tuberculosis have been completed, and patients are given concomitant PCP prophylaxis. In those with $CD4^+$ counts below 99 cells/μL, ART is started as soon as possible after initiation of treatment for tuberculosis.

Two options exist for starting antiretroviral therapy in a patient already being treated for tuberculosis. First, the rifampin-based regimen is continued and ART is commenced—for example, with a combination of two nucleoside RTIs and a non-nucleoside RTI such as efavirenz (if the patient weighs more than 60 kg, the efavirenz dose often is increased to 800 mg given once daily, to compensate for rifampin-induced metabolism of efavirenz). Alternatively, the rifampin is stopped and rifabutin is started: Antiretroviral therapy is given, with a combination of two nucleoside RTI drugs and either a single ritonavir-boosted protease inhibitor or a non-nucleoside RTI. Here the dose of rifabutin is adjusted to take into account the pharmacokinetic effect of the coadministered drug. With a boosted protease inhibitor, it usually is prescribed at a dose of 150 mg thrice weekly, and with efavirenz, it is increased to 450 mg once a day, although as discussed earlier, some centers will use 150 mg rifabutin once daily.

Immune Reconstitution Inflammatory Syndrome

Before the advent of ART, physicians treating patients with tuberculosis recognized that an apparent response to the antimycobacterial treatment would sometimes be followed by a short period of clinical deterioration. This paradoxical reaction (in the context of overall treatment response) was seen as an interesting and probably immune-based phenomenon directed against residual mycobacterial antigen, of generally little consequence. The widespread introduction of ART has led to an increased awareness by clinicians of similar but generally more severe events in HIV-infected persons. In the context of HIV infection, a reaction of this type is now termed *immune reconstitution inflammatory syndrome* (IRIS), or immune reconstitution disease.

Such reactions can manifest in a number of ways, and in association with a range of opportunistic conditions. Perhaps the most common of these is similar to a paradoxical reaction. In this instance, after initiation of ART in a patient being treated for tuberculosis, for example, the original symptoms and signs or new features develop. These often are of an inflammatory nature and may be associated with marked radiographic changes. Manifestations of IRIS may include fever, dyspnea, lymphadenopathy, effusions, parenchymal pulmonary infiltrates, or expansion of cerebral tuberculomas. This form of IRIS is seen most frequently with disease due to mycobacteria (commonly *M. tuberculosis* or MAC), fungi (notably, *Cryptococcus*), and viruses (hepatitis viruses and Herpesviridae).

IRIS develops in up to one third of HIV-infected patients being treated for tuberculosis when ART is started. The median time to onset of tuberculosis-related IRIS is about 4 weeks from beginning antituberculosis treatment or 2 weeks from commencing ART. It appears to be more likely in patients who have disseminated tuberculosis (and hence presumably more stimulating antigen present as well as more potential for significant inflammatory reactions); and a lower baseline blood $CD4^+$ count. A rapid fall in HIV load as well as a large increase in $CD4^+$ counts in response to ART may also predict IRIS; as might circulating inflammatory cytokines such as interferon-γ or markers such as C-reactive protein. The relationship between early use of ART and low blood $CD4^+$ counts suggests that care must be taken when antiretrovirals are started in patients with tuberculosis at sites where rapid expansion of an inflammatory mass could be life-threatening. Examples of this are cerebral, pericardial, or peritracheal disease (**Figure 29-20**).

An important point is that IRIS currently is a diagnosis of exclusion. No specific laboratory test is available to assist with this, and it should be made only after progressive or (multi) drug-resistant tuberculosis, poor drug adherence (to either antituberculosis or antiretroviral agents) and drug absorption, or an alternative pathologic process has been excluded as an explanation for the presentation. Criteria have been drawn up that seek to provide clinical diagnostic guidelines (**Box 29-4**).

The mechanism leading to IRIS is unclear. It is not due to failure of treatment of tuberculosis or to another coexistent disease process, and if anything it is most likely to represent an exuberant and uncontrolled response to mycobacterial antigens (from both dead and alive organisms).

Current treatments include nonsteroidal antiinflammatory drugs and glucocorticoids. The latter are undoubtedly effective although they can lead to hyperglycemia and hypertension. Recurrent aspiration of lymph nodes or effusion also may be needed. Although IRIS often is self-limiting, it may persist for several months. Rarely, temporary discontinuation of ART is required. In this situation there may be precipitous falls in $CD4^+$ counts, and patients are at risk of other opportunistic infections.

Attention also has focused on an issue of possibly greater concern—the form of IRIS referred to as the “unmasking phenomenon”: In some persons with presumably latent

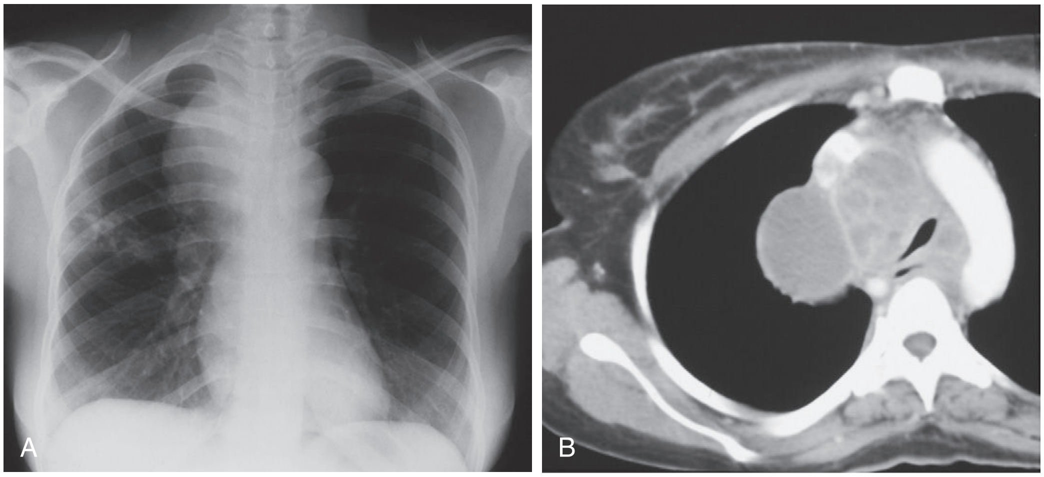

Figure 29-20 Chest radiograph (**A**) and CT scan (**B**) showing massive mediastinal lymphadenopathy in a patient with IRIS due to *Mycobacterium tuberculosis*. *(Reproduced from Buckingham SJ, Haddow LJ, Shaw PJ, Miller RF: Immune reconstitution inflammatory syndrome in HIV-infected patients with mycobacterial infections starting highly active anti-retroviral therapy*, Clin Radiol *59:505–513, 2004.)*

Box 29-4 Diagnostic Criteria for Immune Reconstitution Inflammatory Syndrome in Human Immunodeficiency Virus–Infected Patients with Tuberculosis

Evidence Supporting Diagnosis

1. Initial diagnosis of tuberculosis confirmed by laboratory methods or by appropriate response to treatment
2. Development of new clinical phenomena temporally associated with start of ART, including but not limited to:
   - New or enlarging lymphadenopathy, cold abscesses, or other focal tissue involvement
   - New or worsening central nervous system disease
   - New or worsening radiologic features of tuberculosis
   - New or worsening serositis (pleural effusion, ascites, pericardial effusion, or arthritis)
   - New or worsening constitutional symptoms such as fever, night sweats, and/or weight loss
   - Retrospective review indicating that clinical or radiologic deterioration occurred in the absence of change in tuberculosis treatment regimen
3. Immune restoration (e.g., a rise in $CD4^+$ lymphocyte count in response to ART)
4. A fall in HIV “viral load” in response to ART

Alternative Diagnoses to Be Excluded

Progressive underlying infection
Treatment failure due to drug resistance (MDR or XDR)
Treatment failure from poor adherence
Adverse drug reaction
Comorbidity—another, coexistent diagnosis (e.g., non-Hodgkin lymphoma)

ART, antiretroviral treatment; *MDR*, multidrug-resistant; *XDR*, extensively drug-resistant.

tuberculosis infection who start ART, systemic active (and often infectious) tuberculosis develops within a 3-month period. Although the patient’s disease probably would have manifested in time anyway, and some reported cases may in fact represent progression of previously subclinical tuberculosis, reflecting ascertainment bias, the current view is that this phenomenon is real and constitutes an adverse effect of ART. In view of the fact that persons most at risk live in countries with limited facilities for pre-ART screening, this issue has major implications for ART rollout programs in resource-poor areas. It has led to heightened need for intensified screening using simple algorithms that seek to exclude mycobacterial infection and disease before institution of ART. One consequence of this added awareness is the increased use of regimens to treat LTBI, plus the increased detection of subclinical active tuberculosis cases.

Treatment of Disseminated *Mycobacterium avium* Complex Infection

Combination antimycobacterial therapy by itself does not cure MAC infection. A commonly used regimen is oral clarithromycin 500 mg once daily or every 12 hours with oral ethambutol 15 mg/kg once daily with or without oral rifabutin 300 mg once daily. If clarithromycin is not used, oral rifabutin 600 mg once daily is given—the lower dose adjusting for yet more drug-drug interactions. Use of three drugs has no impact on overall outcome, although it reduces the risk of resistance and possibly enhances early mycobacterial killing. In patients whose clinical status is severely compromised by symptoms, intravenous amikacin 7.5 mg/kg once daily for 2 to 4 weeks also is given. Trough blood levels must be measured to ensure that toxic accumulation of amikacin does not occur. Fluoroquinolones such as moxifloxacin or levofloxacin may be extremely useful because they have good antimycobacterial activity with limited side effects. At present, many of these agents are not licensed for this indication. In view of the concerns regarding XDR tuberculosis, it is important to ensure that patients are adherent to such treatment regimens, thereby reducing the risk for development of fluoroquinolone resistance.

Mycobacterium kansasii Infection

A frequently used regimen consists of rifampin, isoniazid, and ethambutol in conventional doses; all drugs are given by mouth.

TREATMENT OF FUNGAL INFECTIONS

The treatment regimens for fungal infections complicating HIV infection are shown in Table 29-10.

Cryptococcosis

After initial treatment of cryptococcal infection there is a high likelihood of relapse of infection; hence, lifelong secondary preventive therapy is needed unless ART is commenced and

Table 29-10 Treatment of Fungal Pulmonary Infection in Human Immunodeficiency Virus (HIV)-Infected Patients

Infectious Agent	Drug	Comments
Aspergillus spp.	Voriconazole 6 mg/kg IV q12h on day 1, then 4 mg/kg IV q12h, then 200 mg PO q12h	Change to oral therapy once evidence of clinical recovery
	OR Liposomal amphotericin 5 mg/kg IV q24h	Use for severely ill patients, monitor renal function
Cryptococcus neoformans	Liposomal amphotericin 4-6 mg/kg IV q24h plus	Monitor renal function
	Flucytosine 50 mg/kg IV q6h for 2-4 weeks	Monitor blood count, liver and renal function
	OR Fluconazole 300-400 mg PO q12h for 2-4 weeks	
Histoplasma capsulatum	Liposomal amphotericin 3 mg/kg IV q24h , then itraconazole 200 mg PO q8h for 3 days, then 200 mg PO q12h	Use for severely ill patients Monitor renal function Change to oral therapy after 2 weeks or after clinical improvement obtained Monitor itraconazole levels
	Itraconazole 200 mg PO q8h for 3 days, then 200 mg PO q12h for 6-12 weeks	Use for less severely unwell patients Monitor itraconazole levels
Coccidioides immitis	Amphotericin B 0.5-1 mg/kg q24h for 2-4 weeks OR Liposomal amphotericin 4 mg/kg IV q24h for 2-4 weeks	Monitor renal function
Penicillium marneffei	Liposomal amphotericin 3 mg/kg IV q24h for 2 weeks, THEN Itraconazole 400 mg PO q24h for 10 weeks	Use for severely ill patients Monitor renal function Monitor itraconazole levels
	Itraconazole 400 mg PO q24h for 4-6 weeks	Use for mild disease Monitor itraconazole levels

results in sustained improvements in CD4$^+$ counts (greater than 250 cells/μL) and suppression of HIV load in peripheral blood. Secondary prophylaxis most often is with oral fluconazole, 200 to 400 mg four times daily. Just as with mycobacterial disease, "late" IRIS events can occur after months or even years. These should be investigated to exclude active disease and other conditions.

Histoplasmosis

Oral itraconazole 200 mg twice daily is the current treatment of choice. The dose is adjusted to achieve blood trough drug levels that are above the standard lowest effective concentration. There are no data on the impact of ART on which to base decisions about discontinuation of secondary prophylaxis.

Coccidioidomycosis

Treatment of coccidioidomycosis is difficult. After initial treatment with amphotericin B, either itraconazole or fluconazole may be given for long-term suppression. The overall prognosis is poor, with a 40% mortality rate despite therapy. There are no data on the impact of ART on which to base decisions about discontinuation of secondary prophylaxis.

Penicillium marneffei Infection

Oral itraconazole has now replaced amphotericin B as the treatment of choice for *P. marneffei* infection, apart from the subgroup of patients who are acutely unwell. Fluconazole is less effective than itraconazole. After initial treatment, lifelong suppressive therapy with itraconazole is needed. There are no data on the impact of ART on which to base decisions about discontinuation of secondary prophylaxis.

TREATMENT OF PARASITIC INFECTIONS

The treatment regimens are shown in Table 29-11.

Toxoplasmosis

A combination of sulfadiazine and pyrimethamine is the regimen of choice for *T. gondii* infection. The most frequent dose-limiting side effects are rash and fever. Adequate hydration must be maintained to avoid the risk of sulfadiazine crystalluria and obstructive uropathy. Alternative regimens are given in Table 29-11. Once treatment is completed, lifelong maintenance is necessary to prevent relapse, unless ART achieves adequate immune restoration (blood CD4$^+$ count above 250 cells/μL and undetectable HIV load).

Visceral Leishmaniasis

Visceral leishmaniasis usually is treated with liposomal amphotericin B, although this therapy is associated with a high rate of relapse. Second-line therapy (or first-line in cash-poor environments) is to use sodium stibogluconate (see Table 29-11).

Strongyloides stercoralis Infection

The agent of choice for treatment of *S. stercoralis* infection is ivermectin. Risk of treatment failure with thiabendazole in HIV-infected persons is higher than that in non–HIV-infected patients.

TREATMENT OF VIRAL INFECTIONS

Cytomegalovirus Infection

Cytomegalovirus pneumonitis is treated with intravenous ganciclovir 5 mg/kg every 12 hours, for 14 days. Drug-induced

Table 29-11 Treatment of Parasitic Infections in Human Immunodeficiency Virus (HIV)-Infected Patients

Infectious Agent	Drug	Comments
Toxoplasma gondii		
First choice	Sulfadiazine 1-1.5 g PO q6h plus pyrimethamine 200 mg PO q24h on day 1, then 50 mg (in patients weighing <60 kg) or 75 mg (in patients weighing >60 kg) plus folinic acid 15 mg PO q24h for 14-28 days	Rash and fever are common
Second choice	Clindamycin 600 mg PO or IV q6h plus pyrimethamine and folinic acid (doses as above) for 14-28 days	If diarrhea develops, analyze stool for *Clostridium difficile*
Leishmania spp.		
First choice	Liposomal amphotericin B 2-4 mg/kg IV q24h for 10 days	
Second choice	Sodium stibogluconate 20 mg/kg IV or IM q24h for 3-4 weeks	
Strongyloides stercoralis	Ivermectin 200 µg/kg PO q24h for 4 doses over 16 days	

neutropenia is managed with granulocyte colony-stimulating factor. Some centers use valganciclovir, an oral formulation of ganciclovir, at a dose of 900 mg orally every 12 hours, to treat CMV pneumonitis. Side effects and their management are as for ganciclovir. Phosphonoformate (foscarnet) can be used for treatment of CMV end-organ disease (e.g., pneumonitis), although it has an extensive toxicity profile.

Influenza A

HIV-infected patients presenting with documented or suspected influenza A and duration of symptoms for 48 hours or less should receive the neuraminidase inhibitor oseltamivir, in a dose of 75 mg given orally twice a day, or zanamivir, in a dose of 10 mg given by inhalation twice a day, both given for 5 days (assuming that a majority of circulating strains in a given flu season are susceptible). Additionally, in patients with documented influenza A and a CD4$^+$ count below 200 cells/µL, a neuraminidase inhibitor may be given in absence of fever or if duration of symptoms is longer than 48 hours. In patients with H1N1, treatment often is given regardless of duration of symptoms.

CLINICAL COURSE AND PREVENTION

Within the past several years, advances in drug therapy have radically altered the depressingly predictable nature of progressive HIV infection. Combinations of prophylaxis against specific opportunistic infections and ART can reduce both the incidence of common conditions and the associated mortality. The observational North American Multicenter AIDS Cohort Study (MACS) demonstrated that the risk of PCP in patients with blood CD4$^+$ counts less than 100 cells/µL can be reduced almost four-fold (from 47% to 13%) if both specific prophylaxis and ART are taken. However, as common conditions are prevented, other less treatable illnesses may arise.

It has become apparent that specific infection prophylaxis also may confer protection against other agents. This “cross-prophylaxis” is seen particularly with the use of TMP-SMX for PCP which also provides cover against cerebral toxoplasmosis and several common bacterial infections (although not those caused by *S. pneumoniae*), and with use of macrolides for MAC infection, which further reduces the incidence of bacterial disease and also PCP. Use of large amounts of antibiotic raises the possibility of future widespread drug resistance. This concern clearly is of clinical import, and recent reports suggest that indeed in some parts of the world, the incidence of pneumococcal TMP-SMX resistance is rising. Current preventive therapies pertinent to lung disease focus on *P. jirovecii*, MAC, *M. tuberculosis*, and certain bacteria (Table 29-12).

PNEUMOCYSTIS JIROVECII *PNEUMONIA PROPHYLAXIS*

Numerous studies have demonstrated the greatly increased risk of PCP in persons with blood CD4$^+$ counts below 200 cells/µL who do not take adequate drug therapy. Clinical symptoms also constitute an independent risk factor for PCP; accordingly, the current guidelines recommend lifelong prophylaxis against *P. jirovecii* in HIV-infected adults who have had previous PCP, CD4$^+$ counts below 200 cells/µL, constitutional symptoms (documented oral thrush or fever of unknown cause with temperatures above 37.8° C that persists for more than 2 weeks), or clinical AIDS. The importance of secondary prophylaxis (i.e., used after an episode of PCP) becomes clear from historical data, which indicate a 60% risk of relapse in the first 12 months after infection.

The increases in systemic and local immunity that occur with ART have led to several studies evaluating the need for prolonged prophylaxis in persons with sustained elevations in blood CD4$^+$ counts and low HIV RNA load. In summary, it appears that both primary and secondary PCP prophylaxis can be discontinued once CD4$^+$ counts are above 200 cells/µL for more than 3 months. A caveat to this is that the patient should have a low or undetectable HIV RNA load, that the CD4$^+$ percentage is stable or rising and is greater than 14% and that the patient plans to continue ART over the long term with good adherence.

Recent data accrued from a cohort study, a retrospective review and a case series show a low incidence of PCP among patients who discontinued or never started PCP prophylaxis, who were receiving ART and had CD4$^+$ counts between 100 and 200 cells/µL and plasma HIV viral loads of less than 50 to 400 copies/mL. Although these data imply that primary PCP prophylaxis can be safely discontinued in certain patients with CD4$^+$ counts between 100 and 200 cells/µL, with some experts recommending this approach for their patients, this has not been widely adopted.

Trimethoprim-Sulfamethoxazole

As with treatment strategies, TMP-SMX is the drug of choice for prophylaxis of PCP (Table 29-13). It has the advantages of being highly effective for both primary and secondary prophylaxis (with the 1-year risk of PCP during therapy with this

Table 29-12 Prevention of Respiratory Infections in Human Immunodeficiency Virus (HIV)-Infected Adults

Organism	Preventive Method	Specific Agent	Indications	Cost	Comments
Pneumocystis jirovecii	Regular drug	Trimethoprim-sulfamethoxazole (daily)	Persistent thrush, fever, AIDS, CD4$^+$ count <200 cells/μL	Cheap	Provides cross-protection May lead to resistance
Mycobacterium tuberculosis	Regular drug	Isoniazid (6-12 months)	Purified protein derivative positive Close contact with active case	Cheap	Compliance a potential problem, therefore resistance possible
Mycobacterium avium complex	Regular drug	Clarithromycin (daily) or azithromycin (weekly)	CD4$^+$ count <50 cells/μL	Expensive	Provides cross-protection May lead to resistance
Streptococcus pneumoniae	Immunization	23-valent capsular polysaccharide (single dose)	All subjects at diagnosis and at 5 years	Cheap	Uncertain protection Transient increase in HIV "load"
Influenza virus	Immunization	Whole or split virus (yearly)	All subjects	Cheap	Uncertain protection Transient increase in HIV "load"

AIDS, acquired immunodeficiency syndrome

Table 29-13 Primary and Secondary Prophylaxis Regimens for *Pneumocystis jirovecii* Pneumonia

Drug	Dose	Comments
Trimethoprim-sulfamethoxazole	1 double-strength[*] tablet PO q24h	*Other options for primary prophylaxis*: 1 double-strength[*] tablet PO q24h 3×/week OR 1 single-strength[†] tablet PO q24h Protects against toxoplasmosis and certain bacteria
Dapsone	100 mg PO q24h	With pyrimethamine (25 mg PO q24h 3×/week) Protects against toxoplasmosis
Pentamidine	300 mg given by Respirgard II (jet) nebulizer every 4 weeks	Less effective in subjects with CD4$^+$ <100 cells/μL Provides no cross-prophylaxis
Atovaquone	750 mg PO q12h	Absorption increased if administered with food Protects against toxoplasmosis

[*] 160 mg trimethoprim plus 800 mg sulfamethoxazole.
[†] 80 mg trimethoprim plus 400 mg sulfamethoxazole.

agent being 1.5% and 3.5%, respectively). It is cheap, can be taken orally, acts systemically, and provides some cross-prophylaxis against other infections, such as toxoplasmosis and infections due to *Salmonella* spp., staphylococci, and *H. influenzae.* Its main disadvantage is that adverse reactions are common (see earlier), occurring in up to 50% of patients taking the prophylactic dose.

The standard dose of TMP-SMX is one double-strength tablet (containing 160 mg of trimethoprim plus 800 mg of sulfamethoxazole) per day. Other regimens have been tried; these include one "double-strength" tablet thrice weekly and one single-strength tablet per day. In general, when used for primary prophylaxis, these regimens are tolerated well (if not better than the standard) and appear to be as efficacious as one double-strength tablet per day. The data are less clear in secondary prophylaxis, in which subjects are at a much higher risk for recurrent PCP. Attempts to desensitize patients who are intolerant of TMP-SMX have met with some success.

Dapsone

In patients who cannot tolerate TMP-SMX, dapsone is a safe and inexpensive alternative. It has been studied in a number of trials as both primary and secondary prophylaxis and is effective at an oral dose of 100 mg/day. When combined with pyrimethamine (25 mg three times per week), it provides a degree of cross-prophylaxis against toxoplasmosis. Before starting dapsone, patients are tested for glucose-6-phosphate dehydrogenase deficiency.

Pentamidine

Nebulized pentamidine has largely fallen from use as a prophylactic agent. Initial advantages included better clinical tolerance and efficacy similar to that of TMP-SMX for primary preventive therapy. The associated breakthrough rate for this agent, however, is higher in patients who have lower CD4$^+$ counts (i.e., below 100 cells/μL) and in those who take it as secondary prophylaxis. Other disadvantages include delivery equipment costs and complexity (alveolar deposition is crucial, so the nebulizer system used is important), the risk of transmission of respiratory disease (e.g., tuberculosis) to other patients and staff during the nebulization procedure, altered clinical presentation of PCP during pentamidine therapy (increased frequency of radiographic upper zone shadowing, increased incidence of pneumothorax), and a lack of systemic protection against *Pneumocystis* and other infectious agents. In addition, an acute bronchoconstriction effect during nebulization has been noted. Long-term follow-up studies have not demonstrated any significant negative effect on lung function.

Atovaquone

Atovaquone oral suspension is used as a second-line prophylactic agent in patients intolerant of TMP-SMX. It appears to be similar in efficacy to dapsone (given together with weekly pyrimethamine), with a reduced incidence of side effects, of which the most frequent are rash, fever, and gastrointestinal disturbance.

Predictors of *Pneumocystis* Prophylaxis Failure

A low blood CD4$^+$ count (less than 50 cells/µL) is the current best laboratory predictor of prophylaxis failure. This correlation is not particularly surprising because the median blood CD4$^+$ count of subjects not on prophylaxis who develop PCP is below 50 cells/µL. Persistent fever of unknown cause is an important clinical risk factor for PCP. Used as preventive therapy, TMP-SMX significantly reduces the chance for development of *Pneumocystis*. It is therefore vital that subjects who are most vulnerable be encouraged to use this drug on a regular basis.

BACTERIAL INFECTION PROPHYLAXIS

The effective and safe (i.e., replication-incompetent) bacterial vaccines that are available would be expected to be widely used to prevent HIV-related disease. In fact, clinical acceptance of both pneumococcal and the *H. influenzae* type b (Hib) vaccines is poor (current estimates for the former are at most only 40% of the infected population for use of the recommended 23-valent vaccine). One reason for this low uptake rate may be that the protection conferred by vaccination (90%) in the general population is not seen in immunosuppressed HIV-infected persons, reflecting their inability to generate adequate memory B cell responses (especially those with CD4$^+$ counts below 200 cells/µL). In North America, however, the CDC/IDSA recommendation is to give the pneumococcal vaccine as a single dose as soon as HIV infection is diagnosed, with a booster at 5 years, or if an individual patient's blood CD4$^+$ count was less than 200 cells/µL and subsequently increased on ART. Several studies show that pneumococcal immunization reduces the risk of invasive pneumococcal infection in this population. This does not appear to be the case in a developing nation setting, where not only is the 23-valent vaccine ineffective against both invasive and noninvasive pneumococcal disease but the overall incidence of pneumonia is increased. Conjugated pneumococcal vaccines confer enhanced protection but are currently much more expensive. Cost-benefit analyses are awaited.

Infection with Hib is less common in HIV-infected adults. Accordingly, immunization with Hib vaccine is not routinely recommended.

There is little evidence to suggest that the high frequency of bacterial infections in the HIV population is related to bacterial colonization. Therefore, continuous antibiotics are rarely indicated, although both TMP-SMX and the macrolides (clarithromycin and azithromycin) given as long-term prophylaxis for opportunistic infection have been shown to reduce the incidence of bacterial pneumonia, sinusitis or otitis media, and infectious diarrhea. The use of TMP-SMX also confers a survival advantage in many studies performed in resource-poor settings. There is little evidence, however, showing that TMP-SMX protects against pneumococcal infection.

PREVENTION OF INFLUENZA A

All HIV-infected persons, regardless of CD4$^+$ count, should be offered annual immunization against influenza A.

MYCOBACTERIUM TUBERCULOSIS *PROPHYLAXIS*

The interaction between HIV and tuberculosis is of fundamental importance because the annual risk for the development of clinical tuberculosis in a given patient is estimated to be 5% to 15% (i.e., similar to a non–HIV-infected subject's *lifetime* risk). The concern that HIV-infected patients may develop disseminated infection after bacillus Calmette-Guerin (BCG) administration means that despite its undoubted potential protective value in many parts of the world where HIV infection is rife, clinicians may be wary of using it routinely. As such, effective case finding (largely for active infectious disease, though increasingly for LTBI) becomes even more relevant to tuberculosis control. The distinction between LTBI (i.e., clinically asymptomatic disease with a normal appearance on the chest radiograph and negative mycobacterial sputum cultures) and active tuberculosis disease is distorted by HIV. *M. tuberculosis* can be isolated from asymptomatic persons, while active disease symptom screens are so all-encompassing that they are poorly specific.

HIV-infected patients with pulmonary tuberculosis are less likely to be AFB smear–positive than their HIV-negative counterparts, although they are still infectious and can transmit tuberculosis. One of the problems with standard methods of tuberculosis contact tracing when applied to HIV infected subjects is that both TST results and chest radiology may be unreliable. However, in the absence of BCG immunization, a positive PPD (e.g., greater than 5 mm induration with 5 tuberculin units) indicates a greatly increased risk of future active disease (6- to 23-fold compared with nonanergic, PPD-negative, HIV-infected subjects).

The introduction of commercial mycobacterial interferon gamma release assays (IGRAs), which are highly sensitive indicators of mycobacterial infection and are reasonably specific for detection of *M. tuberculosis* (although unaffected by BCG), has renewed interest in screening strategies for LTBI. The tests have some clear advantages over TST (including reducing false positives due to BCG, less potential for reporter error when the TST is read, and no need for a return visit by the subject under investigation if the IGRA result is negative). Because IGRAs detect host immunity, however, they are inevitably affected by HIV infection and are less sensitive in subjects with declining immunity (and low blood CD4$^+$ counts). They cannot discriminate between recent and past infection, so they yield a positive result in large numbers of people in tuberculosis-endemic areas. They do not test for active disease, and results generally do not revert to negative after successful treatment of LTBI or active tuberculosis. In low-tuberculosis-prevalence settings, such as the United States and the United Kingdom, IGRAs may offer a cost-effective means of identifying persons who are at high risk for development of active tuberculosis and hence should be offered LTBI treatment.

The WHO recommends at least 6 months of isoniazid (together with pyridoxine to prevent peripheral neuropathy). This drug is safe and well-tolerated, although compliance is a problem (especially if treatment is for longer than 6 months). There is little evidence to suggest that this single-agent regimen leads to isoniazid resistance, which probably reflects the low mycobacterial load present in such patients. In view of the concerns regarding undertreatment of subclinical active disease, however, some workers are now advocating use of molecular diagnostic methods as part of an initial screen before initiation of LTBI therapy.

Recent studies performed in tuberculosis-endemic settings have shown useful and comparable efficacy of rifapentine plus isoniazid weekly for 3 months, or twice-weekly rifampin and isoniazid also for 3 months, and of 6 months or longer of isoniazid alone. A 36-month monotherapy regimen of isoniazid was superior to a 6-month regimen in a study performed in Botswana. Of note, the benefit of treatment (in preventing the development of active disease) was apparent only in subjects who were TST-positive before LTBI treatment, suggesting that the longer course was not merely preventing exogenous, newly acquired infection.

Secondary LTBI prophylaxis after treatment for active disease generally is not recommended, because ART will reduce the risk of tuberculosis by 50% to 80% after 3 months of therapy and should be encouraged. ART also appears to have an additive (and similar-sized) effect to that of specific antituberculosis therapy in reducing the risk of progression to tuberculosis disease during primary prophylaxis.

MYCOBACTERIUM AVIUM *COMPLEX PROPHYLAXIS*

Data from North America indicate that the prevention of disseminated MAC infection has an effect on survival (25% reduction in mortality rate in subjects taking clarithromycin). The U.S. guidelines advise prophylaxis with a macrolide (either clarithromycin 500 mg orally twice per day or azithromycin 1250 mg orally once a week) in all HIV-infected persons with blood CD4$^+$ counts >50 cells/μL. In Europe, where the prevalence of disseminated MAC infection probably is lower (perhaps because of previous BCG vaccination), this may be less relevant. Here, surveillance cultures of blood may be more cost effective in the at-risk HIV population with low CD4$^+$ counts. Routine stool and sputum cultures probably do not add much to this strategy because disseminated MAC is much more common than isolated organ disease.

Single-agent prophylaxis may lead to antibiotic resistance. This does not seem to be reduced by the addition of a second drug (rifabutin) to the prophylactic regimen. The latter is now a second-line prophylactic agent, largely as a result of its rather worse protective effect and its adverse interaction profile with protease inhibitors. As mentioned earlier, if the patient sustains a rise in CD4$^+$ count above 100 cells/μL for longer than 6 months, it is safe to discontinue prophylaxis.

PROGNOSIS

PNEUMOCYSTIS JIROVECII *PNEUMONIA*

Several clinical and laboratory features have prognostic significance in HIV-infected patients with PCP (Box 29-5). Severity scores based on the patient's age, use of injection drugs, serum albumin, serum bilirubin, and $PO_2(A–a)$, or the patient's age, hemoglobin, PaO_2, presentation with a second or third episode of PCP, the presence of medical comorbidity and of pulmonary Kaposi sarcoma can predict survival reasonably accurately, with the highest scores indicating the worst outcome. In the era of ART the mortality from an episode of PCP is approximately 10%.

Box 29-5 Prognostic Factors Associated with Poor Outcome in *Pneumocystis jirovecii* Pneumonia

On Hospital Admission
Older age
Reduced body mass index
No previous knowledge of HIV serostatus
Tachypnea (respiratory rate higher than 30 breaths/minute)
Second or subsequent episode of *Pneumocystis jirovecii* pneumonia
Poor oxygenation: PaO_2 <53 mm Hg or $PO_2(A–a)$ >30 mm Hg
Low serum albumin (<35 g/dL)
Low hemoglobin (<12.0 g/dL)
Peripheral blood leukocytosis (>10.8 × 10^9/L)
Elevated serum lactate dehydrogenase levels (>300 IU/L)
Elevated serum bilirubin
Elevated C-reactive protein level
CD4$^+$ count <50 cells/μL
Marked chest radiographic abnormalities: diffuse bilateral interstitial infiltrates with or without alveolar consolidation
Medical comorbid or other coexistent condition (e.g., pregnancy)

After Hospital Admission
At bronchoscopy:
1. In bronchoalveolar lavage fluid: detection of
    - copathogens: CMV, bacteria
    - neutrophilia (>5% neutrophils on differential count)
2. Detection of pulmonary Kaposi sarcoma

Serum lactate dehydrogenase levels that remain elevated
Development of pneumothorax
High APACHE II score on ICU admission
Need for mechanical ventilation

APACHE II, Acute Physiology and Chronic Health Evaluation [study] II; *CMV*, cytomegalovirus; *HIV*, human immunodeficiency virus; *ICU*, intensive care unit.

BACTERIAL INFECTION

In general, the outcome with bacterial respiratory infection in HIV-infected patients is similar to that seen in the HIV-negative population. Clinical and laboratory markers of disease severity that have been defined in the adult general population (e.g., those described in the ATS, or the BTS guidelines for the management of community-acquired pneumonia in adults) apply to HIV-infected patients. These are confusion, raised respiratory rate, abnormal renal function, and low blood pressure. Recurrent pneumonia is common (reported in up to 55% of cases) and may lead to chronic pulmonary disease (see earlier).

MYCOBACTERIUM TUBERCULOSIS *INFECTION*

Although tuberculosis normally responds to standard multiple-drug therapy, work from Africa has highlighted the increased mortality rate in HIV-infected compared with non–HIV-infected persons. A relationship also has been described between risk of death and blood CD4$^+$ count: HIV-infected patients with CD4$^+$ counts below 200 cells/μL have a mortality rate of 10%, compared with 4% in those with CD4$^+$ counts of 200 to 499 cells/μL. As discussed previously, early use of ART (i.e., within the first 4 weeks of treatment) is now recommended in subjects with low blood CD4$^+$ counts.

MYCOBACTERIUM AVIUM *COMPLEX INFECTION*

Several case-control studies have indicated that in the absence of effective treatments, MAC-infected patients have a reduced survival compared with CD4$^+$ count–matched control subjects (approximately 4 months versus 9 months, respectively). Currently available treatment regimens may reduce this difference, although severe anemia appears to be an independent predictor of death in patients with this infection.

CONTROVERSIES AND PITFALLS

ANTIRETROVIRAL THERAPY AND OPPORTUNISTIC INFECTIONS

The introduction of ART, together with the wide availability of accurate methods of determining plasma RNA viral load, has led to profound changes in both clinical practice and outcome with HIV disease. Respiratory disease, in particular, bacterial pneumonia and tuberculosis, still occurs more frequently than in HIV-seronegative subjects, despite apparently effective ART. Overall, however, data indicate that clinical progression is rare in subjects who are able to adhere rigorously to at least 95% of their antiretroviral drug regimen. Mortality rates have fallen by 80% for almost all conditions, and it seems that a damaged immune system can, to a clinically significant extent, be reconstituted for a period of at least several years. Thus, clinicians need to consider not only opportunistic infection or malignancy within the diagnostic workup but also the effects of drug therapy itself. The adverse effect profile of ART (e.g., metabolic and mitochondrial toxicities, liver damage, and neuropsychiatric disorders), as well as the large number of drug-drug interactions, makes this a highly complex area of clinical management. The best-characterized example of this issue is HIV-related tuberculosis. Here, not only is there overlap between toxicity and pharmacologic interaction, but IRIS is common. Research is needed to address this area. Studies should inform the decision on when to start ART in patients already on antituberculosis medication: For example, should ART begin at much higher blood $CD4^+$ counts than those currently recommended? What are good and simple predictors of an individual patient's risk for IRIS? Other work needs to focus on elucidation of why full pulmonary immunity is not restored with ART.

PREDICTORS OF DISEASE

Despite the benefits of ART, it is likely that in the long term, HIV infection will progress to severe disease. Currently, little work has been conducted in this area. Research should focus on developing strategies that are cost-effective and practicable in both high and low tuberculosis burden settings. This is important, because in the latter, respiratory disease such as tuberculosis remains a common problem, even in subjects of known HIV serostatus. For example, recent U.K. guidance on screening for LTBI in HIV infection has not been evaluated at a national level.

As discussed previously, immune-based tests have shown promise in immunocompetent patients with LTBI. If these tests can be refined to work consistently in HIV infection at a reasonable cost, the possibility emerges for targeting persons at risk for future tuberculosis, or for predicting tuberculosis "unmasking" after initiation of ART. The recent descriptions of whole genome sequencing and microarrays of host immune signatures to distinguish LTBI from active disease are important in this respect.

Rapid diagnostics that are not exorbitant in cost and complexity are urgently needed. A common clinical scenario is that in which the patient presents with nonspecific signs and symptoms potentially associated with any of numerous entities in an extensive differential diagnosis. Often, the best treatment regimen is multiple and empirical—as, for example, in a patient from an endemic tuberculosis area with low blood $CD4^+$ counts who has both pulmonary and central nervous system disease: Is the clinical problem tuberculosis, toxoplasmosis, cryptococcosis, or viral or bacterial infection? Any such test for tuberculosis would also have to distinguish between the different states of old (treated), old (inactive), old (latent) and active. Although not insurmountable, at present, such distinction is not possible. Some encouraging data have been derived from urine lipoarabinomannan (LAM) assays, which are of less value in HIV-negative subjects than in the HIV-infected. This difference is due to the large amount of renally cleared LAM associated with the overall increased bacterial load present in HIV-related tuberculosis. Utilizing such specific aspects of tuberculosis or HIV pathology may encourage development of novel and specific tests.

Rapid diagnostic assays that assess organism viability also are important. If the clinician can receive early feedback on whether treatment is producing a suitable killing effect, then therapy can be tailored to the individual patient. This feedback enables regimens to be "dose-adjusted" as needed and removes the element of concern that often is present when patients are slow to respond. Such delayed response is well recognized in the treatment of PCP or other fungal or mycobacterial disease, for example.

BACTERIAL INFECTIONS

The frequency of bacterial infection (often recurrent) with its attendant sequelae makes effective strategies for vaccination an important priority. The reason for the observed differential response to vaccination is unclear—even in the United States, African Americans do not seem to derive the same benefit as that observed in whites. This difference merits further research, together with more emphasis on identifying the local immune response present in the lung in such patients.

Bacterial infections may be clinically indistinguishable from other pathogens, and only two thirds of all respiratory infections are formally diagnosed. Improved methods to address this problem are needed. The use of rapid antigen tests may be one way forward. Rapid availability of results is especially important in view of the high incidence of (potentially fatal) bacteremia present in populations of affected patients. For maximum benefit, such screening requires a system that is simple and cheap and hence suitable to both resource-rich and resource-poor countries.

MYCOBACTERIAL DISEASES

M. tuberculosis is globally the most important HIV-related pathogen. Strategies of control and prevention are vital to ensure that millions of people do not become co-infected and that those who are do not go on to develop clinical disease. Rapid diagnostics are critical. The encouraging reports of the simple and cheap MODS assay and also user-friendly molecular techniques, both to diagnose tuberculosis and then to provide resistance data in field settings (see earlier), argue for large-scale rollout and evaluation.

Beyond public health measures such as infection control, rapid case finding, DOTs, use of fixed-dose combination drugs, case management, and education, research needs to improve on current drug therapy. Long-acting preparations such as rifapentine show promise but, as the problem with rifampicin monoresistance demonstrates, much work remains to be done. Several antimycobacterial drugs are now in clinical trials. Initial data are promising, and several agents have novel mechanisms of action. The Global Alliance and the WHO "Stop TB" campaigns have been crucial in this regard. The fluoroquinolones moxifloxacin and gatifloxacin are now widely available. These potent drugs possess considerable ability both to kill mycobacteria and also to "sterilize" infected sites. Trials of treatment-shortening regimens are ongoing worldwide. These drugs also are important as part of treatment protocols and stratagems that will effectively tackle the estimated 500,000 new cases of MDR tuberculosis, in addition to benefiting the 50,000 persons who have currently almost untreatable XDR tuberculosis across the world.

Vaccination against *M. tuberculosis* using BCG has been attempted with caution in immunosuppressed HIV-infected populations. However, a safe vaccine may be the only affordable way of protecting large parts of the world from tuberculosis. So far there appears to be more success with vaccines to either enhance or replace the primary protective effects of BCG.

PNEUMOCYSTIS JIROVECII *DISEASE-RELATED ISSUES*

Newer methods of diagnosis (e.g., PCR tests on oral rinse samples) may prove invaluable for quick and easy disease confirmation, although their applicability to routine samples needs further evaluation.

Despite the efficacy of TMP-SMX for *P. jirovecii* prophylaxis, compliance remains a problem. One concern with widespread use of prophylaxis is that resistance to TMP-SMX will start to emerge. Reports have indicated that certain mutations in the *P. jirovecii* dihydropteroate synthase gene confer resistance. These mutations seem to be increasing over time, although they do not appear to be present in many patients in whom treatment for PCP with TMP-SMX lacks efficacy. The implications of this observation are uncertain but could include a greater likelihood of treatment failure and the possibility of worsening patterns of global bacterial drug resistance.

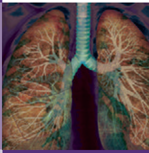
Section 5
INFECTIOUS DISEASES



Chapter 30

Noninfectious Conditions in Patients with Human Immunodeficiency Virus Infection

Thomas Benfield

Although most complications affecting the lungs during the course of HIV infection arise from the viral infection itself, especially as reported early in the epidemic, HIV-infected patients may present with or subsequently develop complications related to alterations in immune regulation. A marked CD8$^+$ T cell infiltrate in the lung may be caused by HIV in both symptomatic and nonsymptomatic patients. The effects of the virus on the pulmonary microenvironment include a progressive decline in local immunocompetence that results in failure to mount a protective immune response against opportunistic infections. The spectrum of noninfectious complications associated with HIV infection encompasses other idiopathic conditions and pulmonary malignancies, which include Kaposi sarcoma, Hodgkin and non-Hodgkin lymphomas, and solid tumors (Table 30-1 and 30-2).

RESPIRATORY SYMPTOMS AND PULMONARY FUNCTION

Respiratory symptoms, impaired diffusion, emphysema, airway obstruction, and small airway disease related to HIV infection are common clinical findings. In a recent study of 167 HIV-1–infected persons, nearly two thirds were found to have diffusion impairment and one fifth had irreversible airway obstruction. The most common symptoms and signs were dyspnea and a cough. Severe symptoms such as shortness of breath at rest were less frequent. Patients with respiratory symptoms were more likely to be current or past injection drug users and smokers. Approximately one fourth reported using respiratory inhaler medication. Smoking and the number of pack-years smoked increased the risk of diffusion impairment and airway obstruction. Prophylaxis for *Pneumocystis jirovecii* pneumonia and low CD4$^+$ cell counts increased the risk for impaired diffusion, and treatment with cART increased the risk for airway obstruction. These associations may be a proxy for the duration of HIV-1 infection and severity of the underlying immunodeficiency. The correlation with low CD4$^+$ cell counts supports this possibility. Overall, the HIV-infected population appears to be more susceptible to noninfectious disease for a number of reasons. Smoking cessation counseling certainly offers one possibility of reducing the increased susceptibility.

NEOPLASIA

Cancer incidence is higher in persons with immunodeficiency of all causes. In HIV-1 infection, cancers that are uncommon in the general population predominate and include mainly lymphoma and Kaposi sarcoma. Other, more common cancers are now seen with increasing frequency; however, as HIV-1 infection has become controllable with antiretrovirals.

KAPOSI SARCOMA

Epidemiology, Risk Factors, and Pathogenesis

In the general population, Kaposi sarcoma is a rare benign skin tumor that develops in the skin of the lower extremities in elderly men from the Mediterranean area. The disease, originally described in 1872 by the Hungarian physician Moricz Kaposi, is 100 to 1000 times more frequent in persons with HIV-1 infection than in the general population and is associated with an aggressive course. The incidence of AIDS-associated Kaposi sarcoma has, however, declined substantially over the past 2 decades. Before the advent of cART, incidence rates ranged from 25 to 50 cases per 1000 person-years of follow-up (PYFU) but have steadily declined, so that the incidence in a cART-treated population is less than 5 per 1000 PYFU. Approximately 5% to 10% of all diagnosed cases of AIDS are based on a finding of Kaposi sarcoma. HIV-1–infected men who have sex with men have a 20 times higher risk for development of this tumor than in persons in other transmission groups. Frequency increases with lower CD4$^+$ T cell counts, but the disease can occur at all levels of immunodeficiency. Thus, when Kaposi sarcoma is the AIDS-defining illness, it may occur at a relatively higher CD4$^+$ T cell count than other such illnesses.

Kaposi sarcoma is an angioproliferative inflammatory condition that is associated with infection with human herpesvirus type 8 (HHV-8). Gene expression profiling shows that the lesions consist of aberrant endothelial and inflammatory cells of lymphatic origin. HHV-8, a γ-2 herpesvirus of the *Rhadinovirus* genus, has been demonstrated in all forms of Kaposi sarcoma, and in situ hybridization has demonstrated the presence of HHV-8 RNA and DNA in spindle, endothelial, and mononuclear cells of the tumor. HHV-8 DNA is detectable in peripheral blood before the development of the tumor, and increased viral replication is evident before onset of symptoms.

Table 30-1 Noninfectious Pulmonary Conditions Associated With Human Immunodeficiency Virus Type 1 Infection

Disease Category	Specific Disease(s)
Neoplastic disease	Kaposi sarcoma Castleman disease Non-Hodgkin lymphoma Primary effusion lymphoma Lung cancer
Inflammatory disease	Nonspecific interstitial pneumonitis Lymphocytic interstitial pneumonitis Lung fibrosis
Airway disease	Chronic obstructive pulmonary disease Emphysema
Pulmonary vascular disease	Pulmonary hypertension
Miscellaneous	Antiretroviral treatment–induced respiratory disease

Table 30-2 Association of Noninfectious Pulmonary Conditions with Degree of Immunodeficiency

Degree of Immunodeficiency	Noninfectious Pulmonary Condition
Severe (CD4$^+$ cell count less than 50 cells/μL)	Kaposi sarcoma Castleman disease Non-Hodgkin lymphoma Primary effusion lymphoma Lung cancer Nonspecific interstitial pneumonitis Lymphocytic interstitial pneumonitis Chronic obstructive pulmonary disease Pulmonary hypertension Antiretroviral treatment–induced respiratory disease
Moderate to severe (CD4$^+$ cell count 50-200 cells/μL)	Kaposi sarcoma Non-Hodgkin lymphoma Lung cancer Nonspecific interstitial pneumonitis Lymphocytic interstitial pneumonitis Chronic obstructive pulmonary disease Pulmonary hypertension Antiretroviral treatment–induced respiratory disease
Moderate (CD4$^+$ cell count 200-350 cells/μL)	Non-Hodgkin lymphoma Lung cancer Chronic obstructive pulmonary disease Pulmonary hypertension Antiretroviral treatment–induced respiratory disease
Normal (CD4$^+$ cell count greater than 350 cells/μL)	Lung cancer Chronic obstructive pulmonary disease Pulmonary hypertension

More than 80% of patients with AIDS-associated Kaposi sarcoma have antibodies to HHV-8. HHV-8 may exert its oncogenic potential in several ways. The HHV-8 genome contains several genes that are homologues to human genes. Among these is a latent nuclear antigen that binds to p53 and associates viral DNA to human DNA during mitosis; a viral cyclin that activates cyclin-dependent kinases to prevent human cells from remaining in a G$_1$ phase; a constitutively expressed receptor (viral interleukin-8 receptor) that may be involved in angiogenesis; a Bcl-2 like protein that prevents apoptosis; and viral homologues to cytokines (viral macrophage inflammatory protein [MIP] and viral interleukin-6) that may be responsible for some of the constitutive symptoms associated with Kaposi sarcoma. Cytokines are required for HHV-8–infected endothelial cells to acquire their phenotype and for continued growth of the tumor. The HIV-1 Tat protein upregulates cytokines and metalloproteinases that further promotes the oncogenic potential of Kaposi sarcoma cells.

Genetics

Genetic polymorphisms of the Fc-γ receptor IIIA, the interleukin-6 and interleukin-8 promoter regions have been associated with an increased risk for development of Kaposi sarcoma. Some human leukocyte antigen (HLA) types also have been associated with this disease.

Clinical Features

Cutaneous and mucocutaneous manifestations of AIDS-associated Kaposi sarcoma are the more common and usually precede visceral disease by months to years. Skin and visceral lesions appear as red or violet macules, papules, or nodules that may coalesce to form plaque-like lesions. Lesions may affect any area of the skin and involve any organ system. Lymphadenopathy is frequent.

Pulmonary Kaposi sarcoma may cause nonproductive cough, hemoptysis, shortness of breath, chest pain, and fever. In rare instances, involvement of the larynx or trachea may cause airway obstruction. Extrapulmonary involvement is frequent, but 15% of cases of Kaposi sarcoma occur without skin lesions. CD4$^+$ cell counts are low (0 to 100/μL) at the time of diagnosis. Examination of the lungs usually shows no abnormalities. Chest radiograph may be normal in appearance but commonly shows singular or multiple peribronchovascular nodules (Figure 30-1, *A* and *B*). Diffuse infiltration and air space consolidation also may be present. Pleural effusion is common. Hilar and mediastinal lymphadenopathy may be visible on chest films but are better visualized with computed tomography (CT) scanning. With pulmonary disease, CT scans typically reveal peribronchovascular nodules that are larger than 1 cm in diameter. The role of magnetic resonance imaging (MRI) or positron emission tomography (PET) in the diagnosis and management of pulmonary Kaposi sarcoma is not clear.

Diagnosis

Pulmonary Kaposi sarcoma is highly likely in a HIV-1–infected person with a CD4$^+$ cell count of less than 100/μL, the characteristic cutaneous or mucocutaneous lesions, and pulmonary symptoms. Bronchoscopy is useful to visualize typical endobronchial lesions (see Figure 30-1, *C*). These are flat or slightly raised and occur throughout the tracheobronchial tree but are seen most frequently at airway bifurcations. Pleural effusions usually are exudative and may be serous or serosanguineous. Serum lactate dehydrogenase may be elevated. Histologic verification is usually not required for a diagnosis of Kaposi sarcoma. Endobronchial biopsy may confer a substantial risk of severe bleeding, but biopsy may be necessary in cases in which bronchial involvement is lacking. In such cases, transbronchial or percutaneous needle biopsy is useful. In cases of pleural Kaposi sarcoma, video-assisted thoracoscopy can be used to visualize pleural lesions and to perform biopsy. Open lung biopsy in this

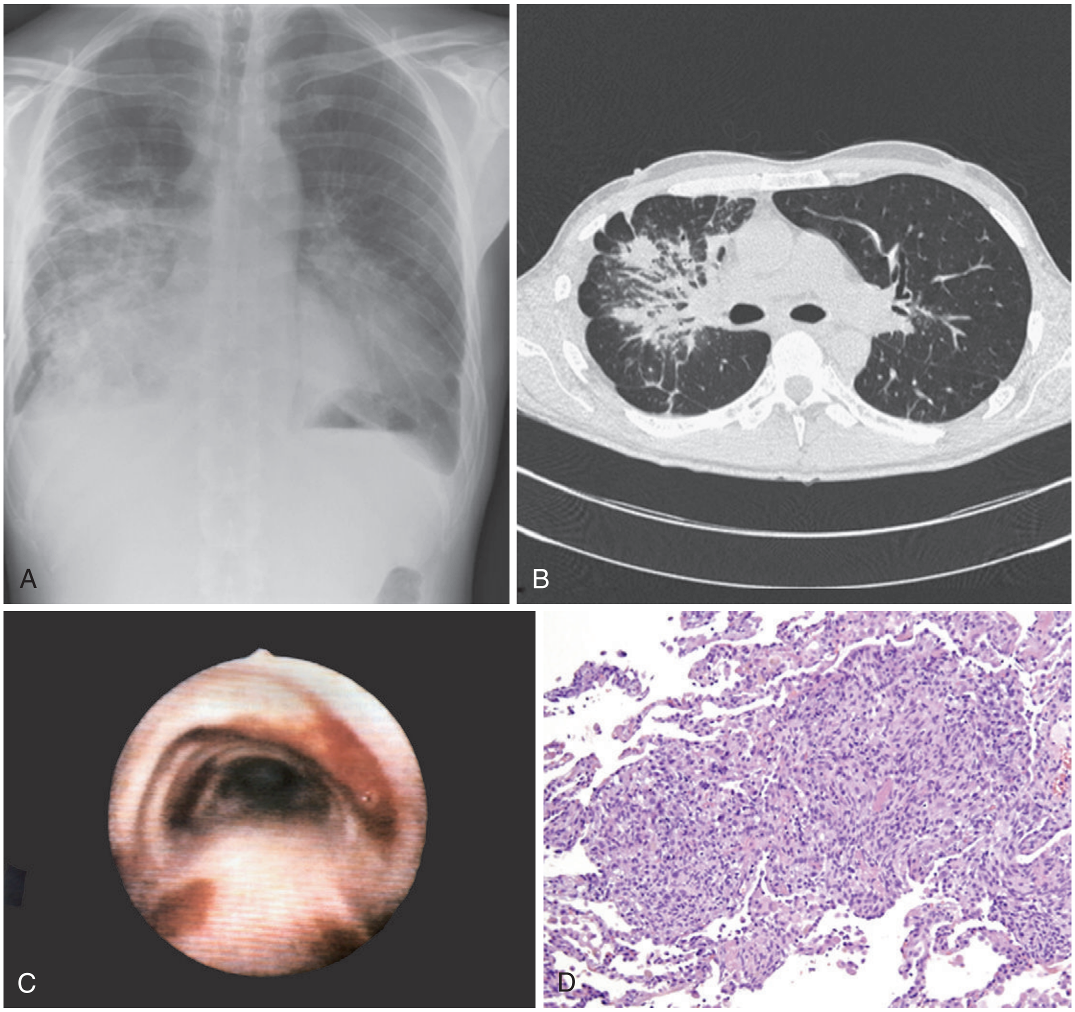


Figure 30-1 Pulmonary Kaposi sarcoma. **A** and **B,** Chest radiographs showing multiple peribronchovascular nodules. **C,** Typical violet-red endobronchial nodule visualized through a fiberbronchoscope. **D,** Transbronchial biopsy specimen of pulmonary Kaposi sarcoma lesion. *(**C,** Courtesy Dr. L. Huang. **D,** Courtesy Dr. J. Junge.)*

setting is obsolete because of the associated complications. Lung biopsy specimens show typical features of Kaposi sarcoma, which include a tumor-like infiltrate with a peribronchovascular distribution of spindle cells. Slitlike spaces without endothelium contain extravasated erythrocytes (see Figure 30-1, *D*). In situ hybridization and immunostaining usually are positive for HHV-8. HHV-8 DNA is detectable in bronchoalveolar lavage fluid (BAL) cells.

Treatment

All patients with Kaposi sarcoma should be treated with cART, but immune reconstitution may induce an inflammatory reaction and flare of the disease within 2 to 8 weeks of initiation of this therapy. Cutaneous and mucocutaneous lesions of AIDS-associated Kaposi sarcoma usually regress with cART without chemotherapy but may require additional local radiotherapy. Visceral Kaposi sarcoma, however, will necessitate chemotherapy. Concomitant use of cART increases the response rate to chemotherapy. All patients should be offered *P. jirovecii* prophylaxis regardless of their $CD4^+$ cell count. Pegylated liposomal doxorubicin or liposomal daunorubicin are used for first-line treatment of Kaposi sarcoma, in addition to cART. In randomized multicenter trials, response rates and adverse effect profiles to both agents given as monotherapy proved to be superior to conventional chemotherapy.

Liposomal anthracyclines are well tolerated overall. Myelosuppression is the most important dose-limiting toxicity. The risk of drug-drug interactions with antiretroviral agents is low for anthracyclines. The taxane paclitaxel, in combination with granulocyte colony-stimulating factor (G-CSF), is approved for second-line treatment of Kaposi sarcoma. Experience with paclitaxel and pulmonary Kaposi sarcoma is limited, and the use of paclitaxel is associated with more severe adverse effects than those reported with anthracyclines. Paclitaxel has potential serious drug-drug interactions with antiretroviral drugs.

Due to the high cost of anthracyclines and taxanes their use may be limited in resource-poor settings. Alternatively, the most widely used regimen for the treatment of pulmonary Kaposi sarcoma, a combination regimen of doxorubicin (Adriamycin), bleomycin, and vincristine (ABV) may be used. Vincristine may be replaced with vinblastine in patients with polyneuropathy. The combination is given every 2 weeks. Response is evaluated after four to six series of chemotherapy. Response rates are 30% to 50%. Adverse side effects include anemia, neutropenia, thrombopenia, neuropathy, mucositis and alopecia. There are potential drug-drug interactions between vincristine or vinblastine and antiretroviral agents.

Investigational agents include thalidomide, imatinib, mTOR inhibitors, IL-12, and fumagilin.

Clinical Course and Prevention

Untreated pulmonary Kaposi sarcoma is associated with a median survival of less than 6 months. Combination ART improves survival in HIV-1–infected patients with pulmonary Kaposi sarcoma receiving chemotherapy to 50% and above. Severe immunodeficiency ($CD4^+$ cell count below 100/µL), pleural effusion and/or hypoxia are associated with a particularly rapid course of this disease. Prevention is best accomplished through treatment of the underlying HIV-1–related immunodeficiency with cART.

MULTICENTRIC CASTLEMAN DISEASE

Epidemiology, Risk Factors, and Pathogenesis

Castleman disease is a rare lymphoproliferative disease characterized by angiofollicular proliferation. Three histologic variants—hyaline vascular, plasma cell, and mixed—and two clinical types, localized and multicentric, have been described. The incidence of Castleman disease is increased in patients with HIV-1 infection. Multicentric Castleman disease (MCD) is associated with concomitant AIDS-associated Kaposi sarcoma. One study found HHV-8 DNA in 14 of 14 cases of HIV-1–associated MCD but in only 7 of 17 non–HIV-1–infected cases. HHV-8 DNA was detected in only 1 of 34 lymph node biopsy specimens from HIV-1–uninfected patients with localized disease. MCD frequently transforms to the non-Hodgkin form of lymphoma. Pulmonary involvement in Castleman in HIV-1 infection is exceedingly rare but probably also is underdiagnosed.

Clinical Features

The localized form of Castleman disease usually manifests as mediastinal lymph node hyperplasia without systemic symptoms. Signs and symptoms of multicentric disease include fever, generalized lymphadenopathy, fatigue, hepatosplenomegaly, and pancytopenia. Symptoms are thought to be related in part to cytokine disarray by viral homologues of IL-6 and IL-10 encoded by the HHV-8 genome. Symptoms and signs of pulmonary involvement include shortness of breath, cough, and bilateral crackles. Worsening of symptoms often is preceded by HHV-8 viremia. $CD4^+$ cell counts vary, ranging from normal to extremely low, indicating severe immunodeficiency. Chest radiographs and CT scans may show noduloreticular interstitial infiltration, mediastinal lymphadenopathy, or pleural effusions.

Diagnosis

Bronchoscopy findings usually are normal. Analysis of BAL fluid cells may show hypercellularity and lymphocytosis. A lung biopsy is required to confirm the diagnosis. HHV-8 DNA usually is detected in biopsy specimens by immunostaining or in situ hybridization techniques.

Treatment

Localized disease is cured by surgical resection. Treatment of MCD is difficult and may include corticosteroids, chemotherapy, immune therapy, and/or radiation therapy. Specific antiherpesvirus therapy with ganciclovir or foscarnet to reduce the HHV-8 replication has been shown to be of some use. Treatment with rituximab (anti-CD20 monoclonal antibody) for HIV-associated MCD is now considered the “gold standard.” The most significant adverse effect may be progression of concomitant Kaposi sarcoma. Mild to moderate infections may occur.

Clinical Course and Prevention

Survival rates are poor but have improved in the era of cART, with a 5-year overall survival of approximately 50%. Patients with multicentric Castleman disease often develop non-Hodgkin lymphoma, discussed next.

NON-HODGKIN LYMPHOMA

Epidemiology, Risk Factors, and Pathogenesis

In the pre-cART era, non-Hodgkin lymphoma (NHL) represented the second most common HIV-1–associated cancer after Kaposi sarcoma. With the introduction of cART, rates of NHL have declined by 40% to 70% for most histologic subtypes. Despite the decline in incidence, NHL is now one of the most common initial AIDS-defining illnesses: The risk of low-grade lymphoma (although not AIDS-defining) is increased 4-fold, the risk of high-grade lymphoma is increased 600-fold, and the risk of primary brain lymphoma is increased 3600-fold with HIV-1 infection over corresponding risks in the absence of infection. Recognized risk factors for development of NHL include concomitant infection with Epstein-Barr virus (EBV) and/or HHV-8, as well as male gender, increased age, and immunodeficiency. A diagnosis of AIDS usually precedes primary pulmonary lymphoma.

Most AIDS-related NHLs belong to one of three categories of high-grade B cell lymphomas: Burkitt lymphoma, centroblastic lymphoma, and immunoblastic lymphoma. Burkitt and Burkitt-like lymphomas tend to occur in patients with relatively high $CD4^+$ cell counts, as compared with centroblastic large cell and immunoblastic lymphomas, which occur at low $CD4^+$ cell counts. The incidence of Burkitt lymphoma is unchanged in the era of cART. Pulmonary NHL can manifest either as primary or secondary involvement. Dissemination is common for NHL, but primary pulmonary lymphoma is a rare condition, accounting for less than 0.5% of HIV-1–related lymphomas.

The pathogenesis of NHL is complex and involves immune dysfunction together with dysregulation of cytokine responses, chronic antigen stimulation, and co-infection with EBV and HHV-8.

Genetics

Somatic mutations of immunoglobulin, c-Myc, Bcl-6, and p53 genes are associated with transformation into lymphoma. Overexpression of Bcl-2 is associated with resistance to chemotherapy and a poor prognosis. Persons heterozygous for the CCR-5 chemokine Δ32 mutation may be at reduced risk for NHL, whereas the stromal cell–derived factor 1 (SDF1)-3′A chemokine variant may be associated with an increased risk for NHL.

Clinical Features

Patients may present with nodal or extranodal disease and may have systemic symptoms. Clinical signs of advanced NHL with pulmonary involvement include fever, night sweats, and weight loss (B symptoms). Manifestations of primary pulmonary involvement include shortness of breath, cough, and chest pain. Primary pulmonary lymphoma is associated with $CD4^+$ cell counts less than 50/µL. Anemia, thrombocytopenia, and leukopenia are frequent findings. Serum lactate dehydrogenase often is elevated with secondary but not primary pulmonary involvement. Chest radiographs and CT scans commonly show isolated or multiple central or peripheral nodules (**Figure 30-2,** *A*). Mediastinal lymphadenopathy and pleural effusion are less common.

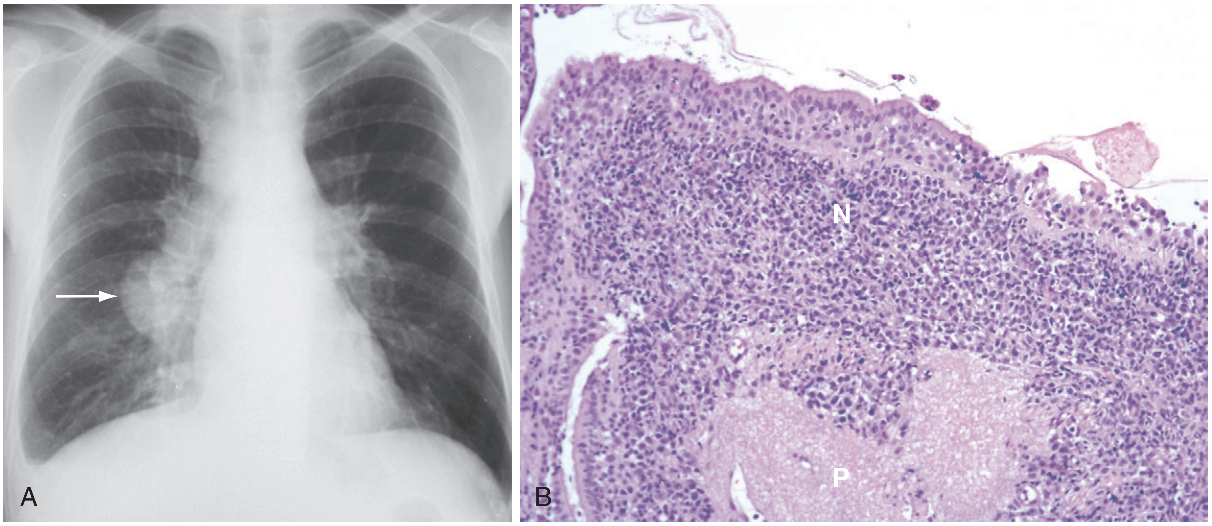

Figure 30-2 Primary pulmonary non-Hodgkin lymphoma. **A,** Chest radiograph showing a single, large central nodule (*arrow*). **B,** Transbronchial biopsy specimen of non-Hodgkin lymphoma (*N*). The patient also had *Pneumocystis jirovecii* pneumonia (*P*). *(Courtesy Dr. J. Junge.)*

Diagnosis

Fiberoptic bronchoscopy usually is normal. Cytologic examination of BAL fluid may reveal lymphoma cells, but biopsy is required to establish a histologic diagnosis. Transbronchial biopsy has reasonable diagnostic yield for secondary but not primary pulmonary lymphoma. Percutaneous thoracic needle biopsy is the most commonly used method to obtain tissue for diagnosis. In rare cases, video-assisted thoracoscopic or open lung biopsy may be necessary. Histologically, the lymphoma invades the alveolar septa and vascular walls (see Figure 30-2, *B*). Necrosis is frequent. Most tumors are high-grade centroblastic or immunoblastic large B cell lymphomas that are EBV-positive and overexpress Bcl-2.

Treatment

There is no evidence to indicate that primary or secondary pulmonary NHL should be treated differently from NHL in general. Chemotherapy regimens that include cyclophosphamide, doxorubicin, vincristine (Oncovin), and prednisone (CHOP), or CHOP-rituximab (CHOP-R), or etoposide, prednisone, vincristine (Oncovin), cyclophosphamide, and doxorubicin (EPOCH) are used in conjunction with cART. CHOP-R may be beneficial in primary pulmonary lymphoma because these often overexpress bcl-2. No significant drug-drug interactions occur between commonly used cART regimens and CHOP. Use of cART is associated with less anemia, thrombocytopenia, and other adverse effects of chemotherapy.

Clinical Course and Prevention

The median survival from primary pulmonary lymphoma is less than 4 months with chemotherapy alone. Survival from lymphoma has improved in the cART era.

PRIMARY EFFUSION LYMPHOMA

Epidemiology, Risk Factors, and Pathogenesis

Primary effusion lymphoma (PEL), or body cavity–associated lymphoma, is a rare type of non-Hodgkin lymphoma that occurs almost exclusively with HIV-1 infection. PELs grow mainly in the body cavities (pleural, pericardial, and peritoneal) as lymphomatous effusions without an identifiable contiguous tumor mass. PEL occurs predominantly in men who have sex with men and are seropositive for HHV-8. In contrast with NHL, PEL lacks c-myc gene rearrangements. PEL is positive for HHV-8 and Epstein-Barr virus, expresses CD45, exhibits clonal immunoglobulin gene rearrangements, and lacks *bcl2*, *bcl6*, *ras*, and *TP53* gene alterations.

Clinical Features

PEL is associated with progressive immunodeficiency and consequently low $CD4^+$ cell counts. Patients usually have a previous diagnosis of Kaposi sarcoma. Clinical manifestations include fever, generalized lymphadenopathy, and fatigue. Symptoms and signs of pleural involvement include shortness of breath and cough. Chest radiographs show unilateral or bilateral effusion. CT scans are useful to rule out localized masses representing NHL, Kaposi sarcoma, or other neoplastic disease. PEL usually remains localized to the body cavity of origin.

Diagnosis

The diagnosis is based on the demonstration of morphologic, immunophenotypic, immunogenotypic, viral and molecular characteristics of pleural fluid. Demonstration of HHV-8 often is necessary.

Treatment

Treatment follows guidelines for treatment of NHL and should include chemotherapy together with cART.

Clinical Course and Prevention

PEL has an aggressive clinical course and is associated with a high mortality rate. The 1-year overall survival rate is 40%.

LUNG CANCER

Epidemiology, Risk Factors, and Pathogenesis

The risk for development of small cell carcinoma, non–small cell carcinoma, and bronchoalveolar carcinoma is two to five times greater among persons with HIV-1 infection than in the general population, and such cancers appear at a younger age. Adenocarcinoma accounts for a majority of cases. Men are affected more often than women. The risk is increased with a $CD4^+$ cell count less than 500/µL. From 60% to 80% of HIV-1–infected persons are smokers, and this factor contributes significantly to the excess risk. Epidemiologic modeling, however, shows that smoking alone cannot account for the excess risk, suggesting that other cofactors are at play. It is possible that smoking may additively or synergistically together with HIV-1 infection affect the lung more severely than in non–HIV-1–infected persons. HIV-1 may enhance lung damage, leading to increased oxidative stress.

Clinical Features

Clinical features do not differ from those of lung cancer in general, but HIV-1–infected patients tend to be younger at presentation. Symptoms and signs of localized disease may be subtle but may include persistent cough, shortness of breath, chest pain, and weight loss as the disease develops. Chest radiographs and CT scans may show nodular or diffuse infiltrates, hilar or mediastinal lymphadenopathy, or pleural effusion.

Diagnosis

Fiberoptic bronchoscopy may reveal bronchial invasion. Biopsy is required to establish a histologic diagnosis, and specimens can be obtained by transbronchial, percutaneous thoracic, open lung, or video-assisted thoracoscopic techniques.

Treatment

Treatment of HIV-1–associated lung cancer follows current guidelines for treatment of non–HIV-1–associated lung cancer, as described in Chapter 67.

Clinical Course and Prevention

Patients with HIV-1 infection tend to present with more advanced disease. Studies indicate that overall survival is shortened for persons with HIV-1 infection and lung cancer compared with the general population.

INFLAMMATORY PULMONARY DISORDERS

NONSPECIFIC INTERSTITIAL PNEUMONITIS

Epidemiology, Risk Factors, and Pathogenesis

Nonspecific interstitial pneumonitis (NIP), also known as chronic interstitial pneumonitis, is a common cause of pulmonary disease in adults with advanced, untreated HIV-1 infection. Half of HIV-1–infected adults without pulmonary symptoms and with $CD4^+$ T lymphocyte counts below 200 cells/µl show histopathologic changes characteristic of NIP. The incidence of NIP at different $CD4^+$ strata is unknown. NIP is rare in children.

The etiology of NIP is unknown. There is evidence of HIV-1 RNA expression in pulmonary $CD4^+$ T lymphocytes and macrophages. Cytotoxic $CD8^+$ T cells are the predominant lymphocyte type, and it is speculated that these cells induce pulmonary inflammation. Other mechanisms of lung damage include increased levels of inflammatory mediators (e.g., cytokines and leukotrienes) and release of superoxide anion from activated alveolar macrophages.

Clinical Features

The signs and symptoms of NIP are unspecific and resemble many clinical manifestations of HIV-1 infection such as cough, shortness of breath, and fever. Extrapulmonary involvement is rare. Examination of the lungs usually yields normal findings. There may be subtle hypoxia that further increases on exercise. Chest radiographs and CT scans may be normal in appearance or show diffuse alveolar, nodular, or interstitial infiltrates that are indistinguishable from those typically seen in other common HIV-1–associated infections (**Figure 30-3**, *A*). Pleural effusion is less common.

Diagnosis

Suspicion of NIP should arise when standard histocytologic studies, microbiologic staining and culture, and molecular techniques do not yield a pathogen. Thus, NIP is a diagnosis of exclusion. Tissue specimens are required to establish the diagnosis and may be obtained by bronchoscopy, fine needle aspiration, or open lung biopsy procedures. Transbronchial biopsy specimens characteristically show various degrees of perivascular, peribronchial, and pleural lymphocyte and plasma cell infiltration. Edema, fibrin deposition, pneumocyte hyperplasia, and thickening of alveolar septa are common; alveolar septal infiltration is uncommon (see Figure 30-3, *B*). Lymphoid aggregates are frequently seen. BAL fluid analysis shows lymphocytosis and a decrease in relative and absolute numbers of alveolar macrophages. Because of the risks involved with biopsy procedures, some clinicians make a presumptive diagnosis after

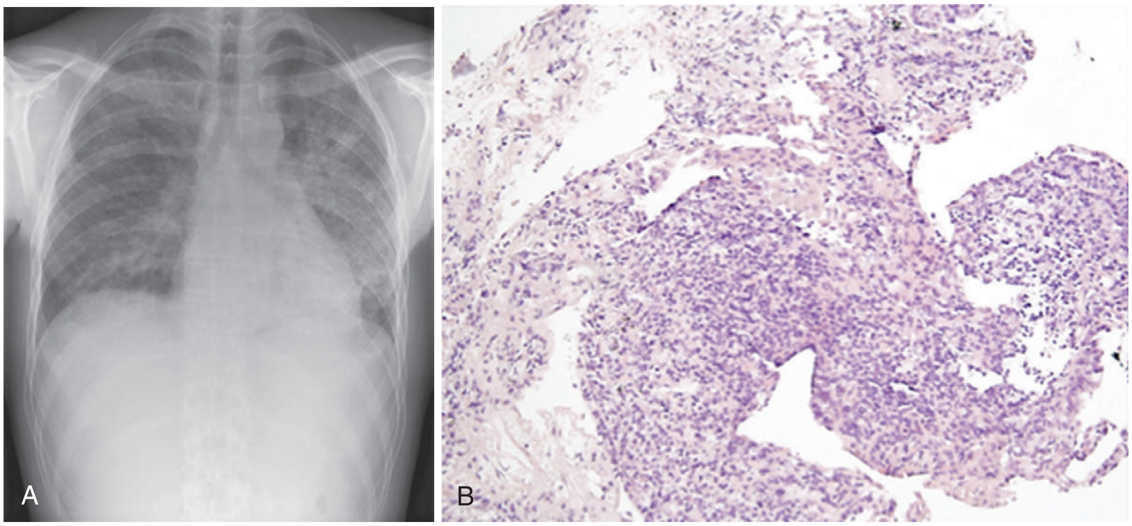

Figure 30-3 Nonspecific interstitial pneumonitis. **A,** Chest radiograph showing noninfectious bilateral diffuse infiltration before start of combination antiretroviral therapy. **B,** Transbronchial biopsy specimen. *(Courtesy Dr. J. Junge.)*

ruling out an infectious cause for the patient's pulmonary symptoms.

Treatment

Symptoms may resolve without therapy. In view of the association of NIP with severe immunodeficiency, however, initiation of cART is almost always indicated. Data from several case series indicate that cART leads to resolution of symptoms and the pathologic changes.

Clinical Course and Prevention

The natural course of NIP without cART is chronic and rarely leads to respiratory failure. Some individuals may be asymptomatic. NIP is best prevented by initiating cART before the development of moderate to severe immunodeficiency.

LYMPHOCYTIC INTERSTITIAL PNEUMONITIS

Epidemiology, Risk Factors, and Pathogenesis

Lymphocytic interstitial pneumonitis (LIP) is a disease of unknown etiology associated with HIV-1 infection and autoimmune disease. LIP occurs predominantly and not infrequently among untreated infants and children, in whom LIP is an AIDS-defining illness. LIP is rare among adults. An association has been observed between LIP and advanced HIV-1 disease. As with NIP, HIV-1 RNA expression in pulmonary CD4$^+$ T lymphocytes and macrophages has been reported.

Clinical Features

As with NIP, the symptoms of LIP are unspecific and include non-productive cough, shortness of breath, and fever. Extrapulmonary involvement of lymph nodes is common and generalized lymphadenopathy is frequent. Peripheral CD8$^+$ T lymphocytosis is characteristic. Clubbing has been reported among children. Chest radiographs may be normal but commonly show diffuse alveolar, nodular, or interstitial infiltration. Pleural effusion is common. CT scans may reveal peribronchial nodules or a diffuse ground glass appearance.

Diagnosis

Similar to NIP, LIP is an exclusion diagnosis that requires tissue samples to establish the diagnosis. Transbronchial biopsy is characterized by peribronchial, perivascular, and pleural infiltration of lymphocytic and plasma cells. These findings are also characteristic of NIP. However, septal infiltration differentiates LIP from NIP. Lymphoid aggregates are common.

Treatment

Treatment of LIP is directed at the underlying immunodeficiency caused by HIV-1. Initiation of cART is associated with resolution of pulmonary symptoms.

Clinical Course and Prevention

The natural course of LIP is variable and ranges from spontaneous remission to respiratory failure. LIP is best prevented by initiating cART before the development of moderate to severe immunodeficiency.

CRYPTOGENIC ORGANIZING PNEUMONIA

The presenting clinical features of cryptogenic organizing pneumonia (COP) in HIV-infected patients may be dramatic, with the development of a flulike illness with acute or subacute symptoms (fever, malaise, anorexia, weight loss, nonproductive cough, and dyspnea). Usually this syndrome develops in immunocompromised patients with infections or malignancy. Physical examination often reveals bibasal crackles, and the chest radiograph shows multiple bilateral alveolar opacities. Linear or nodular opacities also may be present. In patients with typical COP, alveolar lavage may demonstrate an alveolitis characterized by CD8$^+$ T lymphocytes, foamy macrophages, and a small increase in neutrophils, eosinophils, and mast cells. Treatment with glucocorticosteroids causes a remission or stabilization of the disease. However, relapse is common if the steroids are withdrawn.

CHRONIC AIRWAY DISEASE AND EMPHYSEMA

Epidemiology, Risk Factors, and Pathogenesis

HIV-1–infected smokers are 10% to 25% more likely than smokers without infection to have chronic obstructive pulmonary disease (COPD). Several factors that increase the risk for development of COPD are frequent among HIV-1–infected patients, including a high prevalence of tobacco smoking, intravenous drug use, and recurrent bacterial and opportunistic infections. COPD develops at younger age and is more prevalent among African Americans. Currently, it is unknown whether HIV-1 infection per se or the increased life expectancy associated with cART, or a combination of the two factors, accounts for the increased prevalence of COPD. Evidence appears to support all three possibilities. Ongoing viral replication and activation of pulmonary cytotoxic T lymphocytes may lead to parenchymal destruction by mechanisms similar to the effects of tobacco smoking. Advanced HIV-1 disease is associated with impairment of lung function. Some studies suggest a synergistic effect of HIV-1 and smoking, which may explain why HIV-1–infected patients may develop COPD at a younger age. HIV-1–infected intravenous drug users have reduced FEV_1, FVC, and diffusing capacity of carbon monoxide (DL_{CO}) compared with persons in other transmission categories. This respiratory impairment may be explained in part by the fact that these patients more frequently are heavy smokers and suffer from recurrent lower respiratory infections. Pulmonary bacterial and opportunistic infections (e.g., *P. jirovecii* pneumonia) are associated with permanent reductions in FEV_1, FVC, FEV_1/FVC, and DL_{CO} after recovery from the infection.

Chapter 41 deals with COPD in detail.

Genetics

Mutations in the α_1-antitrypsin gene predispose affected persons to the development of emphysema.

Clinical Features

Signs and symptoms of COPD do not differ between persons with and those without HIV-1 infection and include cough, sputum production, shortness of breath, wheezing, and chest tightness. HIV-1–infected patients may be younger.

Diagnosis

Spirometry is central to the diagnosis. Reductions in FEV_1, FVC, and FEV_1/FVC will confirm the diagnosis and establish the severity of the condition. A radiograph is useful to distinguish between COPD or emphysema and other lung and heart conditions manifesting with similar symptoms. Arterial blood gas analysis is performed to confirm hypercapnia or to establish the need for oxygen treatment.

Treatment

Treatment does not differ from COPD treatment in general. Therapy includes bronchodilators, inhaled glucocorticosteroids, and pulmonary rehabilitation. Influenza and pneumococcal vaccination is recommended and does not confer any increased risk for HIV-1 disease progression. Oxygen treatment follows general guidelines.

No important drug interactions between antiretrovirals and bronchodilators have been noted, except between some protease inhibitors and theophylline. There is the potential of drug interactions between protease inhibitors and inhaled glucocorticosteroids, but not with nucleoside and non-nucleoside analogues. Nicotine can be used to treat tobacco dependency together with antiretrovirals. There is a potential drug interaction with bupropion and protease inhibitors and non-nucleoside analogues. Similar interactions may occur with vareniclin.

Clinical Course and Prevention

The clinical course usually is not any different from that for COPD in the general population. Smoking cessation is central to successful prevention of further disease progression. Care also should be taken to avoid secondary smoke exposure. Avoidance of lung irritants is important. COPD is not believed to affect HIV-1 disease progression. Antiretroviral management of HIV-1 infection should follow national and international guidelines and should not be delayed.

HIV-1–ASSOCIATED PULMONARY HYPERTENSION

Non–HIV-1–associated pulmonary hypertension is described in detail in Chapter 58.

Epidemiology, Risk Factors, and Pathogenesis

Pulmonary hypertension is an infrequent cause of pulmonary disease among HIV-1–infected patients. However, the incidence (approximately 0.5%) is higher than for non–HIV-1–infected persons (about 0.02%), and the risk increases with age. A careful examination is required to distinguish between primary and secondary forms of pulmonary hypertension. HIV-1 infection per se is assumed to induce vascular changes associated with primary pulmonary hypertension, whereas drug use (with associated foreign particle microembolism), COPD, interstitial pulmonary disease, essential hypertension, ischemic heart disease, chronic thromboembolism, and valvular heart disease contribute to secondary pulmonary hypertension. Some reports have implicated concurrent infection with HHV-8 in the pathogenesis of pulmonary hypertension.

The pathogenesis remains unclear. Remodeling of the media and adventitia of the arterial pulmonary tree, the extracellular matrix and plexiform lesion characterize HIV-1–related and non–HIV-1–related sporadic forms. The increase in pulmonary vascular resistance may be caused by vascular growth factors, mechanical obstruction of the pulmonary arteries, hypoxia, or other stimuli. Chronic changes may remain even after the initiating insult or factor is removed. Pulmonary vascular resistance increases right ventricular systolic pressure, with consequent dilatation and dysfunction, ultimately leading to right ventricular failure.

Genetics

Familial primary pulmonary hypertension is characterized by autosomal dominant inheritance and incomplete penetrance. A mutation in the type II bone morphogenetic protein receptor (BMPR II) has been associated with this disorder.

Clinical Features

The predominant symptom is dyspnea, particularly exertional dyspnea. This symptom is nonspecific, so the diagnosis often is made late in the clinical course. Other common symptoms and signs may include other nonspecific complaints and findings such as fatigue, angina, syncope or near syncope, and peripheral edema. Pulmonary hypertension may occur at any CD4$^+$ cell count.

Diagnosis

A full diagnostic evaluation is crucial to rule out non–HIV-1–related causes, because they may necessitate other specific therapy. The chest radiograph shows cardiomegaly and enlarged central pulmonary arteries, or signs of emphysema suggestive of chronic obstructive pulmonary disease, or interstitial infiltration suggestive of parenchymal disease. Echocardiogram usually confirms right axis deviation and right ventricular hypertrophy (P pulmonale). Echocardiography provides imaging of right atrial and ventricle enlargement, tricuspidal regurgitation and reduced left ventricular size. Arterial blood gases commonly demonstrate hypoxia. Pulmonary function test is helpful to distinguish between obstructive or restrictive underlying pulmonary causes. Perfusion lung scans or CT performed with use of intravenous contrast can rule out central and peripherally located thrombi. Additionally, the lung parenchymal CT images may establish alternative diagnoses. Magnetic resonance pulmonary angiography is promising because it also provides assessment of right ventricular function. Eventually, cardiac catheterization will be necessary to measure pulmonary artery pressure, cardiac output, and left ventricular filling pressure.

Treatment

HIV-1–associated pulmonary hypertension has been treated with epoprostenol, inhaled prostacyclin, inhaled iloprost, bosentan (an endothelin receptor antagonist), and sildenafil. The effect of each agent is variable, but these drugs generally improve dyspnea and exercise tolerance. The effect is temporary, however, and concerns have emerged regarding adverse effects. Combination ART is associated with improved hemodynamics and survival. Use of anticoagulation is not supported by available evidence.

Clinical Course and Prevention

Pulmonary hypertension progresses to heart failure over 1 to 2 years despite therapy and is associated with a poor survival rate. Higher CD4$^+$ cell counts have been associated with better survival.

MISCELLANEOUS CONDITIONS

ANTIRETROVIRAL THERAPY AND RESPIRATORY SYMPTOMS

Antiretroviral treatment may cause unexpected respiratory symptoms. Lactic acidosis and hepatic steatosis with hepatic failure are rare but severe complications associated with therapy with nucleoside reverse transcriptase inhibitors (RTIs), particularly stavudine, didanosine, and zidovudine, that may occur after a few to several months of treatment. Lactic acidosis carries a high mortality rate. Patients with elevated serum lactate levels may be asymptomatic or critically ill or may report nonspecific symptoms such as dyspnea, tachypnea, fatigue, nausea, diarrhea, vomiting, and abdominal pain.

Another nucleoside RTI, abacavir, can produce a hypersensitivity reaction with fever, rash, and myalgias. Respiratory signs and symptoms, including cough, dyspnea, and pharyngitis, frequently accompany the hypersensitivity reaction. Hypersensitivity is associated with the HLA-B5701 tissue type.

The non-nucleoside RTI analogues (efavirenz and nevirapine) also may cause a hypersensitivity reaction including pulmonary hypersensitivity.

Immune reconstitution inflammatory syndrome (IRIS) may occur weeks to months after initiation of cART. IRIS is an inflammatory reaction to asymptomatic or residual opportunistic pathogens that may cause serious clinical conditions or aggravation of symptoms. Examples of such pulmonary pathogens are the HIV-1 virus, *Mycobacterium avium* complex, *Mycobacterium tuberculosis*, and *P. jirovecii*. Associated noninfectious conditions include sarcoidosis, vasculitis, and other autoimmune disease. Any inflammatory symptoms should be evaluated and treatment instituted when necessary. Optimal therapy has not been determined. Antiinflammatory therapy may attenuate symptoms, but many cases resolve spontaneously.

AGING AND PULMONARY DISEASE

Aging HIV-infected persons are at an increased risk for several chronic diseases including noninfectious pulmonary diseases. A recent observation was that in addition to COPD, lung cancer, and pulmonary hypertension, HIV-infected patients also are at increased risk for development of lung fibrosis. After controlling for smoking, the risk was found to be highest among persons older than 50 years. At present, it is unknown whether lung fibrosis is caused by HIV, by specific interstitial disease, by scarring from previous infection, or by adverse effects of antiretrovirals.

CONTROVERSIES AND PITFALLS

Noninfectious pulmonary complications of HIV-1 infection very often constitute a diagnosis of exclusion, because pulmonary infectious complications are many times more frequent than noninfectious complications. Therefore, extensive microbiologic and histopathologic workup often is required to rule out HIV-related infections such as *Pneumocystis* pneumonia (PCP).

In view of the extended life expectancy with cART and high prevalence of smoking, non–AIDS-related pulmonary malignancies are expected to increase in frequency. Many clinicians have been reluctant to refer HIV-1–infected patients to oncology services because of the dismal prognosis associated with HIV-1 infection, pulmonary cancer, and the adverse effects of aggressive chemotherapy. Recent studies, however, indicate that chemotherapy is better tolerated and response rates are higher with concomitant cART.

Another matter of some controversy is whether or not to initiate cART for nonspecific pulmonary inflammatory disease, COPD, pulmonary hypertension, and other non-AIDS pulmonary disease. In cases associated with immunodeficiency ($CD4^+$ cell count below 350 to 500/µL) or constitutional symptoms, cART should always be offered according to national and international guidelines. In other cases, initiation of cART is prudent if the underlying condition leading to pulmonary inflammatory disease, COPD, pulmonary hypertension, or another disorder is believed to be the HIV-1 infection. Most adverse effects of cART, drug interactions, and compliance issues are easily managed today with the introduction of less toxic compounds and once-daily dosing regimens.

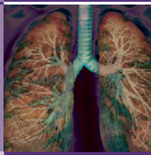
Section 5

INFECTIOUS DISEASES



Chapter 31

Tuberculosis and Nontuberculous Mycobacterial Infections

Nicholas Walter • Charles L. Daley

The genus *Mycobacterium* consists of slow-growing organisms that are widely disseminated throughout the world and range from species that cause no human disease to those such as *Mycobacterium tuberculosis* and *Mycobacterium leprae* that are responsible for enormous morbidity and mortality. Mycobacteria are aerobic bacilli with high concentrations of lipids in their cell wall, which make them impermeable to most common stains. However, because of their ability to retain carbolfuchsin dye despite decolorization attempts with acid alcohol, they are referred to as acid-fast bacilli (AFB). Although mycobacteria can produce disease in almost any site, two groups of mycobacteria have a propensity for causing pulmonary infections: certain members of the *M. tuberculosis* complex and the nontuberculous mycobacteria (NTM).

Tuberculosis (TB) is the disease caused by bacteria of the *M. tuberculosis* complex, which includes the clinically relevant species *M. tuberculosis*, *Mycobacterium bovis*, and *Mycobacterium africanum*. Although *M. tuberculosis* is the most common cause of TB worldwide, both *M. bovis* and *M. africanum* can produce clinically indistinguishable forms of disease. The tubercle bacilli have been around for thousands of years, with evidence of human infection dating back to Neolithic, pre-Columbian, and early Egyptian times. Not until the Industrial Revolution, however, did TB become a major cause of human disease and death. It is estimated that approximately 25% of all adults died from TB in Europe during the 17th and 18th centuries. Throughout this period, the etiology of TB was hotly debated, with some of these early investigators arguing for a hereditary cause and others for a transmissible etiology. Finally, in 1882, Robert Koch presented his momentous discovery: The tubercle bacillus was the cause of TB. Early attempts at therapy, including the sanatorium movement, surgery, and lung collapse therapy, provided little relief from TB, and it was not until the discovery of paraaminosalicylic acid (PAS) and streptomycin in the 1940s that the age of antituberculosis chemotherapy began. Since that time, additional drugs have been developed, and most of the world treats TB with the same four-drug regimen administered for 6 months. More recently, however, co-infection with human immunodeficiency virus (HIV) and the emergence of drug-resistant strains of *M. tuberculosis* have conspired to complicate clinical management and to create barriers to global TB control.

The NTM group consists of nonlepromatous organisms that are not members of the *M. tuberculosis* complex. The NTM have been referred to as “mycobacteria other than tuberculosis” (MOTT), atypical mycobacteria, and environmental mycobacteria. The last designation refers to their widespread presence in the environment. The NTM have several features that distinguish them from *M. tuberculosis*: They have a wide range of pathogenicity, are not always associated with disease, and, unlike *M. tuberculosis*, are not transmissible from human to human. Of note, however, the incidence of NTM disease is increasing in many areas of the world, and the cause for this increase is unknown. Unfortunately, the pathogenic NTM are relatively drug resistant compared with *M. tuberculosis*, so NTM infections typically are difficult to treat. Because of the current poor understanding of the transmission and pathogenesis of these infections, little insight into their prevention has emerged, so no public health strategy for the control of disease caused by these ubiquitous organisms has been formulated.

TUBERCULOSIS

EPIDEMIOLOGY, RISK FACTORS, AND PATHOGENESIS

EPIDEMIOLOGY

The World Health Organization (WHO) estimates that 30% of adults worldwide are infected with organisms in the *M. tuberculosis* complex. From this large reservoir of infected people, an estimated 9 million new cases of TB occurred in 2009, leading to approximately 1.3 million deaths. In 2008, TB was estimated to be the seventh leading cause of death worldwide, and it is the number one killer of HIV-infected patients.

The burden of TB varies significantly throughout the world, with more than 90% of cases occurring among people residing in developing countries (Figure 31-1). The highest incidence rates for TB are in sub-Saharan Africa, particularly in the southern region of the continent. Not surprisingly, the highest prevalence of HIV co-infection also is in this region. Worldwide, approximately 23% of all persons with TB have underlying HIV co-infection; however, in sub-Saharan Africa, an estimated 50% of persons with TB have HIV/AIDS.

Recent reports of outbreaks of multidrug-resistant TB (MDR TB) and extensively resistant TB (XDR TB) have highlighted the importance of providing effective antituberculosis therapy to patients. MDR TB refers to disease caused by isolates of *M. tuberculosis* that are resistant to at least isoniazid (INH) and rifampin, whereas XDR TB refers to that due to MDR TB isolates that also are resistant to fluoroquinolones and at least one second-line injectable agent (amikacin, capreomycin, or

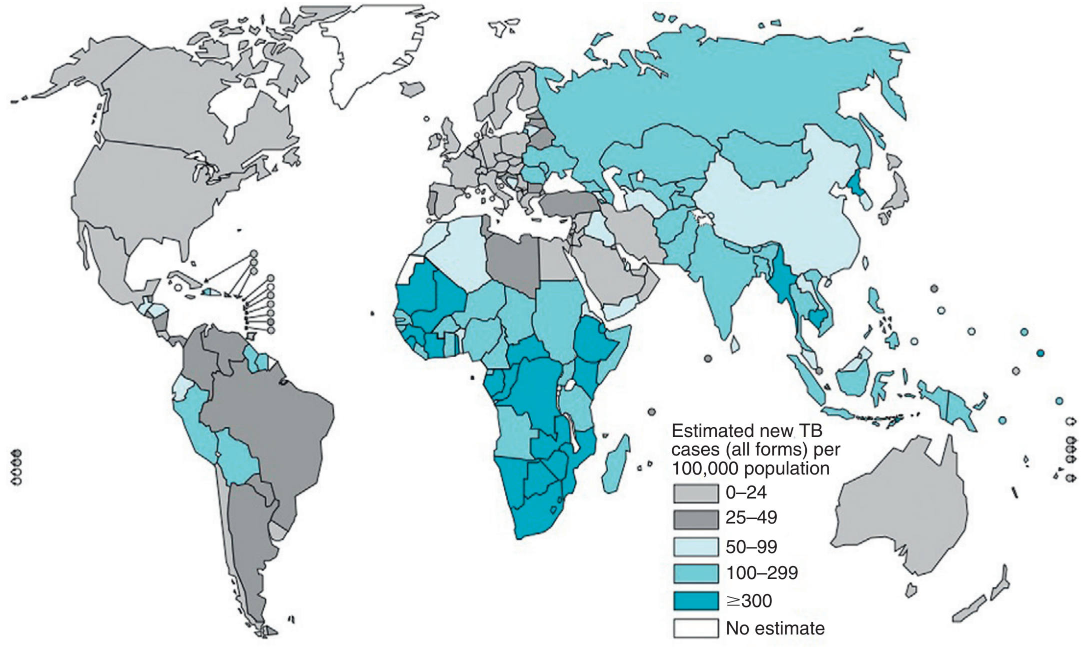


Figure 31-1 Tuberculosis (TB) notification rates, 2009. The legend depicts the number of notified TB cases, which includes both new and relapse cases per 100,000 population. *(From* Global tuberculosis control 2010, *Geneva, World Health Organization, 2010.)*

kanamycin). Surveys have documented that approximately 4.6% of TB cases worldwide are MDR TB, and 5.4% of these cases are XDR TB. More cases of drug-resistant TB exist today than in all of recorded history, and this trend is likely to continue unless more effective TB control measures are implemented globally.

In the United States, the TB case rate declined by 3% to 5% per year from 1953 to 1984. Between 1986 and 1992, the numbers of TB cases increased by approximately 20%. This increase in the number of cases was the result of at least three major factors: (1) inadequate public health measures, (2) immigration from countries where TB is prevalent, and (3) co-infection with HIV. Fortunately, case numbers have declined since 1992 and are now at a historic low. In 2010, a total of 11,181 cases of TB were reported in the United States, for an incidence of 3.6 per 100,000 population. TB case rates declined an average of 4.5% each year during 2000 to 2010. TB rates were 11 times higher among foreign-born persons than among U.S.-born people. Among U.S.-born persons, blacks were 7 times more likely to have TB than whites. Approximately 1% of new cases in the country had MDR TB, approximately 90% of whom were foreign-born. Of these MDR TB cases, approximately 1% to 2% were XDR TB.

RISK FACTORS

Certain people are at higher risk for development of TB simply because they are more likely to be exposed to and thus infected with *M. tuberculosis* (Table 31-1). For example, approximately 60% of reported TB cases in the United States occur among foreign-born people who come from areas where the disease is endemic. Other populations with an increased prevalence of TB infection include certain racial and ethnic groups, low-income populations, the homeless, and injection drug users.

Table 31-1 Criteria for a Positive Reaction on Tuberculin Skin Testing

Induration Size	Risk Groups
≥5 mm	HIV-infected persons Close contact with an infectious tuberculosis case Abnormal-appearing chest radiograph* consistent with previous tuberculosis Immunosuppressed patients receiving the equivalent of ≥15 mg/day of prednisone for at least 1 month
≥10 mm	Foreign-born persons recently arrived (<5 years) from high-prevalence countries Medical conditions† that increase the risk of tuberculosis Injection drug users Medically underserved, low-income populations (e.g., homeless persons) Residents and staff of long-term care facilities (e.g., nursing homes, correctional institutions, homeless shelters) Health care workers Children <4 years of age Tuberculin skin test converters (increase of ≥10 mm induration within a 2-year period)
≥15 mm	All others; these persons should not be screened in the absence of indication

*The predominant chest radiographic finding consistent with previous tuberculosis is presence of fibrotic lesions; other changes such as pleural thickening or isolated calcified granulomas are not related.

†Medical conditions and factors associated with increased risk for development of active disease in a patient with latent tuberculosis infection include silicosis, end-stage renal disease, malnutrition, diabetes mellitus, carcinoma of the head or neck and lung, immunosuppressive therapy, lymphoma, leukemia, weight loss of more than 10% ideal body weight, gastrectomy, and jejunoileal bypass.

Anyone infected with *M. tuberculosis* can develop TB disease, but certain groups are at higher-than-normal risk for progression to active disease (see Table 31-1). Patients who have been recently infected with *M. tuberculosis* and those with medical conditions associated with significant immunosuppression are at particularly high risk for development of TB. HIV co-infection is the strongest known risk factor for the development of TB and is estimated to increase the risk of progression to TB by 50- to 100-fold. Inhibitors of tumor necrosis factor-α (TNF-α) may increase the risk for development of TB by up to 10-fold, and patients taking TNF-α blockers frequently present with disseminated disease. This association appears to be stronger for infliximab and adalimumab than for etanercept. Other medical conditions are associated with a more modest increase in risk for development of disease.

PATHOGENESIS

TB is spread from person to person almost exclusively through the air by droplet nuclei, which are particles 1 to 5 μm in diameter that contain viable tubercle bacilli. Droplet nuclei are expelled into the air when patients with infectious TB create an aerosol by talking, coughing, or singing. Three factors determine the likelihood of transmitting TB: the number of bacilli expelled into the air, the concentration of organisms in the air, and the duration of contact with (i.e., breathing of) the infected air. Whether an inhaled tubercle bacillus establishes an infection in the exposed person's lung depends on both bacterial virulence and host immune defenses.

The tubercle bacillus grows slowly, dividing approximately every 18 to 24 hours. Tubercle bacilli spread through the lymphatics to the hilar lymph nodes or through the bloodstream. Small numbers of bacilli are deposited in other organs, which may then become sites of extrapulmonary disease. An adaptive immune response occurs after 2 to 8 weeks.

Once cell-mediated immunity develops, collections of activated T cells and macrophages form granulomas that wall off the mycobacterial organisms (**Figure 31-2**). For most persons with normal immune function, infection with *M. tuberculosis* seems to be arrested once cell-mediated immunity develops, even though small numbers of viable bacilli remain within the granuloma. Although a primary complex can sometimes be seen on chest radiograph, most TB infections are asymptomatic and can be detected only indirectly with a tuberculin skin test (TST) or interferon-γ release assay (IGRA). Persons with "walled-off" TB infection who do not have active disease are not infectious and thus cannot spread the disease to others.

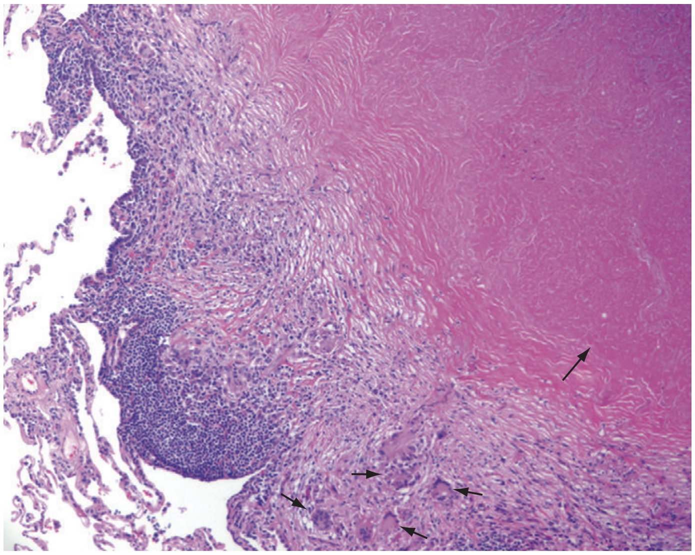

Figure 31-2 Caseating granuloma in lung tissue. This lung biopsy specimen contains a caseating granuloma. The *large arrow* highlights the caseous center. The *smaller arrows* point out giant cells, typical of granulomatous inflammation.

If cell-mediated immunity does not contain the tubercle bacilli, the initial infection progresses to active disease. Without treatment, infected persons have approximately a 5% chance of developing TB in the first 1 to 2 years after infection and an additional 5% chance of developing TB during the remainder of their lifetime (**Figure 31-3**). By contrast, persons who are co-infected with HIV have a 5% to 10% annual risk of active disease developing. When active TB develops soon after infection, the disease is referred to as *primary* TB. By contrast, when TB develops years or even decades after the initial infection, the disease is referred to as *postprimary* or *reactivation* disease. Exogenous reinfection, involving acquisition of a second strain of *M. tuberculosis*, also can lead to disease and seems to be more common in HIV-infected patients.

GENETICS

Both susceptibility and resistance to developing TB have long been thought to have a genetic component. Epidemiologic and genetic studies, including those in animal and human models, support this hypothesis. Recent investigations of specific candidate genes and genome-wide scans have identified people at increased risk for TB. Although polymorphisms in more than 10 genes have been associated with active TB, only polymorphisms in the human leukocyte antigen (HLA)-DR molecules and in the genes for the vitamin D_3 receptor, SCL11A-1, IFN-γ promoter, and mannose-binding lectin all have been associated with increased susceptibility to *M. tuberculosis*. Because each association has been relatively modest at the individual level, the genetic susceptibility is likely to be polygenic in nature. Ultimately, whether an individual with TB infection progresses to disease will depend on the interplay among host, infecting organism, and environment.

CLINICAL FEATURES

The clinical manifestations of TB are protean. Patterns of disease vary depending on whether the disease is primary or reactivation in nature, the host's immune status, and possibly the strain of *M. tuberculosis*. Of note, the clinical features of active TB are the result of a balance between host defenses and bacterial virulence; therefore, a continuum of disease is likely, and the clinical presentation of disease may be altered in severely immunocompromised patients. Most patients initially are seen with pulmonary disease, which is classically divided into primary disease and postprimary disease.

PULMONARY TUBERCULOSIS

The initial infection in the lung, referred to as *primary* infection, causes formation of an inflammatory infiltrate, which may be seen on a chest radiograph, often in the middle or lower lung zones. The draining lymph nodes may enlarge and compress adjacent bronchi, particularly in infants and children. Parenchymal disease usually clears as cell-mediated immunity develops, and it tends to clear more rapidly than nodal involvement. If the parenchymal disease persists beyond the development of

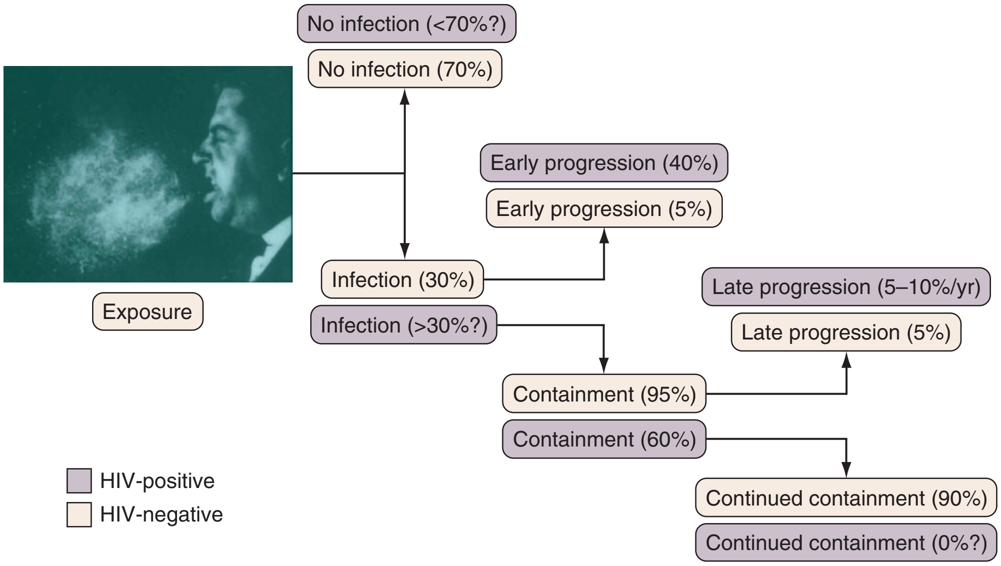

Figure 31-3 Pathogenesis of tuberculosis. After exposure to an infectious case of tuberculosis, approximately 30% of close contacts become infected with *Mycobacterium tuberculosis.* Of the contacts who become infected, approximately 5% will develop active tuberculosis in the first year after infection and an additional 5% will develop active tuberculosis over the course of their lifetime. Therefore, approximately 90% of infected people will not develop tuberculosis. When tuberculosis is introduced into an HIV-infected population, its pathogenesis is altered. Although susceptibility is difficult to establish conclusively, HIV-infected people appear to be more susceptible to initial infection than HIV-negative contacts. In outbreak settings, approximately 40% of HIV-infected contacts develop tuberculosis within the first year of exposure. After tuberculosis infection, HIV-infected people develop active tuberculosis at a rate of 5% to 10% per year. *HIV*, human immunodeficiency virus.

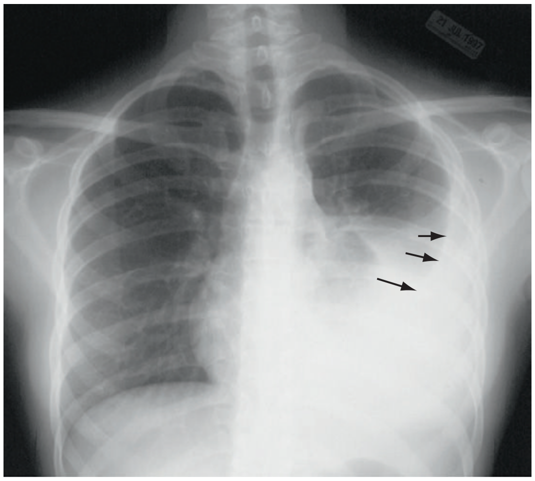

Figure 31-4 Primary tuberculosis in a young adult. The chest radiograph demonstrates a large, left-sided pleural effusion (arrows).

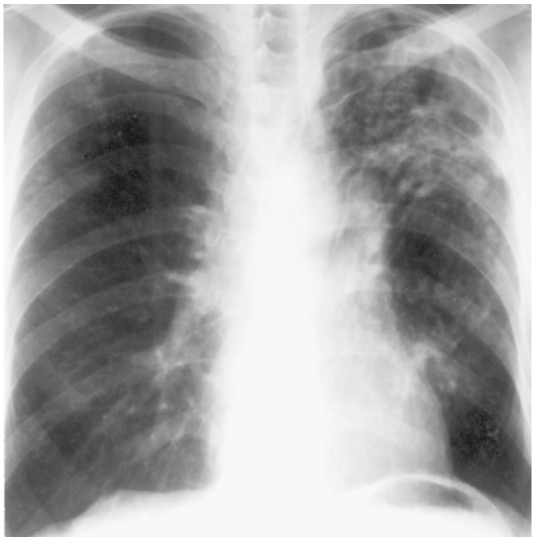

Figure 31-5 Postprimary tuberculosis. The chest radiograph shows upper lobe air space opacities with cavitation. Bronchial spread of the infection is evident in the lower lung zones.

cell-mediated immunity, cavitation may occur, although this finding is uncommon. Pleural effusions are a common manifestation of primary TB and presumably result when a peripheral, caseous focus ruptures into the pleural space (Figure 31-4). Pleuritis caused by TB may manifest as an acute illness characterized by cough, fever, and pleuritic chest pain.

During most initial infections with *M. tuberculosis*, small numbers of organisms are disseminated hematogenously, and some become seeded in the apices of the lung. The organisms seem to grow preferentially in this well-oxygenated environment, with progression to active disease occurring months or years after the initial infection. This accounts for the characteristic radiographic location of reactivation disease, which in most cases occurs in the apical or posterior segments of the upper lobes (Figure 31-5). In areas of chronic infection or areas of caseation, fibrosis may occur. Fibrocaseous lesions may contain live mycobacteria for many years, and these are the lesions that may reactivate years later.

EXTRAPULMONARY TUBERCULOSIS

As tubercle bacilli spread throughout the body during the initial infection, they can lodge in any organ and produce a focus of disease. Approximately 17% of HIV-uninfected patients with TB have an extrapulmonary form of disease only. An extrapulmonary site of infection is more likely to develop in HIV-infected patients than in HIV-seronegative persons, and the risk of extrapulmonary TB increases as the $CD4^+$ lymphocyte count decreases. The two most commonly involved extrapulmonary sites are peripheral lymph nodes and the pleura, but any site or organ can be involved. Other common sites for extrapulmonary TB are within well-vascularized areas such as the kidney, the meninges, the spine, and the growing ends of long bones.

TUBERCULOUS LYMPHADENITIS (SCROFULA)

Lymphadenitis is the most common form of extrapulmonary TB, accounting for approximately 25% of extrapulmonary disease. Lymphadenitis usually manifests as a painless, erythematous, firm mass most commonly involving the anterior and posterior cervical nodes or supraclavicular fossa. In HIV-uninfected people, the mass usually is unilateral, not associated with other sites, and systemic symptoms are absent. However, in HIV-infected patients, tuberculous lymphadenitis often is associated with multifocal disease and systemic symptoms. Without treatment, the mass will enlarge and a fistulous tract may develop.

Diagnosis of tuberculous lymphadenitis usually involves fine needle aspiration or excisional biopsy with histopathologic examination, examination for acid-fast organisms, and culture for mycobacteria. Histopathologic evidence of mycobacterial infection, including caseating granulomas, is seen in nearly all cases, but the smear is positive in only approximately 25% to 50% of cases and the culture in approximately 70% to 80%.

PLEURAL TUBERCULOSIS

Pleurisy usually is a manifestation of primary TB and results when a subpleural caseous focus ruptures into the pleural space. The resulting delayed-type hypersensitivity reaction produces pleural liquid that has a high protein concentration. Most patients are initially seen with chest pain, fever, and a nonproductive cough. If left untreated, the pleural effusion will resolve spontaneously over 2 to 4 months. The rate of reactivation, however, is approximately 65% within the next 5 years.

Diagnosis of tuberculous pleural disease begins with sampling of the pleural fluid. Early in the course of disease, the fluid may have a polymorphonuclear predominance, but in almost all cases, mononuclear cells become the majority. Cell counts typically are in the 100 to 5000 cells/μL range, and the cells are almost all lymphocytes; the presence of mesothelial cells and/or eosinophils makes the diagnosis of TB unlikely.

Pleural fluid AFB smears are seldom positive, and pleural fluid cultures are positive in only approximately 20% to 40% of cases. *M. tuberculosis* can be isolated from 30% to 50% of induced sputum specimens from patients with TB pleuritis; such specimens should therefore be obtained in all patients. Pleural biopsy specimens provide the highest diagnostic yield, with positive culture results in up to 80% to 90% of cases when at least three specimens are obtained. Thoracoscopic biopsies are nearly always diagnostic, but the procedure is invasive, costly, and often not available.

Other tests that may be helpful in the diagnosis of pleuritis are adenosine deaminase and interferon-γ (IFN-γ) assays. The enzyme marker adenosine deaminase has been shown to have high sensitivity but variable specificity. A recent metaanalysis suggested that pleural fluid IFN-γ concentration has sensitivity of 89% and specificity of 97% for pleural TB in HIV-uninfected patients. Sensitivity and specificity also are high in HIV-infected patients.

When faced with a lymphocytic exudative pleural effusion in a patient with a positive TST reaction or IGRA result, the clinician should strongly consider TB. Whether to start treatment empirically or proceed with a pleural biopsy will depend on the certainty of the diagnosis and whether or not the patient is at risk for drug-resistant TB. In the latter situation, pleural tissue should be obtained for smear and culture to direct drug susceptibility testing.

GENITOURINARY TUBERCULOSIS

Genitourinary disease is responsible for approximately 15% of extrapulmonary cases of TB and can affect either the kidneys or genitals. Renal disease may manifest with local symptoms that include dysuria, hematuria, urinary frequency, and flank discomfort. In many cases, however, the patient may be asymptomatic. Urine examination may demonstrate sterile pyuria, hematuria, or both. *M. tuberculosis* can be isolated from urine in 80% to 95% of patients who provide three morning urine specimens for culture. In patients with pulmonary TB, urine cultures have been reported to be positive in approximately 5% of cases. An intravenous pyelogram may show evidence of destructive changes in the kidney or ureteral abnormalities such as strictures and hydronephrosis. Computed tomography (CT) often demonstrates renal enlargement with abscess formation.

Genital involvement is common in patients with renal TB. Men usually present with a slowly enlarging mass in the seminal vesicles, prostate, or epididymis. TB usually is diagnosed using fine needle aspiration or urine culture. In female patients, the fallopian tube is the primary site of involvement. Women tend to present with pelvic pain, abnormal uterine bleeding, irregular menses, amenorrhea, or infertility. Genital TB is diagnosed using urine culture and endometrial biopsy or curettage. Unfortunately, infertility is common even after successful treatment.

BONE AND JOINT TUBERCULOSIS

Skeletal involvement is thought to arise from reactivation from foci that were seeded at the time of initial infection. The infection begins in the subchondral region of the bone and then spreads to cartilage, synovium, and joint space. Although weight-bearing bones are the most likely to be affected, any bone or joint may be involved. In most series, TB of the spine, or Pott's disease, accounts for more than 50% of cases. In children, the upper thoracic spine is the most frequently affected site, whereas in adults, the lower thoracic and upper lumbar vertebrae typically are involved. After the spine, the hips and knees are the most common sites of skeletal TB.

Most patients initially are seen with pain in the involved joint. Systemic symptoms usually are absent, and delays in diagnosis are common. Tuberculous involvement of the joint usually is first suspected after a radiograph shows changes suggestive of the diagnosis. Typical findings include metaphyseal erosion and cysts, loss of cartilage, and narrowing of the joint space. In Pott's disease, two vertebral bodies and the intervening joint space usually are involved. CT and/or magnetic resonance imaging (MRI) should be obtained to better define the pattern and extent of involvement. Confirmation of the diagnosis requires aspiration of joint fluid or of periarticular abscesses or biopsy of affected bone or synovium. Acid-fast smears are positive in 20% to 25% of joint fluid aspirates, with isolation of mycobacteria in 60% to 80%. Histopathologic evidence of granulomatous inflammation is almost always present in bone and synovial biopsy specimens.

CENTRAL NERVOUS SYSTEM TUBERCULOSIS

Meningitis is the most common form of central nervous system (CNS) TB, with tuberculomas occurring less commonly.

Tuberculous meningitis, although less common than in the past, is still associated with the highest rates of morbidity and mortality for any form of TB, with a mortality rate of approximately 20%. Patients usually are initially seen with some combination of headache, abnormal behavior, confusion, fever, cranial nerve abnormalities, and occasionally seizures.

CT and MRI studies may provide evidence for a basilar meningitis or show hydrocephalus or tuberculous abscesses. To confirm the diagnosis, however, cerebrospinal fluid (CSF) must be sampled for examination and culture. CSF protein is usually elevated, and glucose concentration decreased. Very high protein concentrations are associated with a worse prognosis. White blood cell counts are elevated, with values of 100 to 1000 cells/μL, most of which are lymphocytes. As with pleural effusions, however, a polymorphonuclear predominance may be noted early in the disease. AFB smears of cerebrospinal fluid are positive in only 10% to 25% of cases, and cultures are positive in approximately 55% to 80%. An RD-1 antigen–specific ELISPOT assay in combination with other rapid tests (Gram staining and cryptococcal antigen assay) was reported to be a good "rule-in" test for TB meningitis, with a sensitivity of 82% and specificity of 100%.

GASTROINTESTINAL TUBERCULOSIS

Gastrointestinal disease is an uncommon manifestation of extrapulmonary TB, although it is more common in HIV-infected patients. Classically, ileocecal involvement and tuberculous peritonitis are the most common forms. Patients with ileocecal involvement may present with abdominal pain simulating appendicitis or intestinal obstruction. Diagnosis of ileocecal TB can be difficult and often is made at the time of surgery.

Tuberculous peritonitis often manifests with abdominal pain and swelling. Fever, weight loss, and anorexia are also common. Ascitic fluid usually is high in protein. Ascitic fluid white blood cell count typically is more than 150 cells/mm^3 with a lymphocytic predominance. AFB smears are seldom positive, and cultures are positive in approximately 50% to 80% of cases; the higher yield has been reported when 1 L of fluid was cultured. Laparoscopic biopsy usually is required to make the diagnosis of peritoneal TB.

PERICARDIAL TUBERCULOSIS

Tuberculous pericarditis is a relatively uncommon manifestation of extrapulmonary TB. The clinical presentation is quite variable and determined by the stage of disease. Early in the clinical course, fever and chest pain may predominate. Some patients present with large-volume pericardial effusions and signs and symptoms of tamponade. Other patients present with constrictive pericarditis. The pericardial fluid usually is serosanguineous and occasionally grossly bloody. It typically is a lymphocytic exudative fluid with white blood cell counts in the range of 5000 to 7000 cells/μL, although counts up to 50,000 have been reported. AFB smears of the fluid are seldom positive, and cultures are positive in less than a third of cases. Often pericardial biopsy samples show histopathologic evidence consistent with a mycobacterial infection, but in some cases nonspecific inflammatory findings are described.

MILIARY TUBERCULOSIS

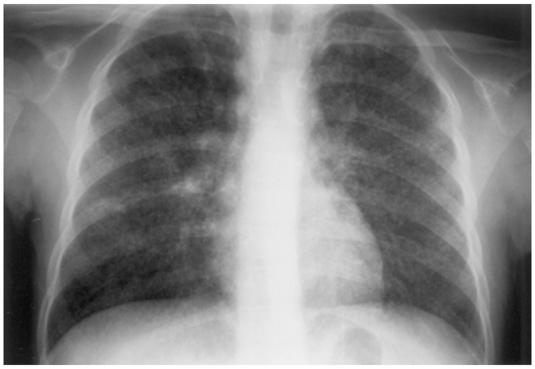

Figure 31-6 Miliary tuberculosis in an older child. The chest radiograph demonstrates diffuse small nodules 2 to 3 mm in diameter. The patient was diagnosed with disseminated tuberculosis with meningitis.

Miliary or disseminated TB occurs when tubercle bacilli spread throughout the body, through the bloodstream, resulting in small (approximately 1 to 2 mm) granulomatous lesions. Miliary TB is seen more commonly in infants, children less than 4 years old, and in immunocompromised people. Disease can result from early dissemination after infection or later after reactivation and dissemination. Disseminated TB usually develops insidiously with systemic symptoms such as fever, weakness, weight loss, fatigue, and anorexia. Cough and dyspnea also may be prominent symptoms. The mean duration of symptoms approaches 16 weeks, but some patients may go undiagnosed for more than 2 years. The chest radiograph typically shows the classic "miliary" pattern of diffuse small nodules (Figure 31-6). Sputum AFB smears are positive in 20% to 25% of cases, and sputum is culture-positive for *M. tuberculosis* in up to 65% of cases. Bronchoscopy should be considered in patients who are unable to produce sputum or who have produced negative sputum smears. Other potential sources include urine, which is culture-positive in up to 25% of patients, and liver and bone marrow, which are culture-positive in up to 25% to 40%.

DIAGNOSIS

To diagnose TB, the disease must first be suspected. TB should be suspected in certain high-risk groups reviewed previously (see Table 31-1) and when the clinical and/or radiographic presentation is consistent with TB. The medical history should elicit whether or not the person suspected of having TB has been exposed to *M. tuberculosis* or has a previous history of TB infection or disease. Symptoms at presentation will vary depending on the sites(s) of involvement and extent of disease as described previously. Guidelines suggest that all persons with an unexplained cough lasting 2 to 3 weeks or more be evaluated for TB. Of note, up to 20% of patients with pulmonary disease are asymptomatic. Findings at physical examination are rather nonspecific and will vary, depending on the site of involvement. Among HIV-infected patients, TB should be considered when any respiratory infection or fever of unknown origin occurs, because the risk for TB in this group is substantially elevated, and signs and symptoms of TB often are atypical.

TUBERCULIN SKIN TEST AND INTERFERON-γ RELEASE ASSAYS

The TST (discussed in more detail later on), which uses purified protein derivative (PPD), is the most common way to identify persons with latent tuberculosis infection (LTBI) but should not be used in the diagnosis of active TB. In general, the sensitivity of the TST for detection of active TB ranges from 65% to 94%, but in critically ill patients with disseminated disease, the sensitivity decreases to only 50%. Thus, a negative TST reaction can never exclude a diagnosis of TB.

IGRAs measure the release of IFN-γ in whole blood in response to stimulation by *M. tuberculosis* antigens. Whole blood is incubated overnight with early secretory antigen target 6 [ESAT-6], culture filtrate protein 10 [CFP10], TB7.7, and control antigens; lymphocytes sensitized by previous exposure to *M. tuberculosis* release IFN-γ. IGRAs currently available include the QuantiFERON-TB (QFT-TB) Gold and QFT-TB Gold In-Tube (QFT-GIT), which measure IFN-γ in the serum using enzyme-linked immunosorbent assay (ELISA) (Cellestis Limited, Carnegie, Victoria, Australia) and the T-Spot.*TB* test, which uses enzyme-linked immunospot (ELISPOT) methodology (Oxford Immunotec, Oxford, United Kingdom) to identify IFN-γ–producing cells.

The reported sensitivity of QFT-GIT in patients with active TB has varied, ranging from 62% to 94%, with a pooled sensitivity of 80%, whereas the T-Spot.*TB* test has a sensitivity of 35% to 100%, with a pooled sensitivity of 81%. By contrast, the TST has a pooled sensitivity of 65% in patients with TB. Although the IGRAs have improved sensitivity compared with the TST, the values are still too low to rule out active TB with confidence, and neither test can differentiate latent from active TB.

RADIOGRAPHIC EXAMINATIONS

Plain chest radiography is a sensitive but nonspecific test to detect pulmonary TB. Radiographic manifestations of TB vary, depending on whether the patient has primary or postprimary TB and whether co-infection with HIV is present. Patients who have primary pulmonary TB at initial evaluation may demonstrate radiographic opacities in the lower lung zones and an associated pleural effusion (see Figure 31-4). TB caused by reactivation typically involves the apical and posterior segments of the upper lobes or superior segment of the lower lobe (see Figure 31-5). Cavitation and volume loss are common in reactivation disease but unusual in primary disease. Findings on the chest radiograph in patients co-infected with HIV depend on the severity of immunosuppression. Early in the course of HIV disease, the radiograph may show a typical reactivation pattern with cavitation (**Figure 31-7**), but as the $CD4^+$ cell count declines, the radiographic appearance is more like the pattern seen in primary TB (**Figure 31-8**). Patients co-infected with HIV may sometimes have a normal-appearing chest radiograph despite being sputum AFB smear–positive.

BACTERIOLOGIC EXAMINATION

Sputum Microscopy

Diagnosis of pulmonary TB begins with obtaining two or three spontaneously expectorated sputum samples collected at 8- to 24-hour intervals, with at least one collected in early morning. Two methods are commonly used for acid-fast staining: the carbolfuchsin methods (Ziehl-Neelsen and Kinyoun methods) and a fluorochrome procedure that uses auramine O or auramine-rhodamine dyes (**Figure 31-9**).

Approximately 5,000 to 10,000 bacilli/mL are necessary to allow detection of these organisms in stained smears. The sensitivity of sputum AFB smears ranges from 50% to 80%, depending on the extent of disease; patients with cavitary

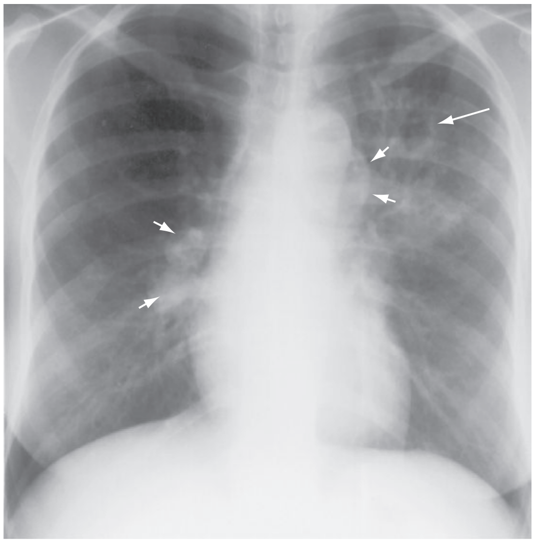

Figure 31-7 Tuberculosis in a human immunodeficiency virus (HIV)-infected patient. The chest radiograph demonstrates a left upper lobe cavitary process (*large arrow*). In addition, bilateral hilar adenopathy and aortopulmonary window adenopathy (*small arrows*) are evident.

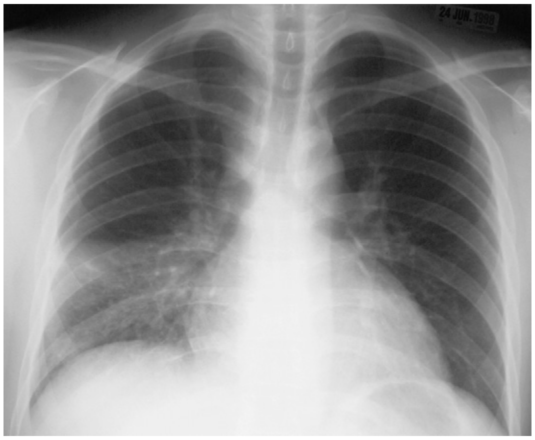

Figure 31-8 Primary-type presentation of tuberculosis in a human immunodeficiency virus (HIV)-infected patient. The chest radiograph demonstrates right lower lobe and right middle lobe air space consolidation with likely right hilar and paratracheal adenopathy.

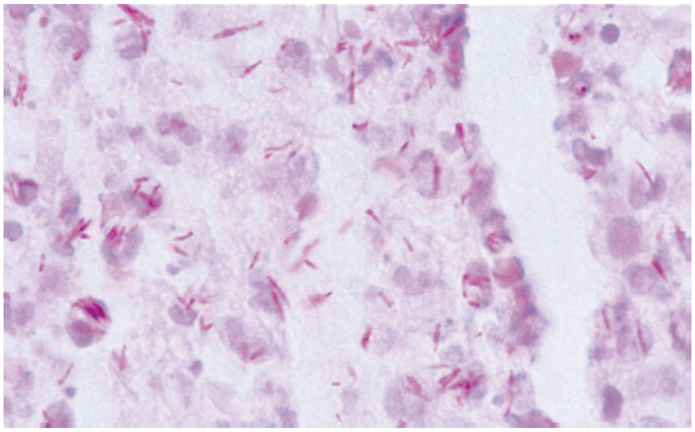

Figure 31-9 Acid-fast stain in tissue showing *Mycobacterium tuberculosis.* (Ziehl-Neelsen stain.)

disease are more likely than those without cavities to expectorate tubercle bacilli. Light-emitting diode (LED)–based fluorescence microscopy allows for more rapid evaluation of specimens and may increase the sensitivity slightly over that for conventional light microscopy. If patients are unable to produce sputum or have negative sputum smears, additional diagnostic tests may be indicated. In such circumstances, either sputum induction or biopsy using fiberoptic bronchoscopy (FOB) may provide adequate specimens. Studies suggest that sputum induction with hypertonic saline and FOB with bronchoalveolar lavage produce similar yields in smear-negative cases. The primary role of FOB is in smear-negative HIV-infected TB suspects, in whom this technique also can help identify alternative causes of the illness.

Mycobacterial Cultures and Identification

Culture of *M. tuberculosis* remains the "gold standard" modality for diagnosis of TB, and isolation of the organism is necessary for drug susceptibility testing and genotyping. Thus, all clinical specimens suspected of containing mycobacteria should be inoculated onto culture media. There are three different types of traditional culture media: egg-based (Lowenstein-Jensen or Ogawa), agar-based (Middlebrook 7H10 or 7H11), and liquid (Middlebrook 7H12) media. Growth in the liquid media is faster than that in solid media, and automated commercial broth systems allow for growth detection within 1 to 3 weeks compared with solid media, for which growth takes 3 to 8 weeks. However, solid media allow for observation of colony morphology and the detection of mixed infections. Because only 10 to 100 organisms are required to detect *M. tuberculosis*, cultures are more sensitive than smears, with reported sensitivity ranging from 80% to 93%. The tubercle bacilli can be identified from cultures and distinguished from NTM species by chemical means or with molecular methods.

Molecular Assays

Nucleic acid amplification assays (NAAs) amplify and detect *M. tuberculosis*–specific nucleic acid sequences in clinical specimens within 24 to 48 hours. Two U.S. Food and Drug Administration (FDA)-approved NAAs are available in the United States: the AMPLICOR *M. tuberculosis* (Roche Diagnostic Systems, Inc., Branchburg, New Jersey) and the Amplified Mycobacterium Tuberculosis Direct (MTD) Test (Gen-Probe, Inc., San Diego, California). The enhanced MTD (E-MTD) assay is approved for use with both smear-negative and smear-positive specimens, but the AMPLICOR assay is approved for use with smear-positive specimens only. The assays show sensitivities of at least 80% to 90% in most studies, with specificities of approximately 98% to 99% in smear-positive specimens. The E-MTD assay has been shown to have a sensitivity and specificity close to 100% in smear-positive specimens, and in smear-negative specimens the sensitivity is 90% and specificity is 99%.

NAAs are particularly valuable for rapidly distinguishing TB from NTM infection. When both the NAA and AFB smear are positive, pulmonary TB is almost certain and TB therapy should be initiated. If the NAA result is negative but the sputum smear is positive, testing the sputum for inhibitors and repeating the NAA is advised. If inhibitors are not detected and a second sputum specimen is NAA-negative but smear-positive, the patient probably has an NTM infection. If smears are negative but the clinical suspicion is intermediate to high, an NAA should be ordered, because a positive NAA result in this setting is likely to indicate TB. However, a negative NAA result in a smear-negative patient does not exclude TB. NAA tests should not be performed on sputum specimens from patients at low risk for development of TB. NAAs have been shown to reduce time to diagnosis, to accelerate contact investigations, and to reduce nonindicated TB treatment and are considered a standard component of the TB-diagnostic armamentarium.

Use of NAA for testing extrapulmonary specimens has been systemically reviewed. The sensitivity of commercial assays for detecting *M. tuberculosis* in CSF and pleural fluid has been approximately 60%, with a specificity of 98%. Therefore, NAAs may be useful in confirming a diagnosis of CNS or pleural TB, but because of the low sensitivity, they cannot be used to rule out disease.

The Xpert MTB/RIF (Cepheid, Sunnyvale, California) is an automated diagnostic system that performs real-time PCR to amplify an MTB-specific sequence of the *rpoB* gene, which is probed with molecular beacons to identify rifampin resistance. The device, which provides results within two hours, indicates both the presence of *M. tuberculosis* and the presence of rifampin resistance. In a large multicountry study, the Xpert MTB/RIF correctly identified 98% of patients with smear-positive and culture-positive TB. The sensitivity for smear-negative, culture-positive disease was 72%.

Drug Susceptibility Testing

Drug susceptibility studies should be performed on all initial isolates and only by laboratories that have experience in culturing mycobacteria. Drug susceptibility testing also should be performed on patients whose treatment is failing or who have a recurrence. The agar proportion method and the liquid radiometric or chemoluminescence methods are the ones most commonly used in the Unites States. Automated radiometric procedures for drug susceptibility testing offer more rapid results but often require confirmation with solid media.
